Anthropometry. **Anthropometry** is a measurement system of the size and makeup of the body. Nurses obtain height and weight for each patient on hospital admission or entry into any health care setting. If you are not able to measure height with the patient standing, position him or her lying flat in bed as straight as possible with arms folded on the chest and measure him or her lengthwise. Serial measures of weight over time provide more useful information than one measurement. Weigh the patient at the same time each day, on the same scale, and with the same type of clothing or linen. Document the patient's actual weight and compare height and weight to standards for height-weight relationships. An **ideal body weight (IBW)** provides an estimate of what a person should weigh. Rapid weight gain or loss is important to note because it usually reflects fluid shifts. One pint or 500 mL of fluid equals 1 lb (0.45 kg). For example, for a patient with renal failure, a weight increase of 2 lbs (0.90 kg) in 24 hours is significant because it usually indicates that the patient has retained 1 L (1000 mL) of fluid.

Other anthropometric measurements often obtained by RDs help identify nutritional problems. These include the ratio of height-to-wrist circumference, mid–upper arm circumference (MAC), triceps skinfold (TSF), and mid–upper arm muscle circumference (MAMC). An RD compares values for MAC, TSF, and MAMC to standards and calculates them as a percentage of the standard. Changes in values for an individual over time are of greater significance than isolated measurements (Nix, 2012).

Body mass index (BMI) measures weight corrected for height and serves as an alternative to traditional height-weight relationships. Calculate BMI by dividing a patient's weight in kilograms by height in meters squared: weight (kg) divided by height^2 (m^2). For example, a patient who weighs 165 lbs (75 kg) and is 1.8 m (5 feet 9 inches) tall has a BMI of 23.15 ($75 \div 1.8^2 = 23.15$). The website for the National Heart Lung and Blood Institute (http://www.nhlbi.nih.gov/) provides an easy way to calculate BMI. A patient is overweight if his or her BMI is 25 to 30. Obesity, defined by a BMI of greater than 30, places a patient at higher medical risk of coronary heart disease, some cancers, DM, and hypertension.

Laboratory and Biochemical Tests. No single laboratory or biochemical test is diagnostic for malnutrition. Factors that frequently alter test results include fluid balance, liver function, kidney function,

Mini Nutritional Assessment
MNA®

Nestlé Nutrition Institute

Last name:		First name:		
Sex:	Age:	Weight, kg:	Height, cm:	Date:

Complete the screen by filling in the boxes with the appropriate numbers. Total the numbers for the final screening score.

Screening

A   Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties?
0 = severe decrease in food intake
1 = moderate decrease in food intake
2 = no decrease in food intake ☐

B   Weight loss during the last 3 months
0 = weight loss greater than 3 kg (6.6 lbs)
1 = does not know
2 = weight loss between 1 and 3 kg (2.2 and 6.6 lbs)
3 = no weight loss ☐

C   Mobility
0 = bed or chair bound
1 = able to get out of bed / chair but does not go out
2 = goes out ☐

D   Has suffered psychological stress or acute disease in the past 3 months?
0 = yes   2 = no ☐

E   Neuropsychological problems
0 = severe dementia or depression
1 = mild dementia
2 = no psychological problems ☐

F1   Body Mass Index (BMI) (weight in kg) / (height in m^2)
0 = BMI less than 19
1 = BMI 19 to less than 21
2 = BMI 21 to less than 23
3 = BMI 23 or greater ☐

IF BMI IS NOT AVAILABLE, REPLACE QUESTION F1 WITH QUESTION F2.
DO NOT ANSWER QUESTION F2 IF QUESTION F1 IS ALREADY COMPLETED.

F2   Calf circumference (CC) in cm
0 = CC less than 31
3 = CC 31 or greater ☐

Screening score
(max. 14 points) ☐☐

12-14 points: Normal nutritional status
8-11 points: At risk of malnutrition
0-7 points: Malnourished

and the presence of disease. Common laboratory tests used to study nutritional status include measures of plasma proteins such as albumin, transferrin, prealbumin, retinol-binding protein, total iron-binding capacity, and hemoglobin. After feeding, the response time for changes in these proteins ranges from hours to weeks. The metabolic half-life of albumin is 21 days, transferrin is 8 days, prealbumin is 2 days, and retinol-binding protein is 12 hours. Use this information to determine the most effective measure of plasma proteins for your patients. Factors that affect serum albumin levels include hydration; hemorrhage; renal or hepatic disease; large amounts of drainage from wounds, drains, burns, or the GI tract; steroid administration; exogenous albumin infusions; age; and trauma, burns, stress, or surgery. Albumin level is a better indicator for chronic illnesses, whereas prealbumin level is preferred for acute conditions (Jensen et al., 2013).

Nitrogen balance is important in determining serum protein status (see discussion of protein in this chapter). Calculate nitrogen balance by dividing 6.25 into the total grams of protein ingested in a day (24 hours). Use laboratory analysis of a 24-hour urine urea nitrogen (UUN) to determine nitrogen output. For patients with diarrhea or fistula drainage, estimate a further addition of 2 to 4 g of nitrogen output. Calculate nitrogen balance by subtracting the nitrogen output from the nitrogen intake. A positive 2- to 3-g nitrogen balance is necessary for anabolism. By contrast, negative nitrogen balance is present when catabolic states exist.

Diet History and Health History. In addition to the general nursing history, use data from a more specific diet history to assess a patient's actual or potential nutritional needs. Box 45-6 lists some specific assessment questions to ask in the diet history. The diet history focuses on a patient's habitual intake of foods and liquids and includes information about preferences, allergies, and other relevant areas such as the patient's ability to obtain food. Gather information about the patient's illness/activity level to determine energy needs and compare food intake. Your nursing assessment of nutrition includes health status; age; cultural background (see Box 45-5); religious food patterns (see Table 45-3); socioeconomic status; personal food preferences; psychological factors; use of alcohol or illegal drugs; use of vitamin, mineral, or herbal supplements; prescription or over-the-counter (OTC) drugs (see Table 45-2); and the patient's general nutrition knowledge.

In an outpatient setting, have a patient keep a 3- to 7-day food diary. This allows you to calculate nutritional intake and to compare it with DRI to see if the patient's dietary habits are adequate. Use food questionnaires to establish patterns over time. In a health care setting nurses collaborate with RDs to complete calorie counts for patients.

Physical Examination. The physical examination is one of the most important aspects of a nutritional assessment. Because improper nutrition affects all body systems, observe for malnutrition during physical assessment (see Chapter 31). Complete the general physical assessment of body systems and recheck relevant areas to evaluate a patient's nutritional status. The clinical signs of nutritional status (Table 45-4) serve as guidelines for observation during physical assessment.

Dysphagia. Dysphagia refers to difficulty swallowing. The causes (Box 45-7) and complications of dysphagia vary. Complications include aspiration pneumonia, dehydration, decreased nutritional status, and weight loss. Dysphagia leads to disability or decreased functional status, increased length of stay and cost of care, increased likelihood of discharge to institutionalized care, and increased mortality (Ellis and Hannibal, 2013).

BOX 45-6   Nursing Assessment Questions

Dietary Intake and Food Preferences
- What type of food do you like?
- How many meals a day do you eat?
- What times do you normally eat meals and snacks?
- What portion sizes do you eat at each meal?
- Are you on a special diet because of a medical problem?
- Do you have any dietary religious or cultural food preferences?
- Who prepares the food at home?
- Who purchases the food?
- How do you cook your food (e.g., fried, broiled, baked, grilled)?

Unpleasant Symptoms
- Which foods cause indigestion, gas, or heartburn?
- Does this occur each time you have the food?
- What relieves the symptoms?

Allergies
- Are you allergic to any foods?
- Which types of problems do you have with these foods?
- How are these food allergies treated (e.g., EpiPen, oral antihistamines)?

Taste, Chewing, and Swallowing
- Have you noticed any changes in taste?
- Did these changes occur with medications or following an illness?
- Do you wear dentures? Are the dentures comfortable?
- Do you have any mouth pain or sores (e.g., cold sore, canker sores)?
- Do you have difficulty swallowing?
- Do you cough or gag when you swallow?

Appetite and Weight
- Have you had a change in appetite?
- Have you noticed a change in your weight?
- Was this change anticipated (e.g., were you on a weight-reduction diet)?

Use of Medications
- Which medications do you take?
- Do you take any over-the-counter medications that your doctor does not prescribe?
- Do you take any nutritional or herbal supplements?

Be aware of warning signs for dysphagia. They include cough during eating; change in voice tone or quality after swallowing; abnormal movements of the mouth, tongue, or lips; and slow, weak, imprecise, or uncoordinated speech. Abnormal gag, delayed swallowing, incomplete oral clearance or pocketing, regurgitation, pharyngeal pooling, delayed or absent trigger of swallow, and inability to speak consistently are other signs of dysphagia. Patients with dysphagia often do not show overt signs such as coughing when food enters the airway. *Silent aspiration* is aspiration that occurs in patients with neurological problems that lead to decreased sensation. It often occurs without a cough, and symptoms usually do not appear for 24 hour. Silent aspiration accounts for most of the 51% to 78% of aspiration in patients with dysphagia following stroke (Sorensen et al., 2013).

Dysphagia often leads to an inadequate amount of food intake, which results in malnutrition. Frequently patients with dysphagia become frustrated with eating and show changes in skinfold thickness and albumin. During the rehabilitation period patients experience longer adjustment periods regarding new dietary restrictions. Furthermore, malnutrition significantly slows swallowing recovery and may increase mortality (Jensen et al., 2013).

TABLE 45-4 Physical Signs of Nutritional Status

Body Area	Signs of Good Nutrition	Signs of Poor Nutrition
General appearance	Alert: responsive	Listless, apathetic, cachectic
Weight	Weight normal for height, age, body build	Obesity (usually 10% above ideal body weight [IBW]) or underweight (special concern for underweight)
Posture	Erect posture; straight arms and legs	Sagging shoulders; sunken chest; humped back
Muscles	Well-developed, firm; good tone; some fat under skin	Flaccid, poor tone, underdeveloped tone; "wasted" appearance; impaired ability to walk properly
Nerve conduction and mental status	Good attention span; not irritable or restless; normal reflexes; psychological stability	Inattention; irritability; confusion; burning and tingling of hands and feet (paresthesia); loss of position and vibratory sense; weakness and tenderness of muscles (may result in inability to walk); decrease or loss of ankle and knee reflexes
Gastrointestinal function	Good appetite and digestion; normal regular elimination; no palpable organs or masses	Anorexia; indigestion; constipation or diarrhea; liver or spleen enlargement
Cardiovascular function	Normal heart rate and rhythm; lack of murmurs; normal blood pressure for age	Rapid heart rate (above 100 beats/min), enlarged heart; abnormal rhythm; elevated blood pressure
General vitality	Endurance; energy; sleeps well; vigorous	Easily fatigued; no energy; falls asleep easily; tired and apathetic
Hair	Shiny, lustrous; firm; not easily plucked; healthy scalp	Stringy, dull, brittle, dry, thin, and sparse, depigmented; easily plucked
Skin (general)	Smooth and slightly moist skin with good color	Rough, dry, scaly, pale, pigmented, irritated; bruises; petechiae; subcutaneous fat loss
Face and neck	Uniform color; smooth, pink, healthy appearance; not swollen	Greasy, discolored, scaly, swollen; dark skin over cheeks and under eyes; lumpiness or flakiness of skin around nose and mouth
Lips	Smooth; good color; moist; not chapped or swollen	Dry, scaly, swollen; redness and swelling (cheilosis); angular lesions at corners of mouth; fissures or scars (stomatitis)
Mouth, oral membranes	Reddish-pink mucous membranes in oral cavity	Swollen, boggy oral mucous membranes
Gums	Good pink color; healthy and red; no swelling or bleeding	Spongy gums that bleed easily; marginal redness, inflammation; receding
Tongue	Good pink or deep reddish color; no swelling; smooth, presence of surface papillae; lack of lesions	Swelling, scarlet and raw; magenta, beefiness (glossitis); hyperemic and hypertrophic papillae; atrophic papillae
Teeth	No cavities; no pain; bright, straight; no crowding; well-shaped jaw; clean with no discoloration	Unfilled caries; missing teeth; worn surfaces; mottled (fluorosis), malocclusion
Eyes	Bright, clear, shiny; no sores at corner of eyelids; moist and healthy pink conjunctivae; prominent blood vessels; no fatigue circles beneath eyes	Eye membranes pale (pale conjunctivas); redness of membrane (conjunctival injection); dryness; signs of infection; Bitot's spots; redness and fissuring of eyelid corners (angular palpebritis); dryness of eye membrane (conjunctival xerosis); dull appearance of cornea (corneal xerosis); soft cornea (keratomalacia)
Neck (glands)	No enlargement	Thyroid or lymph node enlargement
Nails	Firm, pink	Spoon shape (koilonychia); brittleness; ridges
Legs, feet	No tenderness, weakness, or swelling; good color	Edema; tender calf; tingling; weakness
Skeleton	No malformations	Bowlegs; knock-knees; chest deformity at diaphragm; prominent scapulae and ribs

From Nix S: *Williams' basic nutrition and diet therapy,* ed 14, St Louis, 2012, Mosby.

Dysphagia screening quickly identifies problems with swallowing and helps you initiate referrals for more in-depth assessment by an RD or a speech-language pathologist (SLP) (see Skill 45-1 on pp. 1083-1085). Early and ongoing assessment of patients with dysphagia using a valid dysphagia-screening tool increases quality of care and decreases incidence of aspiration pneumonia. Dysphagia screening includes medical record review; observation of a patient at a meal for change in voice quality, posture, and head control; percentage of meal consumed; eating time; drooling or leakage of liquids and solids; cough during/after a swallow; facial or tongue weakness; palatal movement; difficulty with secretions; pocketing; choking; and a spontaneous dry cough. A number of validated screening tools are available such as the Bedside Swallowing Assessment, Burke Dysphagia Screening Test, Acute Stroke Dysphagia Screen, and Standardized Swallowing Assessment (Edmiaston et al., 2010). The Acute Stroke Dysphagia screen is an easily administered and reliable tool for health care professionals who are not speech-language pathologists (SLPs). Screening for and treatment of dysphagia requires a multidisciplinary team approach of nurses, RDs, health care providers, and SLPs (Sorensen et al., 2013).

BOX 45-7   Causes of Dysphagia

Myogenic
- Myasthenia gravis
- Aging
- Muscular dystrophy
- Polymyositis

Neurogenic
- Stroke
- Cerebral palsy
- Guillain-Barré syndrome
- Multiple sclerosis
- Amyotrophic lateral sclerosis (Lou Gehrig disease)
- Diabetic neuropathy
- Parkinson's disease

Obstructive
- Benign peptic stricture
- Lower esophageal ring
- Candidiasis
- Head and neck cancer
- Inflammatory masses
- Trauma/surgical resection
- Anterior mediastinal masses
- Cervical spondylosis

Other
- Gastrointestinal or esophageal resection
- Rheumatological disorders
- Connective tissue disorders
- Vagotomy

BOX 45-8   Nursing Diagnostic Process

Imbalanced Nutrition: Less Than Body Requirements

Assessment Activities	Defining Characteristics
Body mass index (BMI)	Body mass index (BMI) = 17
Obtain weight	68-year-old woman 24-lb (10.8-kg) weight loss Weight is 20% below her ideal body weight
Obtain 24-hour food and fluid history	Lack of satiety Lack of interest in food Fluid intake is juice and coffee Eats sandwich in afternoon
Physical assessment	Poor muscle tone Fatigue Hair loss Dry scaly skin Pale conjunctiva and mucous membranes
Medication	Takes sertraline for depression
Social	Husband died 6 months ago Has quit attending monthly quilting club Started counseling 3 months ago

◆ Nursing Diagnosis

Cluster all assessment data to identify appropriate nursing diagnoses (Box 45-8). A nutritional problem occurs when overall intake is significantly decreased or increased or when one or more nutrients are not ingested, completely digested, or completely absorbed. When identifying a problem-focused nursing diagnosis, you select the appropriate related factors (e.g., inability to digest food or reduced daily activity). Related factors need to be accurate so you select the right interventions. For example, *Imbalanced Nutrition: Less Than Body Requirements* related to economic disadvantage will require very different interventions than *Imbalanced Nutrition: Less Than Body Requirements* related to an inability to ingest food.

A patient will have a risk nursing diagnosis when assessment reveals risk factors. For example, *Risk for Overweight* can be identified by the presence of risk factors such as excessive alcohol consumption or high frequency of eating restaurant food and adult BMI approaching 25 kg/m². Be specific so you can direct interventions toward risk factors.

Defining characteristics may also point to a health promotion diagnosis such as *Readiness for Enhanced Nutrition*. The following are nursing diagnoses applicable to nutritional problems:
- *Risk for Aspiration*
- *Diarrhea*
- *Overweight*
- *Imbalanced Nutrition: Less Than Body Requirements*
- *Readiness for Enhanced Nutrition*
- *Feeding Self-Care Deficit*
- *Impaired Swallowing*
- *Obesity*

In addition, there are clinical situations in which patients have multiple related nursing diagnoses. The concept map in Figure 45-5 shows the relationship of nursing diagnoses for Mrs. Cooper.

◆ Planning

Planning to maintain patients' optimal nutritional status requires a higher level of care than simply correcting nutritional problems. Often there is a need for patients to make long-term changes for nutrition to improve. Synthesis of patient information from multiple sources is necessary to create an individualized approach of care that is relevant to a patient's needs and situation (Figure 45-6). Apply critical thinking to ensure that you consider all data sources in developing a patient's plan of care. The accurate identification of nursing diagnoses related to patients' nutritional problems results in a care plan that is relevant and appropriate (see the Nursing Care Plan). Referring to professional standards for nutrition is especially important during this step, because scientific findings support current published standards.

Goals and Outcomes. Goals and outcomes of care reflect a patient's physiological, therapeutic, and individualized needs. Nutrition education and counseling are important to prevent disease and promote health. Educate your patients about the therapeutic diet prescribed, specifically on how it controls their illnesses and if there are any implications. When planning care, be aware of all factors that influence a patient's food intake. For example, patients with heart failure experience decreased hunger, dietary restrictions, fatigue, shortness of breath, and sadness, which influence their food intake.

Individualized planning is essential. Explore patients' feelings about their weight and diet and help them set realistic and achievable goals. Mutually planned goals negotiated among the patient, RD, and nurse ensure success. For the patient with heart failure described previously, an overall goal is "Patient will achieve appropriate BMI height-weight range or be within 10% of IBW." The following outcomes help to achieve this goal:
- Patient's daily nutritional intake meets the minimal DRIs.
- Patient's daily nutritional fat intake is less than 30%.
- Patient removes sugared beverages and high carbohydrate foods from diet.
- Patient refrains from eating unhealthy foods between meals and after dinner.
- Patient loses at least ½ to 1 lb (0.2 to 0.45 kg) per week.

Meeting nutritional goals requires input from the patient and the interprofessional team. Knowledge of the role of each discipline in providing nutrition support is necessary to maximize nutritional outcomes. For example, collaboration with an RD helps develop appropriate nutrition treatment plans. Calorie counts are frequently ordered, and help is necessary to obtain accurate data. An effective plan of care requires accurate exchange of information among disciplines.

Setting Priorities. After identifying patients' nursing diagnoses, determine priorities to plan timely and successful interventions. For

FIGURE 45-5 Concept map for Mrs. Cooper.

example, managing a patient's oral pain will be a priority over the intervention of diet education to improve nutrition if the patient is unable to swallow and maintain adequate food intake. *Deficient Knowledge* regarding diet therapy will become a priority if it is necessary to promote long-term and effective weight loss for a patient being discharged from a hospital.

During acute illness and surgery, food intake varies in the perioperative period. The priority of care is to provide optimal preoperative nutrition support in patients with malnutrition. The priority for the resumption of food intake after surgery depends on the return of bowel function, the extent of the surgical procedure, and the presence

of any complications (see Chapter 50). For example, when patients have oral and throat surgery, they chew and swallow food in the presence of excision sites, sutures, or tissue manipulated during surgery. The priority of care is to first provide comfort and pain control. Then address nutritional priorities and plan care to maintain nutrition that does not cause pain or injury to the healing tissues.

The patient and family must collaborate with the nurse in planning care and setting priorities. This is important because food preferences, food purchases, and preparation involve the entire family. The plan of care cannot succeed without their commitment to, involvement in, and understanding of the nutritional priorities.

Knowledge
- Role of registered dietitians/nutritionists in caring for patients with altered nutrition
- Effect of community support groups/resources in assisting patients to manage nutrition
- Effect of poor diets on patients' nutritional status

Experience
- Previous patient responses to nursing interventions for altered nutrition
- Personal experiences with dietary change strategies (what worked and what did not)

PLANNING
- Select nursing interventions to promote optimal nutrition
- Select nursing interventions consistent with therapeutic diets
- Consult with other health care professionals (e.g., registered dietitians, nutritionists, physicians, pharmacists, physical and occupational therapists) to adopt interventions that reflect the patient's needs
- Involve family when designing interventions

Standards
- Individualize therapy according to patient needs
- Select therapies consistent with established standards of normal nutrition (e.g., USDA, FDA, WHO)
- Select therapies consistent with established standards for therapeutic diets (e.g., AHA, ADA)

Attitudes
- Display confidence in selecting interventions
- Creatively adapt interventions for the patient's physical limitations, culture, personal preferences, budget, and home care needs

FIGURE 45-6 Critical thinking model for nutrition planning. *ADA,* American Diabetes Association; *AHA,* American Heart Association; *FDA,* Food and Drug Administration; *USDA,* US Department of Agriculture; *WHO,* World Health Organization.

Teamwork and Collaboration. The care of a patient often extends beyond the acute hospital setting, requiring continued collaboration among members of the health care team. It is important that discharge planning include nutritional interventions as patients return to their homes or extended care facilities. Communicate patient goals and planned interventions to all team members to achieve expected patient outcomes. In addition, as nurses, consult with an SLP, RD, pharmacist, and/or occupational therapist about patients with dysphagia and those who need ongoing nutritional assessment and interventions to meet their nutritional needs.

Administration of enteral tube feedings typically enters through the stomach or intestines via a tube inserted through the nose or a percutaneous access (see Skills 45-2 and 45-3 on pp. 1085-1094). These enteral feedings supplement a patient's oral nutritional intake in the home, acute care, extended care, or rehabilitation setting when they cannot meet their nutritional needs by mouth. Regardless of the setting, the RD assesses and monitors the patient's nutritional status and intake and makes recommendations for changes. RDs are expert in the choice of enteral formulas and dietary modifications required for specific disease states. Long-term management of nutritional problems is a challenge that requires collaboration among the patient, family, and health care team members.

Patients who cannot tolerate nutrition through the GI tract receive total PN, a solution consisting of glucose, amino acids, lipids, minerals, electrolytes, trace elements, and vitamins, through an indwelling peripheral or central venous catheter (CVC) (see Chapter 42). The pharmacist is an expert who reviews medications to identify drug-nutrient interactions. Pharmacists are also experts in preparing mixtures of total PN (TPN).

When patients have difficulty feeding themselves, occupational therapists work with them and their families to identify assistive devices. Devices such as utensils with large handles and plates with elevated sides help a patient with self-feeding. A speech-language pathologist (SLP) helps a patient with swallowing exercises and techniques to reduce the risk of aspiration. Occupational therapists also help patients maintain function in the home setting by rearranging food preparation areas in an effort to maximize a patient's functional capacity.

◆ **Implementation**

Diet therapies are numerous and chosen on the basis of a patient's overall health status, ability to eat and digest normally, and long-term nutritional needs. The focus of health promotion is to educate patients and family caregivers about balanced nutrition and to help them obtain resources to eat high-quality meals. In acute care your role as a nurse is to manage acute conditions that alter patients' nutritional status and help in ways to promote their appetite and ability to take in nutrients. Patients who are ill or debilitated often have poor appetites (anorexia). Anorexia has many causes (e.g., pain, fatigue, and the effects of medications). Help patients understand the factors that cause anorexia and use creative approaches to stimulate appetite. In the restorative care setting you help patients learn how to follow the therapeutic diets necessary for recovery and treatment of chronic health conditions.

Health Promotion. As a nurse you are in a key position to educate patients about healthy diet choices and good nutrition. Incorporating knowledge of nutrition into patients' lifestyles serves to prevent the development of many diseases. Outpatient and community-based settings are optimal locations for nursing assessment of nutritional practices and status. Early identification of potential or actual problems is the best way to avoid serious problems. Similarly, in other health care settings patients with nutritional problems such as obesity often require help in menu planning and compliance strategies. Your role as educator includes assessing the patient's and family's health literacy (i.e., how much do they understand regarding their nutritional need) and providing nutritional education and information about community resources. Telephone numbers of an RD or nurse for follow-up questions are always a part of counseling.

Meal planning takes into account a family's budget and different preferences of family members. Choose specific foods on the basis of the dietary prescription and recommended food groups. For families on limited budgets, use substitutes. For example, bean or cheese dishes often replace meat in a meal, and the use of evaporated milk or dry skim milk when cooking is a low-cost nutritional supplement. Have patients modify the method of preparation when it is necessary to minimize certain substances. Baking rather than frying reduces fat intake, and patients can use lemon juice or spices to add flavor to low-sodium diets.

◎ NURSING CARE PLAN

Imbalanced Nutrition: Less Than Body Requirements

ASSESSMENT

A nurse practitioner in a senior citizens' center is seeing Mrs. Cooper, who is 68 years old and has a history of heart failure. Recently Mrs. Cooper experienced an unexpected 15% weight loss. Three months have passed since she started taking sertraline (Zoloft) for depression related to the loss of her husband 6 months ago. She no longer participates in her monthly quilting club. Mrs. Cooper started receiving counseling 3 months ago for help with grief and depression through a local senior service agency. When the nurse inquires about her financial situation, Mrs. Cooper responds by saying that it was tight living on a small pension and Social Security but she was able to manage.

Assessment Activities	*Findings/Defining Characteristics**
Ask Mrs. Cooper about her food intake during the last 2 days.	She responds that she drinks some juice in the morning and two or three cups of coffee. In addition, she often has a sandwich in the late afternoon. She often skips dinner.
	"**I'm just not interested in food.** It has no taste."
Ask Mrs. Cooper about social interaction.	Mrs. Cooper complains of loneliness and says that she does not get out much, although her psychologist recommended more socializing. Her friends at church call her to come back to meetings, but she is just not ready.
	She says that she tires easily and no longer attends the monthly meetings of her quilt club.
Weigh patient and assess posture.	Her **weight is 20% below her ideal body weight (IBW)** and her body mass index (BMI) is 17.
	This weight loss has happened over the past 6 months, and she has **lost 24 lbs.**
	Stooped posture
Observe Mrs. Cooper for signs of poor nutrition.	**Hair loss**
	Sore oral mucous membranes
	Pale mucous membranes

***Defining characteristics** are shown in bold type.

NURSING DIAGNOSIS: Imbalanced nutrition: less than body requirements related to a decreased ability to ingest food as a result of depression and insufficient intake

PLANNING

Goals	*Expected Outcomes (NOC)*[†]
	Weight Gain Behavior
Mrs. Cooper will progressively gain weight.	Mrs. Cooper gains 1 to 2 lbs per month until reaching a goal of 130 lbs.
	Nutritional Status
Mrs. Cooper will consume adequate nourishment each day.	Mrs. Cooper ingests 1900 kcal/day, including 50 g of protein per day.
	Nutritional Status: Biochemical Measures
Mrs. Cooper will exhibit no signs of malnutrition.	Physical assessment findings are within normal limits.
	Laboratory values are within normal limits.

[†]Outcome classification labels from Moorhead S et al: *Nursing outcomes classification (NOC),* ed 5, St Louis, 2013, Mosby.

INTERVENTIONS (NIC)[‡]	RATIONALE
Nutritional Counseling	
Coordinate plan of care with health care provider, psychologist, Mrs. Cooper, and registered dietitian.	Successful nutrition care planning is a multidisciplinary approach throughout the continuum of care (Jensen et al., 2013).
Individualize menu plans according to Mrs. Cooper's preferences.	Incorporating her food preferences into the meal plans encourages the patient to eat (Jensen et al., 2013).
Teach Mrs. Cooper about MyPlate for Older Adults.	MyPlate for Older Adults is adapted to meet the nutritional requirements for older adults (Tufts University, 2011).
Nutrition Management	
Encourage Mrs. Cooper to eat small nutritious meals and snacks and increase dietary intake to help offset anorexia secondary to sertraline.	Sertraline is a selective serotonin reuptake inhibitor (SSRI) antidepressant medication that causes diminished taste and anorexia. Frequent small nutritious meals and snacks help to reduce anorexia-associated weight loss.
Encourage fluid intake.	Older adults need eight 8-oz (240 mL) glasses per day of fluid from beverage and food sources. Concentrating intake in the morning and early afternoon is acceptable to prevent nocturia (Meiner, 2011).
Encourage fiber intake.	Deters constipation and enhances appetite.
Encourage Mrs. Cooper to eat lunch at the senior center 5 times per week.	Eating with others encourages good nutrition and promotes socialization with peers (American Dietetic Association, 2010a; Nix, 2012).

[‡]Intervention classification labels from Bulechek GM et al: *Nursing interventions classification (NIC)*, ed 6, St Louis, 2013, Mosby.

◎ NURSING CARE PLAN

Imbalanced Nutrition: Less Than Body Requirements—cont'd

EVALUATION

Nursing Actions	Patient Response/Finding	Achievement of Outcome
Monitor Mrs. Cooper monthly for weight gain, anemia, serum albumin level, and transferrin levels.	After 2 weeks Mrs. Cooper has gained 3 lbs, and her hemoglobin B level is 12.	Mrs. Cooper is making progress with weight gain; her hemoglobin level still reflects mild anemia.
Ask Mrs. Cooper to keep a food diary for 3 days.	Food diary reflects that she ate her main meal at the senior center, has fruit and bran flakes for breakfast, and in the evening either has soup or a sandwich with fruit.	Mrs. Cooper is selecting more nutritionally rich foods, consistent with current guidelines.
Observe Mrs. Cooper's physical appearance.	At 2 weeks her mucous membranes are less pale, and her hair appears to be in better condition and styled.	Mrs. Cooper has improved physical parameters of nutrition; still needs follow-up.
Ask Mrs. Cooper about appetite and energy level.	Mrs. Cooper responds that on days that she eats at the senior center her appetite seems better and she "wants to do more things." She notes that weekends are very lonely.	Weekday support for nutritional status appears effective; needs to increase patient's activity status and nutritional intake during weekends.

TABLE 45-5 Food Safety

Foodborne Disease	Organism	Food Source	Symptoms*
Botulism	*Clostridium botulinum*	Improperly home-canned foods, smoked and salted fish, ham, sausage, shellfish	Symptoms varied from mild discomfort to death in 24 hours; initially nausea, vomiting, dizziness, and weakness progressing to motor (respiratory) paralysis
Escherichia coli	*E. coli*	Undercooked meat (ground beef)	Severe cramps, nausea, vomiting, diarrhea (may be bloody), renal failure; appears 1-8 days after eating; lasts 1-7 days
Listeriosis	*Listeria* *L. monocytogenes*	Soft cheese, meat (hot dogs, pâté, lunch meats), unpasteurized milk, poultry, seafood	Severe diarrhea, fever, headache, pneumonia, meningitis, endocarditis; appears 3-21 days after infection
Perfringens enteritis	*Clostridium* *C. perfringens*	Cooked meats, meat dishes held at room or warm temperature	Mild diarrhea, vomiting; appears 8-24 hours after eating; lasts 1-2 days
Salmonellosis	*Salmonella* *S. typhi* *S. paratyphi*	Milk, custards, egg dishes, salad dressings, sandwich fillings, polluted shellfish	Mild-to-severe diarrhea, cramps, vomiting; appears up to 72 hours after ingestion; lasts 4-7 days
Shigellosis	*Shigella* *S. dysenteriae*	Milk, milk products, seafood, salads	Cramps, diarrhea to fatal dysentery; appears 12-50 hours after ingestion; lasts 3-14 days
Staphylococcus	*Staphylococcus* *S. aureus*	Custards, cream fillings, processed meats, ham, cheese, ice cream, potato salad, sauces, casseroles	Severe abdominal cramps, pain, vomiting, diarrhea, perspiration, headache, fever, prostration; appears 1-6 hours after ingestion; lasts 1-2 days

From Nix S: *Williams' basic nutrition and diet therapy*, ed 14, St Louis, 2012, Mosby.
*Symptoms are generally most severe for youngest and oldest age-groups.

Planning menus a week in advance has several benefits. It helps ensure good nutrition or compliance with a specific diet and helps a family stay within their allotted budget. Nurses or RDs need to check menus for content. Often a simple tip is helpful in meal planning such as avoiding grocery shopping when hungry, which can lead to impulsive purchases of more expensive or less nutritious foods that are not included in meal plans. The U.S. Department of Agriculture (USDA, 2011) provides sample weekly meal-planning services for a range of budgets on its website.

Support individuals who are interested in losing weight. A high percentage of those who attempt to lose weight are unsuccessful, regaining lost weight over time. Diet and exercise compliance affects success with weight loss. Information on weight loss is available from multiple sources. Help patients develop a successful weight-loss plan

that considers their preferences and resources and includes awareness of portion sizes and knowledge of energy content of food (AHA, 2010).

Food safety is an important public health issue. Foodborne bacteria can occur from improper food cleaning, preparation, or poor hygiene practices of food workers. Health care professionals not only need to be aware of the factors related to food safety but also should provide patient education to reduce the risks for foodborne illnesses (Table 45-5; Box 45-9).

Acute Care. The nutritional care of acutely ill patients requires a nurse to consider a variety of factors that influence nutritional intake. Diagnostic testing and procedures in the acute care setting disrupt food intake. Often a patient must refrain from eating or drinking anything by mouth (NPO) as he or she prepares for or recovers from a

BOX 45-9 PATIENT TEACHING

Food Safety

Objective
- Patient is able to verbalize measures to protect from foodborne illness.

Teaching Strategies
- Explain that food safety is an important public health issue. Populations particularly at risk are older and younger people and immunosuppressed individuals.
- Instruct patients using the following four principles:
  1. CLEAN
     - Wash hands with warm, soapy water before touching or eating food.
     - Wash fresh fruits and vegetables thoroughly.
     - Clean the inside of refrigerator and microwave regularly to prevent microbial growth.
     - Clean cutting surfaces after each use.
     - When possible, use separate surfaces for fruit, meat, poultry, fish
  2. SEPARATE
     - Wash cooking utensils and cutting boards with hot soapy water.
     - Wash hands after handling foods, especially meats, poultry, and eggs.
     - Clean vegetables and lettuce used in salads thoroughly.
     - Wash dishrags, towels, and sponges regularly or use paper towels.
  3. COOK
     - Use a food thermometer to verify that meat, poultry, and fish are cooked properly.
     - Do not eat raw meats or unpasteurized milk.
  4. CHILL
     - Keep foods properly refrigerated at 40° F (4.4° C) and frozen at 0° F (−17.8° C).
     - Do not save leftovers for more than 2 days in refrigerator.

Evaluation
- Ask patient to verbalize measures to prevent foodborne illnesses.
- Observe patient at home for safe practices if making home visit.

QSEN QSEN: BUILDING COMPETENCY IN TEAMWORK AND COLLABORATION You are the nurse in charge of developing an interdisciplinary team to help senior citizens with heart failure manage their diet at home. Knowing that it is important to have heart-failure patients lower their sodium content, cholesterol, and saturated fat to preserve their cardiac function, you bring your nursing knowledge to the team. Which strengths and limitations do you bring to the interdisciplinary team? Who would be on the team to help prepare the care plan for the heart-failure patients? How would you promote effective teamwork?

ⓔ *Answers to QSEN Activities can be found on the Evolve website.*

---

diagnostic test. Frequent interruptions during mealtimes occur in the health care setting, or patients have poor appetites. Patients often are too tired or uncomfortable to eat. It is important to assess a patient's nutritional status continuously and adopt interventions that promote normal intake, digestion, and metabolism of nutrients. Patients who are NPO and receive only standard IV fluids for more than 4 to 7 days are at nutritional risk.

Advancing Diets. Acute and chronic conditions affect a patient's immune system and nutritional status. Patients with decreased immune function (e.g., from cancer, chemotherapy, human immunodeficiency virus/acquired immunodeficiency syndrome [HIV/AIDS], or organ transplants) require special diets that decrease exposure to microorganisms and are higher in selected nutrients. Table 45-6 provides an overview of the immune system, the impact of malnutrition, and beneficial nutrients. In addition, patients who are ill, who have had surgical procedures, or who were NPO for an extended time have specialized dietary needs. Health care providers order a gradual progression of dietary intake or therapeutic diet to manage patients' illness (Box 45-10).

Promoting Appetite. Providing an environment that promotes nutritional intake includes keeping a patient's environment free of odors, providing oral hygiene as needed to remove unpleasant tastes, and maintaining patient comfort. Offering smaller, more frequent meals often helps. In addition, certain medications affect dietary intake and nutrient use. For example, medications such as insulin, glucocorticoids, and thyroid hormones affect metabolism. Other medications such as antifungal agents frequently affect taste. Some of the

GI, Gastrointestinal.

BOX 45-10   Diet Progression and Therapeutic Diets

Clear Liquid
Clear fat-free broth, bouillon, coffee, tea, carbonated beverages, clear fruit juices, gelatin, fruit ices, popsicles

Full Liquid
As for clear liquid, with addition of smooth-textured dairy products (e.g., ice cream), strained or blended cream soups, custards, refined cooked cereals, vegetable juice, pureed vegetables, all fruit juices, sherbets, puddings, frozen yogurt

Dysphagia Stages, Thickened Liquids, Pureed
As for clear and full liquid, with addition of scrambled eggs; pureed meats, vegetables, and fruits; mashed potatoes and gravy

Mechanical Soft
As for clear and full liquid and pureed, with addition of all cream soups, ground or finely diced meats, flaked fish, cottage cheese, cheese, rice, potatoes, pancakes, light breads, cooked vegetables, cooked or canned fruits, bananas, soups, peanut butter, eggs (not fried)

Soft/Low Residue
Addition of low-fiber, easily digested foods such as pastas, casseroles, moist tender meats, and canned cooked fruits and vegetables; desserts, cakes, and cookies without nuts or coconut

High Fiber
Addition of fresh uncooked fruits, steamed vegetables, bran, oatmeal, and dried fruits

Low Sodium
4-g (no added salt), 2-g, 1-g, or 500-mg sodium diets; vary from no-added-salt to severe sodium restriction (500-mg sodium diet), which requires selective food purchases

Low Cholesterol
300 mg/day cholesterol, in keeping with American Heart Association guidelines for serum lipid reduction

Diabetic
Nutrition recommendations by the American Diabetes Association: focus on total energy, nutrient and food distribution; include a balanced intake of carbohydrates, fats, and proteins; varied caloric recommendations to accommodate patient's metabolic demands

Gluten Free
Eliminates wheat, oats, rye, barley and their derivatives

Regular
No restrictions unless specified

---

psychotropic medications affect appetite, cause nausea, and alter taste. You and the RD help patients select foods that reduce the altered taste sensations or nausea. Consult with an RD regarding using seasonings that improve food taste. In other situations medications need to be changed. Assessing patients for the need for pharmacological agents to stimulate appetite such as cyproheptadine, megestro, or dronabinol or to manage symptoms that interfere with nutrition requires health care provider consultation.

Mealtime is usually a social activity. If appropriate, encourage visitors to eat with a patient. When patients experience anorexia, encourage other nurses or care providers to converse and engage them in conversation. Mealtime is also an excellent opportunity for patient education. Instruct a patient about any therapeutic diets, medications, energy conservation measures, or adaptive devices to help with independent feeding.

Assisting Patients with Oral Feeding. When a patient needs help with eating, it is important to protect his or her safety, independence, and dignity. Clear the table or over-bed tray of clutter. Assess his or her risk of aspiration (see Skill 45-1). Patients at high risk for aspiration have decreased level of alertness, decreased gag and/or cough reflexes, and difficulty managing saliva (see Assessment section of this chapter).

Patients with dysphagia are at risk for aspiration and need more help with feeding and swallowing. A speech-language pathologist (SLP) identifies patients at risk and provides recommendations for therapy (Ellis and Hannibal, 2013). Provide a 30-minute rest period before eating and position the patient in an upright, seated position in a chair or raise the head of the bed to 90 degrees. Have the patient flex the head slightly to a chin-down position to help prevent aspiration. If the patient has unilateral weakness, teach him or her and the caregiver to place food in the stronger side of the mouth. With the help of an SLP, determine the viscosity of foods that the patient tolerates best using trials of different consistencies of foods and fluids. Thicker fluids are generally easier to swallow. The American Dietetic Association published the National Dysphagia Diet Task Force National Dysphagia Diet in 2010 to provide uniformity of diets provided to patients with dysphagia (NDDTF, 2010). There are four levels of diet: dysphagia puree, dysphagia mechanically altered, dysphagia advanced, and regular. The four levels of liquid include thin liquids (low viscosity), nectarlike liquids (medium viscosity), honeylike liquids (viscosity of honey), and spoon-thick liquids (viscosity of pudding) (NDDTF, 2010).

Feed a patient with dysphagia slowly, providing smaller-size bites. Allow him or her to chew thoroughly and swallow the bite before taking another. More frequent chewing and swallowing assessments throughout the meal are necessary. Allow the patient time to empty the mouth after each spoonful, matching the speed of feeding to the patient's readiness (see Skill 45-1). If he or she begins to cough or choke, remove the food immediately (Ellis and Hannibal, 2013). Sometimes it is necessary to have oral suction equipment available at the patient's bedside.

Provide opportunities for patients to direct the order in which they want to eat the food items and how fast they wish to eat. Determine a patient's food preferences and, unless contraindicated, try to have these items included on his or her dietary tray. Ask the patient if the food is the right temperature. These seem like small acts, but they go a long way in maintaining the patient's sense of independence.

Patients with visual deficits also need special assistance. Patients with decreased vision are able to feed themselves when given adequate information. For example, identify the food location on a meal plate as if it were a clock (e.g., meat at 9 o'clock and vegetable at 3 o'clock). Tell the patient where the beverages are located in relation to the plate. Be sure that other care providers set the meal tray and plate in the same manner. Patients with impaired vision and those with decreased motor skills are more independent during mealtimes with the use of large-handled adaptive utensils (Figure 45-7). These are easier to grip and manipulate.

Enteral Tube Feeding. **Enteral nutrition (EN)** provides nutrients into the GI tract. It is the preferred method of meeting nutritional needs if a patient is unable to swallow or take in nutrients orally yet has a functioning GI tract. EN provides physiological, safe, and economical nutritional support. Patients with enteral feedings receive formula via nasogastric, jejunal, or gastric tubes. Patients with a low

FIGURE 45-7 Adaptive equipment. Clockwise from upper left: Two-handled cup with lid, plate with plate guard, utensils with splints, and utensils with enlarged handles.

risk of gastric reflux receive gastric feedings; however, if there is a risk of gastric reflux, which leads to aspiration, jejunal feeding is preferred. Box 45-11 lists indications for tube feeding. Either the nurse or a family caregiver can easily give enteral tube feedings in the home setting. After insertion of an enteral tube, it is necessary to verify tube placement by x-ray film examination. Confirmation of placement is needed before a patient receives the first enteral feeding (see Skill 45-2 on pp. 1085-1089).

An enteral formula is usually one of four types. Polymeric (1 to 2 kcal/mL) includes milk-based blenderized foods prepared by hospital dietary staff or in a patient's home. The polymeric classification also includes commercially prepared whole-nutrient formulas. For this type of formula to be effective, a patient's GI tract needs to be able to absorb whole nutrients. The second type, modular formulas (3.8 to 4 kcal/mL), are single macronutrient (e.g., protein, glucose, polymers, or lipids) preparations and are not nutritionally complete. You can add this type of formula to other foods to meet your patient's individual nutritional needs. The third type, elemental formulas (1 to 3 kcal/mL), contain predigested nutrients that are easier for a partially dysfunctional GI tract to absorb. Finally, specialty formulas (1 to 2 kcal/mL) are designed to meet specific nutritional needs in certain illness (e.g., liver failure, pulmonary disease, or HIV infection).

Typically tube feedings start at full strength at slow rates (see Skill 45-3 on pp. 1090-1094; Box 45-12). Increase the hourly rate every 8 to 12 hours per health care provider's order if no signs of intolerance appear (high gastric residuals, nausea, cramping, vomiting, and diarrhea). Studies have demonstrated a beneficial effect of enteral feedings compared with PN. Feeding by the enteral route reduces sepsis, minimizes the hypermetabolic response to trauma, decreases hospital mortality, and maintains intestinal structure and function (Khalid et al., 2010). EN is successful within 24 to 48 hours after surgery or trauma to provide fluids, electrolytes, and nutritional support. If the patient develops a gastric ileus, it prevents instituting nasogastric feedings. Nasointestinal or jejunal tubes allow successful postpyloric feeding because the formula instills directly into the small intestine or jejunum or beyond the pyloric sphincter of the stomach (Hodin et al., 2014).

A serious complication associated with enteral feedings is aspiration of formula into the tracheobronchial tree. Aspiration of enteral formula into the lungs irritates the bronchial mucosa, resulting in decreased blood supply to affected pulmonary tissue (McCance et al., 2014). This leads to necrotizing infection, pneumonia, and potential abscess formation. The high glucose content of a feeding serves as a bacterial medium for growth, promoting infection. Acute respiratory distress syndrome (ARDS) is also an outcome frequently associated

---

BOX 45-11 Indications for Enteral and Parenteral Nutrition

Enteral Nutrition
(Used with patients who have a functional gastrointestinal tract)
- Cancer
  - Head and neck
  - Upper GI
- Critical illness/trauma
- Neurological and muscular disorders
  - Brain neoplasm
  - Cerebrovascular accident
  - Dementia
  - Myopathy
- Parkinson's disease
- GI disorders
  - Enterocutaneous fistula
  - Inflammatory bowel disease
  - Mild pancreatitis
- Respiratory failure with prolonged intubation
- Inadequate oral intake
  - Anorexia nervosa
  - Difficulty chewing, swallowing
  - Severe depression

Parenteral Nutrition
- Nonfunctional GI tract
  - Massive small bowel resection/GI surgery/massive GI bleed
  - Paralytic ileus
  - Intestinal obstruction
  - Trauma to abdomen, head, or neck
  - Severe malabsorption
  - Intolerance to enteral feeding (established by trial)
  - Chemotherapy, radiation therapy, bone marrow transplantation
- Extended bowel rest
  - Enterocutaneous fistula
  - Inflammatory bowel disease exacerbation
  - Severe diarrhea
  - Moderate-to-severe pancreatitis
- Preoperative total parenteral nutrition
  - Preoperative bowel rest
  - Treatment for co-morbid severe malnutrition in patients with nonfunctional GI tracts
- Severely catabolic patients when GI tract not usable for more than 4 to 5 days

GI, Gastrointestinal.

---

with pulmonary aspiration. Some of the common conditions that increase the risk of aspiration include coughing, gastroesophageal reflux disease (GERD), nasotracheal suctioning, an artificial airway, decreased level of consciousness, and lying flat. Prokinetic medications such as metoclopramide, erythromycin, or cisapride promote gastric emptying and decrease the risk of aspiration (Metheny et al., 2012). Keep the head of the bed elevated a minimum of 30 degrees, preferably 45 degrees, unless medically contraindicated (Hodin et al., 2014). You need to measure gastric residual volumes (GRVs) every 4 to 6 hours in patients receiving continuous feedings and immediately before the feeding in patients receiving intermittent feedings (Metheny et al., 2012). Delayed gastric emptying is a concern if 250 mL or more remains in a patient's stomach on two consecutive assessments (1 hour apart) or if a single GRV measurement exceeds 500 mL (Stewart, 2014). There is a lack of consensus for recommendations for stopping feedings; decisions to stop feedings must include assessment of patient's condition (Metheny et al., 2012). The North American Summit on Aspiration in the Critically Ill Patient recommends the following: (1) stop feedings immediately if aspiration occurs; (2) withhold feedings and reassess patient tolerance to feedings if GRV is over 500 mL; (3) routinely evaluate the patient for aspiration; and (4) use nursing measures to reduce the risk of aspiration if GRV is between 250 and 500 mL (Stewart, 2014).

Enteral Access Tubes. The inability of patients to ingest food but still able to digest and absorb nutrients supports the use of enteral tube feeding. Feeding tubes are inserted through the nose (nasogastric or nasointestinal), surgically (gastrostomy or jejunostomy), or endoscopically (percutaneous endoscopic gastrostomy or jejunostomy [PEG or PEJ]). If EN therapy is for less than 4 weeks, total, nasogastric, or nasojejunal feeding tubes may be used. Surgical or endoscopically placed tubes are preferred for long-term feeding (more than 6 weeks) to reduce the discomfort of a nasal tube and provide a more secure, reliable access (Yantis and Velander, 2011). Some patients such as those with gastroparesis (decreased or absent innervation to the stomach that results in delayed gastric emptying), esophageal reflux, or a history of aspiration pneumonia require placement of tubes beyond the stomach into the intestine (Metheny et al., 2012; Yantis and Velander, 2011).

BOX 45-12 Advancing the Rate of Tube Feeding

Protocols for advancing tube feedings are commonly institution specific. Most of these protocols are untested for validity. There does not appear to be a benefit to slow initiation of enteral nutrition over days. Most patients are able to tolerate feeding 24 to 48 hours after initiation. Do not dilute formulas with water; this increases the risk of bacterial contamination (Stewart, 2014).

Intermittent
1. Start formula at full strength for isotonic formulas (300 to 400 mOsm) or at ordered concentration.
2. Infuse bolus of formula over at least 20 to 30 minutes via syringe or feeding container.
3. Begin feedings with a volume of 2.5-5 mL/kg 5 to 8 times per day. Increase by 60-120 mL per feeding every 8-12 hours to achieve needed volume and calories in four to six feedings (Stewart, 2014).

Continuous
1. Start formula at full strength for isotonic formulas (300 to 400 mOsm) or at ordered concentration.
2. Begin infusion rate at designated rate typically at 10 to 40 mL/hr (Stewart, 2014).
3. Advance rate slowly (e.g., 10 to 20 mL/hr every 8 to 12 hours) to target rate if tolerated (tolerance indicated by absence of nausea and diarrhea and low gastric residuals) (Stewart, 2014).

Most health care settings use small-bore feeding tubes because they create less discomfort for a patient (Figure 45-8, A). Adult patients typically have an 8- to 12-Fr tube that is 36 to 44 inches (90 to 110 cm) long. Using a stylet makes the very flexible tube stiffer for easier insertion. Once receiving confirmation that it is in the correct location, the stylet needs removal before starting feedings and should not be reinserted in the tube. It is now standard to use an enteral-only connector (ENFit) designed for the specific enteral tube. Standardization of connector tubing improves patient safety (Figure 45-8, B). Tubing standards are designed to reduce tubing misconnections that result in patient injury (TJC, 2014). Skill 45-3 describes the procedure for initiating beginning nasogastric, gastrostomy, and jejunostomy enteral feedings.

Historically nurses verified feeding tube placement by injecting air through the tube while auscultating the stomach for a gurgling or bubbling sound or asking the patient to speak. However, evidence-based research repeatedly demonstrates that auscultation is ineffective in detecting tubes accidentally placed in the lung (Yantis and Velander, 2011). Some patients are able to speak despite placement of feeding tubes in the lung. Furthermore, auscultation is not effective in distinguishing between gastric and intestinal placement for feeding tubes. The measurement of pH of secretions withdrawn from the feeding tube helps to differentiate the location of a tube (Box 45-13). At present the most reliable method for verification of placement of small-bore feeding tubes is x-ray film examination (Box 45-14).

Table 45-7 outlines major complications of EN. Of special note, severely malnourished patients are at risk for electrolyte disturbances from refeeding syndrome during EN or PN therapy. In refeeding syndrome, potassium, magnesium, and phosphate move intracellularly, resulting in low serum (extracellular) levels and edema. These changes may cause cardiac dysrhythmias, heart failure, respiratory distress, convulsions, coma, or death.

Parenteral Nutrition. **Parenteral nutrition** (PN) is a form of specialized nutrition support provided intravenously. A basic PN formula is a combination of crystalline amino acids, hypertonic dextrose, electrolytes, vitamins, and trace elements. Total PN (TPN), administered through a central line, is a 2-in-1 formula in which administration of fat emulsions occurs separately from the protein and dextrose solution (Krzywda and Meyer, 2010). Safe administration depends on appropriate assessment of nutrition needs, meticulous management of the CVC, and careful monitoring to prevent or treat metabolic complications. Administration of PN happens in a variety of settings, including a patient's home. Regardless of the setting, adhere to

FIGURE 45-8 A, Enteral tubes, small-bore. **B,** Enteral-only connector (ENFit) designed to fit the specific enteral tube.

BOX 45-13 PROCEDURAL GUIDELINES

Obtaining Gastrointestinal Aspirate for pH Measurement, Large-Bore, and Small-Bore Feeding Tubes: Intermittent and Continuous Feeding

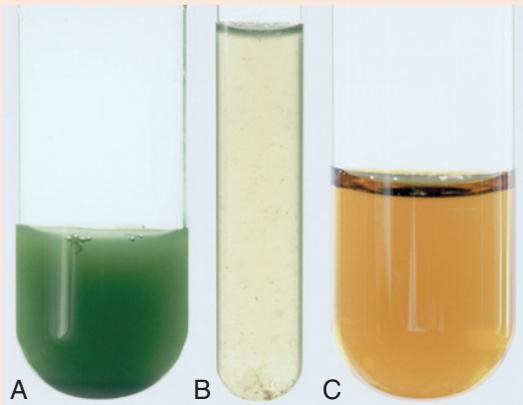
Delegation Considerations

Do not delegate the skill of measuring pH in gastrointestinal (GI) aspirate to nursing assistive personnel.

Equipment

Cone-tipped or Asepto syringe, pH test paper (scale of 1.0 to 11.0 or greater), paper towel, small medication cup, clean gloves

Steps

1. Perform measures to verify placement of tube:
   a. For intermittently fed patients, test placement immediately before feeding (usually a period of at least 4 hours has elapsed since previous feeding). More frequent checking has been associated with increased clogging of small-bore tubes. To avoid clogging, flush tube with 30 mL water after aspirating for the gastric residual volume (Yantis and Velander, 2011).
   b. For continuously tube-fed patients, test placement every 4 to 6 hours (Yantis and Velander, 2011). If patient is tolerating the feedings without incident and other indicators of correct location are present (i.e., the mark on the tube at the exit site has remained in its original position, and the most recent x-ray films confirm correct position of tube), it is reasonable to continue feedings. If risk of tube displacement is high, and the tube has moved, consider the need for an x-ray film to verify placement (Stewart, 2014). Plan pH testing at times when feeding may be withheld (e.g., during diagnostic testing or chest physiotherapy or to avoid medication interaction).
   c. Wait at least 1 hour after medication administration by tube or mouth.
2. Perform hand hygiene and apply clean gloves.
3. Draw up 30 mL of air into syringe and attach to end of feeding tube. Flush tube with 30 mL of air before attempting to aspirate fluid. It is likely to be more difficult to aspirate fluid from the small intestine than from the stomach. Repositioning patient from side to side is helpful. More than one bolus of air through the tube is necessary in some cases. Burst of air aids in aspirating fluid more easily.
4. Draw back on syringe and obtain 5 to 10 mL of gastric aspirate.
   a. Observe appearance of aspirate (see illustration).


STEP 4a Gastrointestinal contents. **A,** Stomach. **B,** Stomach. **C,** Intestinal. (Courtesy Dr. Norma Metheny, Professor, St Louis University School of Nursing.)

   b. Gently mix aspirate in syringe. Expel a few drops into a clean medicine cup. Dip the pH strip into the fluid or apply a few drops of the fluid to the strip (see illustration). Compare the color of the strip with the color on the chart provided by the manufacturer (Yantis and Velander, 2011).

STEP 4b Comparing pH strip with color chart.

   - Gastric fluid from patient who has fasted for at least 4 hours usually has pH range of 1.0 to 4.0.
   - Fluid from nasointestinal tube of fasting patient usually has pH greater than or equal to 6.0 (Stewart, 2014).
   - Patient with continuous tube feeding often has pH of 5.0 or higher.
   - pH of pleural fluid from tracheobronchial tree is generally greater than 6.0.
5. Remove gloves and discard supplies. Perform hand hygiene.

CLINICAL DECISION: If after repeated attempts you cannot aspirate fluid from a tube that was originally established by x-ray film examination to be in desired position and (a) there are no risk factors for tube dislocation, (b) there is no change in external marked tube length, and (c) patient is not experiencing difficulty, assume that tube is placed correctly (Yantis and Velander, 2011).

Accuracy in Determining Placement of Feeding Tubes

PICO Question: In adult patients which method of assessment provides the most accurate information that an enteral feeding tube is in the correct location?

Evidence Summary

Two of the most frequent complications associated with tube feedings are pulmonary aspiration, potentially leading to pneumonia, and accidental placement of a nasoenteric feeding tube into the lung. Patients at highest risk for aspiration present with dysphagia, decreased level of consciousness, confusion, uncooperativeness, agitation, presence of an endotracheal tube, and absent or poor gag reflex (Metheny et al., 2012). Gastric residual volume has not been found to be consistently related to aspiration (Stewart, 2014). A traditional bedside method used to assess for pulmonary aspiration of enteral feeding into the respiratory tract was the glucose method. The premise of the glucose method was that normal tracheal secretions contain minimal levels of glucose. Therefore, if aspiration of glucose-rich enteral formula occurs into the airway, glucose levels of tracheal secretions increase. However, researchers have shown that the glucose levels of tracheal secretions vary widely and this method is not sufficiently sensitive or specific to be useful to detect aspiration (Metheny et al., 2012). Researchers are currently trying to develop new bedside methods for assessing for pulmonary aspiration such as using electromagnetic tracking devices and assessing for the presence of pepsin, a substance produced in the stomach in tracheal secretions (Stewart, 2014).

Traditionally nurses have used the auscultatory method of assessing placement, which is unreliable. Auscultation does not detect when a feeding tube has inadvertently been placed into the respiratory tract and does not distinguish between placement in the stomach versus the intestine. The most accurate method for checking feeding tube placement is x-ray film examination (Kenny and Goodman, 2010; Stewart, 2014). The most effective nonradiological methods include aspirating fluid from the feeding tube, measuring its pH, and describing its appearance (Stewart, 2014). However, gastric aspirate may not be accurate if the patient is being administered medication to suppress gastric acid (Yantis and Velander, 2011).

Application to Nursing Practice

- X-ray film verification of feeding tube placement is the most reliable method available to confirm correct tube location. It is required in most acute care facilities immediately after insertion of a small-bore tube.
- Verify the placement of the feeding tube every 4 to 6 hours by aspirating gastric contents, observing its appearance, and testing pH. A properly obtained pH of 0 to 4.0 is a good indication of gastric placement. A pH of 6.0 or higher likely indicates placement in the lung, intestine, or even the stomach when gastric pH is unusually high. Intestinal fluid is usually bile stained (dark golden yellow). Gastric fluid is usually grassy green, off-white to tan, or clear and colorless (Stewart, 2014).
- Do not use the auscultatory method to determine tube location.
- Do not use the glucose detection method to determine if aspiration has occurred.
- Check gastric residual volumes every 4 hours in patients at high risk for aspiration (Stewart, 2014).

principles of asepsis and infusion management to ensure safe nutrition support.

Patients who are unable to digest or absorb EN benefit from PN. Patients in highly stressed physiological states such as sepsis, head injury, or burns are candidates for PN therapy (see Box 45-11).

PN therapy requires clinical and laboratory monitoring by a multidisciplinary team. Consistent reevaluation for the continuation of PN is required. The goal to move toward use of the GI tract is constant (Fletcher, 2013). Disuse of the GI tract has been associated with villus atrophy and generalized cell shrinkage. Furthermore, the disuse of the GI tract may cause bacteria to move from the unused gut into the bloodstream, resulting in gram-negative septicemia.

Sometimes adding **intravenous fat emulsions** to PN supports the patient's need for supplemental kilocalories to prevent essential fatty-acid deficiencies and help control hyperglycemia during periods of stress (Phillips, 2010). Administer these emulsions through a separate peripheral line, through the central line by using Y-connector tubing (see Chapter 42), or as an admixture to the PN solution. The addition of fat emulsion to a PN solution is called a *3-in-1 admixture* or *total nutrient admixture*. The patient receives it over a 24-hour period. Do not use the admixture if you observe oil droplets or an oily or creamy layer on the surface of the admixture. This observation indicates that the emulsion has broken into large lipid droplets that cause fat emboli if administered. IV fat emulsions are white and opaque. Take care to avoid confusing enteral formula with parenteral lipids.

Initiating Parenteral Nutrition. Patients with short-term nutritional needs often receive IV solutions of less than 10% dextrose via a peripheral vein in combination with amino acids and lipids. TPN is more calorically dense than peripheral solutions; therefore peripheral solutions are usually temporary. PN with greater than 10% dextrose requires a CVC that a health care provider places into a high-flow central vein such as the superior vena cava under sterile conditions (see Chapter 41). If you are using a CVC that has multiple lumens, use a port exclusively dedicated for the TPN. Label the port for TPN and do not infuse other solutions or medications through it (Krzywda and Meyer, 2010). Nurses with special training insert peripherally inserted central catheters (PICCs) that start in a vein of the arm and then thread into the subclavian or superior vena cava vein.

After catheter placement wait to flush and use the catheter until position confirmation by radiology. The health care provider secures the CVC with a securement device and covers the site with a sterile bio-occlusive dressing. Before applying the sterile dressing, stabilize the PICC with sterile strips of tape. A chest x-ray film verifies catheter tip placement for a CVC or PICC before starting a PN infusion (Fletcher, 2013).

Before beginning any PN infusion, verify the health care provider's order and inspect the solution for particulate matter or a break in the fat emulsion. Always use an infusion pump to deliver a constant rate. The initial rate delivers no more than 50% of estimated needs for the first 24 to 48 hours and gradually increases the rate until a patient's complete nutrition needs are supplied (National Guideline Clearinghouse, 2013). Patients receiving PN at home frequently administer the entire daily solution over 12 hours at night. This allows the patient to disconnect from the infusion each morning, flush the central line, and have independent mobility during the day. Home PN therapy often interferes with patients' normal activities, causing a poorer quality of life.

Preventing Complications. Complications of PN include catheter-related problems and metabolic alterations (Table 45-8). Pneumothorax results from a puncture insult to the pulmonary system and involves the accumulation of air in the pleural cavity with subsequent collapse of the lung and impaired breathing. The clinical symptoms of a pneumothorax include sudden sharp chest pain, dyspnea, and coughing. In relation to PN, pneumothorax most often occurs during CVC placement. Monitor a patient with a CVC for the first 24 hours for signs and symptoms of pulmonary distress.

TABLE 45-7 Enteral Tube-Feeding Complications

Problem	Possible Cause	Intervention*
Pulmonary aspiration	Regurgitation of formula	Verify tube placement. Place patient in high-Fowler's position or elevate head of bed a minimum of 30 (preferably 45) degrees during feedings and for 2 hours afterward.
	Feeding tube displaced	Reposition tube and verify tube placement.
	Deficient gag reflex	Reassess for return of normal gag reflex; until then place patient on aspiration precautions and in semi-Fowler's position.
	Delayed gastric emptying	See delayed gastric emptying that follows.
Diarrhea	Hyperosmolar formula or medications	Deliver formula continuously, lower rate, dilute, or change to isotonic enteral nutrition.
	Antibiotic therapy	Antibiotics destroy normal intestinal flora; consult with health care provider to consider changing medication; treat symptoms with antidiarrheal agents; culture stool for *Clostridium difficile.*
	Bacterial contamination	Do not hang formula longer than 4-8 hours in bag, wash bag out well when refilling, change tube-feeding bags and tubing q24h and use aseptic practices. Check expiration dates.
	Malabsorption	Check for pancreatic insufficiency; use low-fat, lactose-free formula and continuous feedings.
Constipation	Lack of fiber	Consult with a dietitian to select a formula containing fiber.
	Lack of free water	Add water during tube flushes.*
	Inactivity	Monitor patient's ability to ambulate; collaborate with health care provider and/or physical therapist for activity order.
Tube occlusion	Pulverized medications given per tube	Irrigate with 30 mL water before and after each medication per tube.* Use liquid medications when available. Completely dissolve crushed medications in liquid if liquid medication is not available.
	Sedimentation of formula	Shake cans well before administering (read label).
	Reaction of incompatible medications or formula	Read pharmacological information on compatibility of drugs and formula.
Tube displacement	Coughing, vomiting	Replace tube and confirm placement before restarting tube feeding.
	Not taped securely	With placement verification check that tape is secure (nasoenteric).
Abdominal cramping, nausea/vomiting	High osmolality of formula	Suggest an isotonic formula or dilution of current formula to health care provider.
	Rapid increase in rate/volume	Lower rate of delivery to increase tolerance. Maintain head of bed at least 45 degrees.
	Lactose intolerance	Suggest use of lactose-free formula.
	Intestinal obstruction	Stop feeding with GI obstruction.
	High-fat formula used	Use greater proportion of carbohydrate.
	Cold formula used	Warm formula to room temperature.
Delayed gastric emptying	Diabetic gastroparesis	Consult with health care provider regarding prokinetic medication for increasing gastric motility.
	Serious illnesses	Consult health care provider regarding advancing tube to intestinal placement.
	Inactivity	Monitor medications and pathological conditions that affect GI motility.
Serum electrolyte imbalance	Excess GI losses	Monitor serum electrolyte levels daily. Provide free water per registered dietitian recommendation.
	Dehydration	
	Presence of disease states such as cirrhosis, renal insufficiency, heart failure, or diabetes mellitus	
Fluid overload	Refeeding syndrome in malnutrition	Restrict fluids if necessary and use either a specialized formula or a diluted enteral formula at first.
	Excess free water or diluted (hypotonic) formula	Monitor levels of serum proteins and electrolytes. Use more concentrated formula with fluid volume excess without risk of refeeding syndrome.
Hyperosmolar dehydration	Hypertonic formula with insufficient free water	Slow rate of delivery, dilute, or change to isotonic formula.

*First check for fluid-restricted conditions that affect how much water can be given safely.
GI, Gastrointestinal.

An air embolus possibly occurs during insertion of the catheter or when changing the tubing or cap. Turn the patient into a left lateral decubitus position and have him or her perform a Valsalva maneuver (holding the breath and "bearing down") during catheter insertion to help prevent air embolus. The increased venous pressure created by the maneuver prevents air from entering the bloodstream. Maintaining integrity of the closed IV system also helps prevent air embolus.

Catheter occlusion is present when there is sluggish or no flow through the catheter. Temporarily stop the infusion and flush with saline or heparin per protocol or orders. If this is unsuccessful, attempt to aspirate a clot. If still unsuccessful, follow institution protocol for use of a thrombolytic agent (e.g., urokinase).

Suspect catheter sepsis if a patient develops fever, chills, or glucose intolerance and has a positive blood culture. To prevent infection,

TABLE 45-8	Metabolic Complications of Parenteral Nutrition	
Problem	**Signs/Symptoms**	**Intervention**
Electrolyte imbalance	See Chapter 42 for signs of deficiency/toxicity	Check TPN for supplemental electrolyte levels. Notify health care provider of imbalances. Maintain steady rate of infusion. Monitor intake and output.
Hypercapnia	Increased oxygen consumption, CO_2, respiratory quotient (>1), and minute ventilation	Ventilator-dependent patients are at risk; provide 30% to 60% of energy requirements per health care provider's order.
Hypoglycemia	Diaphoresis, shakiness, confusion, loss of consciousness	To prevent hypoglycemia, do not abruptly discontinue TPN but taper rate down to within 10% of infusion rate 1 to 2 hours before stopping. If you suspect hypoglycemia, test blood glucose and administer IV bolus of 50% dextrose or glucagon per order or protocol if necessary.
Hyperglycemia	Thirst, headache, lethargy, increased urination	Monitor blood glucose level every 6 hours. Initiate TPN slowly and taper up to maximal infusion rate to prevent hyperglycemia. Additional insulin may be required during therapy if problem persists or patient has diabetes mellitus.
Hyperglycemic hyperosmolar nonketotic coma (HHNKC) or hyperosmolar hyperglycemic nonketotic syndrome (HHNS)	Hyperglycemia (>500 mg/dL), glycosuria, serum osmolarity >350 mOsm/L, confusion, azotemia, headache, severe signs of dehydration (see Chapter 41), hypernatremia, metabolic acidosis, convulsions, coma	Monitor blood glucose, BUN, serum osmolarity, glucose in urine, and fluid losses; administer insulin as ordered; replace fluids as ordered; maintain constant infusion rate; and provide 30% of daily energy needs as fat. Patients at risk are those receiving steroids; older adults diagnosed with diabetes who have impaired renal or pancreatic function or increased metabolism or who are septic.

BUN, Blood urea nitrogen; *IV,* intravenous; *TPN,* total parenteral nutrition.

change the TPN infusion tubing every 24 hours. Do not hang a single container of PN for more than 24 hours or lipids more than 12 hours. Change the administration system every 72 hours when infusing a 2-in-1 solution and every 24 hours for a 3-in-1 solution (Phillips, 2010). During CVC dressing changes always use a sterile mask and gloves and assess insertion sites for signs and symptoms of infection (see Chapter 42). Change the CVC dressing per institution policy and anytime it becomes wet or contaminated. Use either alcohol or an alcoholic solution of chlorhexidine gluconate to clean the injection port or catheter hub 15 seconds before and after each time it is used (National Guideline Clearinghouse, 2013). Use a 1.2-micron filter for 3-in-1 formulas and an inline 0.22-micron filter for PN solutions that do not include IV fat emulsions.

PN solutions contain most of the major electrolytes, vitamins, and minerals. Patients also need supplemental vitamin K as ordered throughout therapy. Synthesis of vitamin K occurs by the microflora found in the jejunum and ileum with normal use of the GI tract; however, because PN circumvents GI use, patients need to receive exogenous vitamin K.

Electrolyte and mineral imbalances often occur. Administration of concentrated glucose accompanies an increase in endogenous insulin production, which causes cations (potassium, magnesium, and phosphorus) to move intracellularly. Monitor blood glucose levels every 6 hours to assess for hyperglycemia and administer supplemental insulin as needed (Phillips, 2010) (see Skill 45-4 on pp. 1094-1097).

Too-rapid administration of hypertonic dextrose can result in an osmotic diuresis and dehydration (see Chapter 42). If an infusion falls behind schedule, do not increase the rate in an attempt to catch up. Sudden discontinuation of a solution can cause hypoglycemia. Usually it is recommended to infuse 10% dextrose when discontinuing PN solution suddenly. Patients with diabetes are more at risk.

The goal is to move patients from PN to EN and/or oral feeding. Once patients are meeting one third to one half of their kilocalorie needs per day, health care providers usually decrease PN by half the original volume and increase EN feedings to meet the patient's nutritional needs. Patients who make the transition from PN to oral feedings typically have early satiety and decreased appetite. Gradually decrease PN in response to increased oral intake. If oral intake is inadequate, small frequent meals are helpful. Recommend calorie/protein counts when patients begin taking soft foods. When meeting 75% of nutritional needs by enteral feedings or reliable dietary intake, it is usually safe to discontinue PN therapy. Discontinuation of PN may also happen if complications occur or the health care provider determines that it is not benefiting the patient (Krzywda and Meyer, 2010).

Restorative and Continuing Care. Patients discharged from a hospital with diet prescriptions often need dietary education to plan meals that meet specific therapeutic requirements. Restorative care includes both immediate postsurgical care and routine medical care and therefore includes patients in the hospital and at home. The following sections address nutritional interventions for some common disease states.

Medical Nutrition Therapy. Optimal nutrition is just as important in illness as it is in health. As a result, dietary modifications and intake are often needed to maintain the nutritional requirements of patients with certain illnesses. **Medical nutrition therapy (MNT)** is the use of specific nutritional therapies to treat an illness, injury, or condition. It is necessary to help the body metabolize certain nutrients, correct nutritional deficiencies related to the disease, and eliminate foods that may exacerbate disease symptoms. It is most effective using a team approach that promotes collaboration between the health care team and an RD (American Dietetic Association, 2010b).

Gastrointestinal Diseases. Control peptic ulcers with regular meals and medications such as histamine receptor antagonists that block secretion of HCl or proton pump inhibitors. Marshall and Warren first identified *Helicobacter pylori* in 1984. *H. pylori,* a bacterium that causes up to 85% of peptic ulcers, is confirmed by laboratory tests or a biopsy during endoscopy (Nix, 2012). Antibiotics treat and

control the bacterial infection. Stress and overproduction of gastric HCl also irritate a preexisting ulcer. Encourage patients to avoid foods that increase stomach acidity and pain such as caffeine, decaffeinated coffee, frequent milk intake, citric acid juices, and certain seasonings (hot chili peppers, chili powder, black pepper). Discourage smoking, alcohol, aspirin, and nonsteroidal antiinflammatory drugs (NSAIDs). Teach patients to eat a well-balanced, healthy diet; avoid eating large meals; and eat three regular meals (or several small meals) without snacks, especially at bedtime (Nix, 2012). Family members of the patient with *H. pylori* infection also need to be tested and, if indicated, treated.

Inflammatory bowel disease includes Crohn's disease and idiopathic ulcerative colitis. Treatment of acute inflammatory bowel disease includes elemental diets (formula with the nutrients in their simplest form ready for absorption) or PN when symptoms such as diarrhea and weight loss are prevalent. In the chronic stage of the disease, a regular highly-nourishing diet is appropriate. Vitamins and iron supplements are often required to correct or prevent anemia. Patients manage irritable bowel syndrome by increasing fiber, reducing fat, avoiding large meals, and avoiding lactose or sorbitol-containing foods for susceptible individuals.

The treatment of **malabsorption** syndromes such as celiac disease includes a gluten-free diet. Gluten is present in wheat, rye, barley, and oats. Short-bowel syndrome results from extensive resection of bowel, after which patients suffer from malabsorption caused by lack of intestinal surface area. These patients require lifetime feeding with either elemental enteral formulas or PN.

Diverticulitis is a condition that results from an inflammation of diverticula, which are abnormal but common pouchlike herniations that occur in the bowel lining. Nutritional treatment for diverticulitis includes a moderate- or low-residue diet until the infection subsides. Afterward prescribing a high-fiber diet for chronic diverticula problems ensues.

Diabetes Mellitus. Type 1 DM requires both insulin and dietary restrictions for optimal control, with treatment beginning at diagnosis (ADA, 2012). By contrast, patients often control type 2 DM initially with exercise and diet therapy. If these measures prove ineffective, it is common to add oral medications. Insulin injections often follow if type 2 DM worsens or fails to respond to these initial interventions.

Individualize the diet according to a patient's age, build, weight, and activity level. Maintaining a prescribed carbohydrate intake is the key in diabetes management. The ADA recommends a diet that includes carbohydrates from fruits, vegetables, whole grains, legumes, and low-fat milk (American Dietetic Association, 2010b). Monitoring carbohydrate consumption is a key strategy in achieving glycemic control (ADA, 2012). Limit saturated fat to less than 7% of the total calories and cholesterol intake to less than 200 mg/day. In addition, varieties of foods containing fiber are recommended. Patients are able to substitute sucrose-containing foods for carbohydrates but need to make sure to avoid excess energy intake. Patients with diabetes can eat sugar alcohols and nonnutritive sweeteners as long as they follow the recommended daily intake level (ADA, 2012). Patients with diabetes and normal renal function should continue to consume usual amounts of protein (15% to 20% of energy) (ADA, 2012).

The goal of MNT treatment is to have glycemic levels that are normal or as close to normal as safely possible; lipid and lipoprotein profiles that decrease the risk of microvascular (e.g., renal and eye disease), cardiovascular, neurological, and peripheral vascular complications; and blood pressure in the normal or near-normal range (ADA, 2012). Be aware of signs and symptoms of hypoglycemia and hyperglycemia.

Cardiovascular Diseases. The goal of the American Heart Association (AHA) dietary guidelines (AHA, 2010) is to reduce risk factors for the development of hypertension and coronary artery disease. Diet therapy for reducing the risk of cardiovascular disease includes balancing calorie intake with exercise to maintain a healthy body weight; eating a diet high in fruits, vegetables, and whole-grain high-fiber foods; eating fish at least 2 times per week; and limiting food and beverages that are high in added sugar and salt. The AHA guidelines also recommend limiting saturated fat to less than 7%, trans-fat to less than 1%, and cholesterol to less than 300 mg/day. To accomplish this goal, patients choose lean meats and vegetables, use fat-free dairy products, and limit intake of fats and sodium (Nix, 2012).

Cancer and Cancer Treatment. Malignant cells compete with normal cells for nutrients, increasing a patient's metabolic needs. Most cancer treatments cause nutritional problems. Patients with cancer often experience anorexia, nausea, vomiting, and taste distortions. The goal of nutrition therapy is to meet the increased metabolic needs of a patient (Nix, 2012). Malnutrition in cancer is associated with increased morbidity and mortality. Enhanced nutritional status often improves a patient's quality of life.

Radiation therapy destroys rapidly dividing malignant cells; however, normal rapidly dividing cells such as the epithelial lining of the GI tract are often affected. Radiation therapy causes anorexia, stomatitis, severe diarrhea, strictures of the intestine, and pain. Radiation treatment of the head and neck region causes taste and smell disturbances, decreased salivation, and dysphagia. Nutrition management of a patient with cancer focuses on maximizing intake of nutrients and fluids. Individualize diet choices to a patient's needs, symptoms, and situation (Nix, 2012). Use creative approaches to manage alterations in taste and smell. For example, patients with altered taste often prefer chilled foods or foods that are spicy. Encourage patients to eat small frequent meals and snacks that are nutritious and easy to digest.

Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome. Patients with HIV/AIDS typically experience body wasting and severe weight loss related to anorexia, stomatitis, oral thrush infection, nausea, or recurrent vomiting, all resulting in inadequate intake. Factors associated with weight loss and malnutrition include severe diarrhea, GI malabsorption, and altered metabolism of nutrients. Systemic infection results in hypermetabolism from cytokine elevation. The medications that treat HIV infection often cause side effects that alter patients' nutritional status.

Restorative care of malnutrition resulting from AIDS focuses on maximizing kilocalories and nutrients. Diagnose and address each cause of nutritional depletion in the care plan. The progression of individually tailored nutrition support begins with administering oral, to enteral, and finally to parenteral. Good hand hygiene and food safety are essential because of a patient's reduced resistance to infection. For example, minimization of exposure to *Cryptosporidium* in drinking water, lakes, or swimming pools is important. Small, frequent, nutrient-dense meals that limit fatty and overly sweet foods are easier to tolerate. Patients benefit from eating cold foods and drier or saltier foods with fluid in between (Nix, 2012).

◆ **Evaluation**

Through the Patient's Eyes. Patients expect competent and accurate care. If ongoing nutrition therapies do not result in successful outcomes, patients expect nurses to recognize this and alter the plan of care accordingly. Expectations and health care values held by nurses frequently differ from those held by patients. Successful interventions and outcomes require nurses to know what patients expect in addition to nursing knowledge and skill. Work closely with patients to define

their expectations and talk with them about their concerns if their expectations are not realistic. Consider the limits of their conditions and treatment, their dietary preferences, and their cultural beliefs when evaluating outcomes.

Patient Outcomes. Care plans need to reflect achievable goals and outcomes. Evaluate the actual outcomes of nursing actions and compare them with expected outcomes to determine if the goals were met (Figure 45-9). Interprofessional collaboration remains essential in providing nutritional support. Nutrition therapy does not always produce rapid results. You need to evaluate a patient's current weight in comparison with his or her baseline weight, serum albumin or prealbumin, and protein and kilocalorie intake routinely. If you do not observe gradual weight gain or if weight loss continues, evaluate the dietary EN prescription and determine if the patient is experiencing any adverse effects from medications that are affecting his or her nutritional status. Changes in condition also indicate a need to change the nutritional plan of care. Consult multidisciplinary members of the health care team in an effort to better individualize this plan. The patient is an active participant whenever possible. In the end a patient's ability to incorporate dietary changes into his or her lifestyle with the least amount of stress or disruption facilitates attainment of outcome measures. Failing to meet expected outcomes requires revising the nursing interventions or expected outcomes on the basis of the patient's needs or preferences. When not meeting outcomes, ask questions such as, "How has your appetite been?" "Have you noticed a change in your weight?" "How much would you like to weigh?" or "Have you changed your exercise pattern?"

Knowledge
- Characteristics of normal nutritional status
- Impact of the patient's adherence to a therapeutic diet on overall health and nutritional status

Experience
- Previous patient responses to nursing interventions for altered nutrition
- Personal experiences with dietary change strategies (what worked and what did not)

EVALUATION
- Reassess signs and symptoms associated with altered nutrition (weight, intake of Kcal and protein, laboratory results)
- Determine patient's satisfaction with nutritional therapy

Standards
- Use established expected outcomes to evaluate the patient's response to care (e.g., patient's weight increases by 0.5 kg/week, improved laboratory results)

Attitudes
- Use discipline to objectively analyze the patient's data to determine the success of nursing interventions
- Be creative when designing innovative nursing interventions to meet the patient's nutritional needs
- Demonstrate responsibility by following through with evaluation and counseling to successfully reach goals

FIGURE 45-9 Critical thinking model for nutrition evaluation.

SAFETY GUIDELINES FOR NURSING SKILLS

Ensuring patient safety is an essential role of the professional nurse. To ensure patient safety, communicate clearly with members of the health care team, assess and incorporate a patient's priorities of care and preferences, and use the best evidence when making decisions about your patient's care. When performing the skills in this chapter, remember the following points to ensure safe, individualized patient care.
- Verify that the appropriate ENFit connector is attached to the enteral tube when administering tube feedings (TJC, 2014).
- Use aseptic technique when preparing and delivering enteral feedings. Check agency policy for wearing gloves when handling feedings (Stewart, 2014).
- Label enteral equipment with patient name and room number; formula name, rate, and date and time of initiation; and nurse initials (Stewart, 2014).
- Practice "right patient, right formula, right tube, right ENFit adaptor" by matching formula and rate to feeding order and verifying that enteral tubing set connects formula to a feeding tube (Stewart, 2014).
- Position the patient upright or elevate the head of the bed a minimum of 30 (preferably 45) degrees unless medically contraindicated for patients receiving enteral feedings (Stewart, 2014).
- Trace all lines and tubing back to the patient to ensure only enteral-to-enteral connections (Stewart, 2014).
- Do not add food coloring or dye to EN because the use of dye has been linked to hypotension, metabolic acidosis, and death (Metheny, 2009).
- Refer to manufacturer guidelines to determine hang time for enteral feedings. Maximum hang time for formula is 8 hours in an open system and 24 to 48 hours in a closed, ready-to-hang system (if it remains closed). There is increased risk of bacterial growth in feedings that exceed the recommended hang time.
- Always use an infusion pump for continuous enteral feedings and PN.

SKILL 45-1	ASPIRATION PRECAUTIONS

DELEGATION CONSIDERATIONS

The skill of assessing a patient's risk for aspiration and determining positioning cannot be delegated to nursing assistive personnel (NAP). NAP may feed patients after receiving instructions in aspiration precautions. Instruct NAP to:

- Position patient upright (45 to 90 degrees preferred) or according to medical restrictions.
- Follow aspiration precautions while feeding patient.
- Report any onset of coughing, gagging, or pocketing of food in the mouth.

EQUIPMENT

- Chair or electric bed (to allow patient to sit upright)
- Thickening agents as designated by RD or SLP (rice, cereal, yogurt, gelatin, commercial thickening agent)
- Tongue blade
- Oral-hygiene supplies (see Chapter 40)
- Penlight
- Suction equipment
- Clean gloves
- *Option:* Pulse oximeter

STEP	RATIONALE

ASSESSMENT

1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.
2. Perform hand hygiene. Perform nutrition screening.

3. Perform dysphagia screening or review results of dysphagia screen by an SLP. Note symptoms such as cough, pharyngeal pooling, change in voice after swallowing. Use a validated screening tool (when available).
4. *Option:* Measure patient's oxygen saturation.

5. Assess mental status: alertness, orientation, ability to follow simple commands.
6. Observe patient during previous mealtime for signs of dysphagia and allow him or her to attempt to feed self. Observe patient eat various consistencies of foods and liquids. Note at end of meal if patient becomes tired.
7. Assess patient's oral cavity (apply gloves as needed) for level of hygiene, missing teeth, or poorly fitting dentures.
8. Ask patient and or family caregiver about any difficulties with chewing or swallowing various textures of food.
9. Assess patient's swallowing reflex before initial feeding by placing fingers on patient's throat at level of larynx and asking patient to swallow saliva. Feel for movement of larynx.
10. Take tongue blade and, while asking patient to say "Ah," observe movement of the tongue. Then gently elicit gag reflex. This should be done on initial assessment or if there is a change in patient's swallowing ability.

Rationale:

Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).

Patients at risk for aspiration from dysphagia often alter their eating patterns or choose foods that do not provide adequate nutrition (Ochoa, 2012).

Patients at risk for dysphagia include those who have neurological or neuromuscular diseases and those who have had trauma to or surgical procedures of the oral cavity or throat (see Box 45-7).

Provides baseline to help determine if aspiration develops. However, changes in oxygen saturation may not be related to aspiration; further research is needed (ASHA, 2014).

Determines patient's ability to participate in feeding.

Helps detect abnormal eating patterns such as frequent clearing of throat or prolonged eating time. Fatigue increases risk of aspiration and may reveal a need to plan smaller, more frequent meals.

Poor oral hygiene (decayed teeth, plaque) causes growth of bacteria in the mouth, which can be aspirated.

Certain types of foods are easier to aspirate than others.

Movement of larynx can be palpated.

Tongue movement may reveal weakness on one side of the mouth, impairing swallowing.

PLANNING

1. Arrange equipment and supplies at bedside.
2. Explain to patient what you will be doing while he or she eats.
3. Provide a 30-minute rest period before meals.

Rationale:

Increases patient cooperation.

Swallowing difficulty is less likely in a well-rested patient (Metheny et al., 2012).

IMPLEMENTATION

1. Perform hand hygiene. Apply clean gloves, then have patient perform hand hygiene.
2. Perform oral hygiene, including brushing of tongue, before meal. Remove and dispose of gloves. Perform hand hygiene.
3. Position patient upright in a chair or elevate head of patient's bed to a 45- to 90-degree angle or to the highest position allowed by patient's medical condition during feeding.
4. Using penlight and tongue blade, gently inspect mouth for pockets of food.

5. Have patient assume a chin-tuck position. Begin by having patient try sips of water. Monitor for swallowing and respiratory difficulties continuously. If patient tolerates water, offer a larger volume of water and then different consistencies of foods and liquids.

6. Add thickener to thin liquids to create consistency of mashed potatoes or serve patient pureed foods per SLP evaluation.
7. Encourage patient to feed self.

Rationale:

Reduces transmission of microorganisms.

Risk of aspiration pneumonia is associated with poor oral hygiene (Borrelli and Talih, 2012).

Positions aim to prevent gastric reflux and reduces occurrence of aspiration (Grodner et al., 2012; Metheny and Frantz, 2013).

Pockets of food in mouth often indicate difficulty swallowing (Remig and Weeden, 2012).

Chin-tuck or chin-down position may help reduce aspiration (Terré and Mearin, 2012). Supine position increases probability of aspiration (Metheny et al., 2012).

Thin liquids such as water and fruit juice are difficult to control in mouth and are more easily aspirated (Ellis and Hannibal, 2013).

SKILL 45-1	ASPIRATION PRECAUTIONS—cont'd

STEP	RATIONALE
8. If patient is unable to feed self, place ½ to 1 teaspoon of food on unaffected side of mouth, allowing utensil to touch mouth or tongue.	Provides tactile cue to begin eating. Placement of food on affected (or weakened) side increases risk for aspiration.
9. Place hand on throat and gently palpate swallowing event as it occurs. Swallowing twice is often necessary to clear pharynx.	Helps evaluate swallowing effort.
10. Provide verbal coaching while feeding patient and give positive reinforcement, as follows:	Verbal cueing keeps patient focused on swallowing. Positive reinforcement enhances patient's confidence in ability to swallow (Metheny et al., 2012).
a. Open your mouth.	
b. Feel the food in your mouth.	
c. Chew and taste the food.	
d. Raise your tongue to the roof of your mouth.	
e. Think about swallowing.	
f. Close your mouth and swallow.	
g. Swallow again.	
h. Cough to clear airway.	
11. Avoid mixing food of different textures in same mouthful.	Single textures are easier to swallow than multiple textures.
12. Observe for coughing, choking, gagging, and drooling food; suction airway as necessary.	These are indications of dysphagia and risk for aspiration (National Stroke Association, 2013).
13. Do not rush patient, and avoid distractions. Provide rest periods as necessary during meal.	Avoiding fatigue decreases risk of aspiration (Metheny et al., 2012). Environmental distractions and conversation during meal increases risk for aspiration (Chang and Roberts, 2011).
14. Use tongue blade to inspect patient's mouth for pocketed food. (Apply gloves if needed.)	Checking for pocketed food provides information on patient's swallowing ability and prevents aspiration.
15. Have patient remain sitting upright for at least 30 to 60 minutes after meal.	Requiring patients to remain upright after meals or snacks reduces chance of aspiration by allowing food particles remaining in pharynx to clear (Frey and Ramsberger, 2011).
16. Help patient perform hand hygiene and mouth care. (Apply gloves if necessary.)	Mouth care after meals helps prevent dental caries and reduces colonization of bacteria, which reduces risk of pneumonia (Metheny et al., 2012).
17. Consult with registered dietician (RD) or speech-language pathologist to advance diet to thicker foods that require more chewing and, finally, to thin liquids.	RD or speech-language pathologist develop a safe patient-centered plan to advance the diet.
18. Return patient's tray to appropriate place and perform hand hygiene.	Reduces spread of microorganisms.

EVALUATION

1. Observe patient's ability to swallow foods of various textures and thickness.	Indicates whether aspiration risk increases with thin liquids.
2. Observe patient for signs of choking, coughing, and wet voice.	Provides continual data about patient's ability to effectively swallow and if the aspiration risk increases.
3. Inspect patient's oral cavity after meal to detect pockets of food.	Determines patient's ability to completely swallow food.
4. Monitor patient's intake and output, calorie count, food intake, and weight.	Aids in prompt detection of nutritional deficits, decreased caloric intake, or dehydration.
5. *Option:* For high-risk patients, monitor pulse oximetry readings throughout the feeding session.	Deteriorating oxygen saturation levels may help indicate aspiration, but currently more research is needed to determine efficacy (ASHA, 2014).
6. Use **Teach Back** to determine patient's and family's understanding about dysphagia. State, "I want to be sure I explained what dysphagia is and how to prevent choking. Can you explain to me the steps you can take to protect yourself from choking?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what the patient is able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Patient coughs, gags, complains of food "stuck in throat," or has pockets of food in mouth.
   - Stop feeding. If choking persists, suction oral cavity and place patient on NPO.
   - Notify health care provider.
   - Patient may require a swallowing evaluation.
   - Initiate consultation with health care provider so that a referral to a speech-language pathologist (SLP) can be made for different swallowing exercises and techniques to improve swallowing and reduce risk of aspiration.
2. Patient avoids certain textures of food.
   - Change consistency and texture of food.
3. Patient experiences weight loss.
   - Discuss findings with health care provider, SLP, and/or registered dietitian.

RECORDING AND REPORTING

- Record assessment findings, patient's tolerance of various food textures, amount of help required, position during meal, absence or presence of any symptoms of dysphagia, and amount eaten on flow sheet or nurses' notes in EHR or chart.
- Place information in patient's medical record indicating aspiration precautions.
- Document your evaluation of patient learning.
- Report any coughing, gagging, choking, or swallowing difficulties to health care provider.

SKILL 45-2	INSERTING AND REMOVING A SMALL-BORE NASOENTERIC TUBE FOR ENTERAL FEEDINGS

DELEGATION CONSIDERATIONS

The skill of inserting a small-bore feeding tube cannot be delegated to nursing assistive personnel (NAP). The nurse guides the NAP to assist with patient positioning during tube insertion.

EQUIPMENT

Insertion

- Small bore nasogastric or nasoenteric feeding tube with or without stylet (select smallest diameter possible to enhance patient comfort)
- Stethoscope and pulse oximeter/capnography device
- Water-soluble lubricant
- 60-mL or larger Luer-Lok or catheter-tip syringe
- Hypoallergenic tape and tincture of benzoin or tube fixation device
- pH indicator strip (scale 1.0 to 11.0 or greater)
- Glass of water and straw
- Emesis basin
- Towel
- Facial tissues
- Clean gloves
- Suction equipment in case of aspiration
- Penlight to check placement in nasopharynx
- Tongue blade

Removal

- Towel
- Facial tissue
- Oral hygiene supplies
- 30-mL Luer-Lok catheter-tip syringe

STEP	RATIONALE

ASSESSMENT

1. Verify health care provider's order for type of tube and enteric feeding schedule. Order should indicate delivery site and device, patient's name and identifying information (see agency policy), formula type, and administration method and rate.

Health care provider's order is needed to intubate patients with feeding tubes.

2. Review patient's medical history for basilar skull fracture, nosebleeds, oral facial surgery, facial trauma, nasal septum deviation, past history of aspiration, anticoagulation therapy, or coagulopathy.

A history of these problems may contraindicate tube placement and require you to consult with health care provider to change route of nutrition support. Passage of tube intracranially can cause neurological injury.

3. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.

Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).

4. Assess patient's knowledge of procedure.

Encourages cooperation, reduces anxiety, and minimizes risks. Identifies patient teaching needs.

5. Assess data on patient's height, weight, hydration status and I&O, electrolyte balance, and caloric needs in medical record.

Provides baseline information to measure nutritional improvement after enteral feedings are initiated.

6. Perform hand hygiene. Have patient close each nostril alternately and breathe. Examine each naris for patency and skin breakdown.

Sometimes nares are obstructed or irritated, or a septal defect or facial fractures are present. Place tube in most patent nostril.

7. Assess patient's mental status (ability to cooperate with procedure, sedation level), presence of cough and gag reflex, ability to swallow, presence of an artificial airway.

These are risk factors for inadvertent feeding tube placement into the tracheobronchial tree (Krenitsky, 2011). Patients with impaired level of consciousness often have impaired gag reflex; their risk of aspiration increases during insertion of feeding tubes and subsequent tube feedings (Altman et al., 2013).

CLINICAL DECISION: *Recognize situations in which blind placement of a feeding tube poses an unacceptable risk for patient. Devices for detecting accidental insertion of a tube into the airway, such as carbon dioxide sensors or electromagnetic tracking devices, enhance patient safety. Electromagnetically guided nasointestinal (NI) tubes enhance placement with real-time tip tracking to verify tube placement (Taylor et al., 2010). Only clinicians trained in the use of visualization or imaging techniques should perform blind placement of tubes (AACN, 2012; Krenitsky, 2011).*

SKILL 45-2	INSERTING AND REMOVING A SMALL-BORE NASOENTERIC TUBE FOR ENTERAL FEEDINGS—cont'd

STEP	RATIONALE
8. Perform physical assessment of abdomen.	Absence of bowel sounds or presence of abdominal pain, tenderness, or distention may indicate GI problem, contraindicating feeding.
9. Check medical record to determine if health care provider wants prokinetic agent administered before tube placement.	Prokinetic agents such as metoclopramide given before tube placement help advance tube into intestine (Metheny, 2006).

PLANNING

1. Explain procedure to patient, including sensations anticipated during insertion (burning in nasal passages) and to raise index finger to indicate gagging or discomfort during insertion.	Reduces anxiety and helps patient assist in insertion.
2. Perform hand hygiene. Organize supplies at bedside.	
3. Stand on same side of bed as naris chosen for insertion and help patient to high-Fowler's position unless contraindicated. Place pillow behind head and shoulders. If patient is comatose, raise HOB as tolerated in semi-Fowler's position with head tipped forward, using a pillow chin to chest. If necessary, have NAP assist. If patient is forced to lie supine, place in reverse Trendelenburg's position.	Allows easier manipulation of tube. Fowler's position reduces risk of aspiration and promotes effective swallowing.
4. Place bath towel over patient's chest. Keep facial tissues within reach.	Prevents soiling of gown. Insertion of tube frequently produces tearing.
5. Determine length of tube to be inserted and mark with tape.	
a. Measure distance from tip of nose to earlobe to xiphoid process of sternum (see illustration).	Length approximates distance from nose to stomach. The NEX (nose-earlobe-xiphoid) method is commonly used in clinical settings.
b. Measure distance from tip of nose to earlobe to mid-umbilicus for pediatric patients.	
c. Add additional 20 to 30 cm (8 to 12 inches) for nasointestinal (NI) tubes.	Length approximates distance from nose to intestine.
6. Prepare nasogastric or nasointestinal tube for insertion: **NOTE:** Do not ice plastic tubes.	Tubes becomes stiff and inflexible, causing trauma to mucous membranes.
a. If tube has guidewire or stylet, inject 10 mL of water from the Luer-Lok or catheter-tip syringe into tube.	Ensures tube is patent. Activates lubrication of tube for easier passage and ensures the tube is patent. Aids in guidewire or stylet removal once the tube is placed.
b. If using stylet, ensure that is it securely positioned within tube and that both Luer-Lok connections are snugly fit.	Promotes smooth passage of tube into GI tract. Improperly positioned stylet induces serious trauma.
7. Prepare materials for tube fixation. Tear off a 3- to 4-inch length of hypoallergenic tape or open membrane dressing or other fixation device). (See Step 13a in Implementation.)	Fixation devices allow the tube to float free of the nares, thus reducing pressure on the nares and preventing device-related pressure ulcer (DRPU).

IMPLEMENTATION

1. Perform hand hygiene. Apply clean gloves.	Reduces transmission of microorganisms.
2. Apply pulse oximeter/capnography device and measure vital signs.	Provides objective assessment of respiratory status during tube insertion.
3. *Option:* Dip tube with surface lubricant into glass of room temperature water or apply water soluble lubricant (see manufacturer's directions).	Activates lubricant to facilitate passage of tube into naris to GI tract.

STEP 5a Determine length of tube to be inserted. (Copyright © Mosby's Clinical Skills: Essentials Collection.)

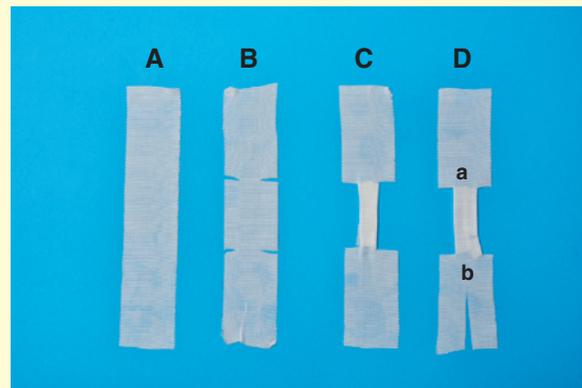
STEP	RATIONALE
4. Hand an alert patient a cup of water if able to hold cup and swallow. Explain that you are about to insert tube.	Swallowing water facilitates tube passage.
5. Explain next steps. Insert tube gently through nostril to back of throat (posterior nasopharynx). Aim back and down toward ear.	Natural contour facilitates passage of tube into GI tract and reduces gagging by patient.
6. Have patient relax and flex head toward chest after tube has passed through nasopharynx.	Closes off glottis and reduces risk of tube entering trachea.
7. Encourage patient to swallow by taking small sips of water when possible. Advance tube as patient swallows. Rotate tube gently 180 degrees while inserting.	Swallowing facilitates passage of tube past oropharynx. A tug may be felt as patient swallows, indicating tube is following desired path.
8. Emphasize need to mouth breathe and swallow during procedure.	Helps facilitate passage of tube and alleviates patient's fears during procedure.
9. Do not advance tube during inspiration or coughing becuase it will likely enter respiratory tract. Monitor oximetry/capnography.	Can cause tube to inadvertently enter patient's airway, which will be reflected in changes in O_2 saturation or end tidal CO_2.
10. Advance tube each time patient swallows until you have reached desired length (see illustration).	Reduces discomfort and trauma to patient.

CLINICAL DECISION: *Do not force the tube. If patient starts to cough or has a drop in oxygen saturation or an increased CO_2, withdraw tube into the posterior nasopharynx until normal breathing resumes.*

11. Using penlight and tongue blade, check to be sure tube is not positioned in back of throat.	Tube could become coiled, kinked, or enter the trachea.
12. Temporarily anchor tube to nose with a small piece of tape.	Movement of tube stimulates gagging. Allow for assessment of tube position before anchoring the tube securely.
13. Keep tube secure. Attach syringe to end of feeding tube and obtain gastric aspirate; assess amount, color, and quality of return. Measure gastric pH.	Proper tube position is essential before initiating feeding. Properly obtained pH of 1.0 to 4.0 is good indication of gastric placement (Fernandez et al., 2010).

CLINICAL DECISION: *Auscultation of the insufflation of air is not a reliable method for verification of tube placement because a tube inadvertently placed in the lungs, pharynx, or esophagus also transmits a sound similar to that of air entering the stomach (Kenny and Goodman, 2010; Stewart, 2014).*

14. Anchor tube to nose with a fixation device. Avoid pressure on nares. Mark tube at exit site with indelible ink. Select one of the following fixation methods.
   a. Apply tape.
     (1) Apply tincture of benzoin or other skin adhesive on tip of patient's nose and tube and allow it to become "tacky."
     (2) Remove gloves. Tear small horizontal slits at $\frac{1}{3}$ and $\frac{2}{3}$ length of tape without splitting tape (see illustration). Fold middle sections forward and seal.
     (3) Place top end of tape over bridge of patient's nose. Print date and time on the tape.
	Properly secured tube allows patient more mobility and prevents trauma to nasal mucosa.
	
	Helps tape adhere better. Protects skin.

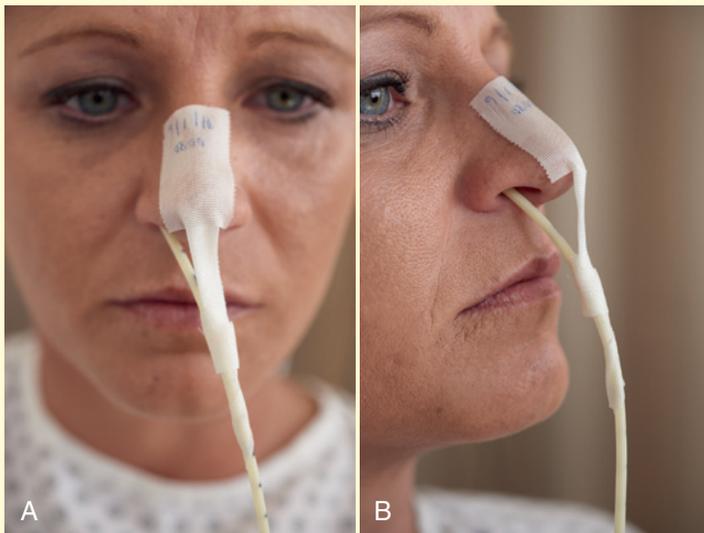
STEP 10 Insert NG tube through nose and esophagus into stomach.


STEP 14a(2) Taping method. **A,** Start with a piece of tape. **B,** Make two slits on both sides of tape. **C,** Fold middle section inward. **D,** Tear a new slit in bottom of tape. The top part (*a*) should attach to the patient's nose and the bottom part (*b*) should be wrapped around the tube.

SKILL 45-2	**INSERTING AND REMOVING A SMALL-BORE NASOENTERIC TUBE FOR ENTERAL FEEDINGS—cont'd**

STEP	**RATIONALE**
(4) Wrap bottom end of tape around tube as it exits nose (see illustration).	Securing tape to nares in this method reduces pressure on nares and reduces the risk for device-related pressure ulcer (AACN, 2014).
b. Apply tube fixation device using shaped adhesive patch (see manufacturer directions)..	Secures tube and reduces friction on naris.
(1) Apply wide end of patch to bridge of nose (see illustration).	
(2) Slip connector around tube as it exits nose (see illustration).	
15. Fasten end of nasogastric tube to patient's gown with piece of tape (see illustration). Do not use safety pins to fasten tube to gown.	Reduces traction on naris if tube moves. Safety pins become unfastened and possibly cause injury to patient.
16. Keep head of bed elevated at least 30 degrees (preferably 45 degrees) unless contraindicated (Metheny and Frantz, 2013). For intestinal tube placement, place patient on right side when possible until radiographic confirmation of correct placement.	Positioning patient on right side promotes passage of tube into small intestine.
17. Remove gloves, perform hand hygiene, and help patient to comfortable position.	Prevents transmission of infection.

CLINICAL DECISION: *Leave guidewire or stylet in place until a radiologist verifies correct position by x-ray film. Never attempt to reinsert partially or fully removed guidewire or stylet while feeding tube is in place.*

18. Obtain ordered x-ray film of chest/abdomen.	X-ray film examination is gold standard for verifying tube placement (Stewart, 2014).


STEP 14a(4) **A,** Applying tape to anchor nasoenteral tube. **B,** Nares are free of pressure from tape and feeding tube.

STEP 14b(1) Apply patch to bridge of nose.

STEP 14b(2) Slip connector around feeding tube.

STEP 15 Fasten feeding tube to patient's gown.

STEP	RATIONALE
19. After proper tube placement is verified, measure the amount of tube that is external and mark the exit of the tube at the nares with indelible marker as a guide for displacement.	The mark alert nurses to possible tube displacement, which will require confirmation of tube placement before further use.
20. Apply clean gloves and administer oral hygiene (see Chapter 40). Clean tubing at nostril.	Promotes patient comfort and integrity of oral mucous membranes.
21. Remove gloves, dispose of equipment, and perform hand hygiene.	Reduces transmission of microorganisms.

TUBE REMOVAL

STEP	RATIONALE
22. Verify health care provider's order for tube removal.	
23. Gather equipment and explain procedure to patient.	Informs patient and enhances cooperation.
24. Perform hand hygiene and apply clean gloves.	Reduces transmission of microorganisms.
25. Position patient upright in high-Fowler's unless contraindicated.	Reduces risk of aspiration in the event the patient vomits.
26. Place disposable pad or towel on patient's chest. If present, disconnect tube from feeding administration set and cap end..	Prevents mucus and secretions from soiling patient's gown.
27. Remove tape or tube fixation device from patient's nose and gown.	Allows for easy tube removal.
28. Instruct patient to take a deep breath and hold it.	Prevents inadvertent aspiration of gastric contents during tube removal.
29. Kink end of tubing securely by folding it over on itself. Then completely withdraw tube by pulling it out steadily and smoothly. Dispose of tubing in proper receptacle.	Prevents residual leakage of fluid from tube. Minimizes patient discomfort. Reduces transmission of microorganisms.
30. Offer tissues to patient to blow nose. Clean nares and provide oral care.	Provides patient comfort.
31. Remove gloves and perform hand hygiene.	Reduces transmission of microorganisms.

EVALUATION

STEP	RATIONALE
1. Inspect naris and oropharynx for any irritation after insertion.	If insertion was difficult, irritation of naris or oropharynx may have occurred.
2. Ask if patient feels comfortable.	Evaluates patient's level of comfort.
3. Observe patient for any difficulty breathing, coughing, or gagging.	Malposition of tube causes these symptoms.
4. Auscultate lung sounds.	Abnormal lung sounds are early sign of aspiration.
5. Confirm x-ray film results.	Verifies position of tube before initiating enteral feeding.
6. Routinely check location of external exit site marking on the tube as well as color and pH of fluid withdrawn from the feeding tube.	Routine checking ensures correct tube placement and reduces the risk of aspiration.
7. Use **_Teach Back_** to determine patient's and family's understanding about feeding tube. State, "I want to be sure I explained the feeding tube and its purpose. Can you explain to me why I placed this tube?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient and family are able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Suspected aspiration of stomach contents into the respiratory tract
- Position patient on side.
- Suction nasotracheally and orotracheally.
- Consult health care provider immediately to order chest x-ray film examination.
- Prepare for possible initiation of antibiotics.

2. Displacement of feeding tube to another site (e.g., from duodenum to stomach, mark at exit site if tube is moved); possibly occurs when patient coughs or vomits
- Aspirate GI contents and measure pH.
- Remove displaced tube; insert and verify placement of new tube.
- If there is a question of aspiration, obtain order for chest x-ray film.

RECORDING AND REPORTING

- Record the type and size of tube placed, location of distal tip of tube, patient's tolerance of procedure, pH value, and confirmation of tube position by x-ray film examination on flow sheet or nurses' notes in EHR or chart.
- Document your evaluation of patient learning.
- If patient develops signs of aspiration, notify health care provider immediately.

SKILL 45-3	ADMINISTERING ENTERAL FEEDINGS VIA NASOENTERIC, GASTROSTOMY, OR JEJUNOSTOMY TUBES

DELEGATION CONSIDERATIONS

The skill of administering enteral tube feeding via a NG, NI, gastrostomy, or jejunostomy tube can be delegated to nursing assistive personnel (NAP) after the tube placement is verified by the nurse (refer to agency policy). However, the nurse must verify tube placement and patency and that the feeding formula and fluid (water) to be administered are correct. The nurse must monitor the patient for effectiveness and tolerance of the feeding being delivered. The nurse directs the NAP to:

- Elevate the head of the bed to a minimum of 30 degrees (45 degrees is preferred) or sit patient up in bed or in a chair.
- Infuse feeding as ordered.
- Report any difficulty infusing feeding or any discomfort voiced by patient.
- Report any gagging, paroxysms of coughing, or choking.

EQUIPMENT

- Disposable feeding bag and tubing or ready-to-hang system. **NOTE:** Feeding tubes must have ENFit adapter (see Figure 45-8, *B*).
- 30-mL or larger Luer-Lok or catheter-tip syringe
- Stethoscope
- pH indicator strip (scale 1.0 to 11.0 or greater)
- Infusion pump (required for continuous or intestinal feedings): use pump designed for tube feedings
- Prescribed enteral feedings
- Clean gloves
- Equipment to obtain blood glucose by fingerstick

STEP	RATIONALE

ASSESSMENT

1. Verify health care provider's order for formula, rate, route, and frequency. Health care provider also orders laboratory data and bedside assessments such as fingerstick blood glucose measurement.

Tube feedings, laboratory tests, and bedside tests must be ordered by health care provider.

2. Review medical record to assess patient's need for enteral tube feedings: impaired swallowing, decreased level of consciousness, head or neck surgery, facial trauma, surgeries of upper alimentary canal.

Identify patients who need tube feedings before they become nutritionally depleted.

3. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.

Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).

4. Assess patient's nutritional status (see Table 45-4). Obtain baseline weight and review laboratory values (e.g., electrolytes, capillary blood glucose measurement). Assess patient for fluid volume excess or deficit, electrolyte abnormalities, and metabolic abnormalities such as hyperglycemia.

Enteral feedings are to restore or maintain a patient's nutritional status. Provides objective data to measure effectiveness of feedings.

5. Assess patient for food allergies or intolerances.

Prevents patient from developing localized or systemic allergic responses to feeding.

6. Perform physical assessment of abdomen.

Absent bowel sounds are not a contraindication to feeding, but you need to report a change from baseline abdominal assessment. If tenderness or distention develop, determine if feeding can proceed safely (Bankhead et al., 2009). May need to hold tube feeding (see agency policy).

7. For feedings administered through abdominal wall, assess insertion site for breakdown, irritation, drainage, discomfort, or presence of an external disk that is not excessively snug. Monitor that length of external tube remains the same as when originally placed.

Infection, pressure from tube, or drainage of gastric secretions causes skin breakdown. A disk that is too snug may cause skin breakdown. Internal tube migration may block pylorus and cause patient distress.

PLANNING

1. Explain procedure to patient.

Well-informed patient is more cooperative and at ease.

2. Perform hand hygiene and apply clean gloves.

Reduces transmission of microorganisms.

3. Prepare feeding container and formula:

Tube feedings administered within designated shelf life from container without cracks or breaks reduce patient's risk of obtaining tube feeding–borne GI infections. In addition, container without cracks or breaks prevents leakage of tube feeding.

   a. Check expiration date on formula and integrity of container.

   b. Have tube feeding at room temperature.

Cold formula causes gastric cramping and discomfort because mouth and esophagus do not warm liquid.

   c. Connect tubing to container as needed or prepare ready-to-hang container. Use proper ENFit connector and aseptic technique and avoid handling feeding system or touching can tops, container openings, spike, and spike port.

Correct enteral access connector designed for the specific of enteral tube reduces enteral tube misconnections and medication errors (TJC, 2016). These devices are not compatible with Luer-Lok or needleless connectors. Ensures that feeding system, including bag, connections, and tubing, is free of contamination to prevent bacterial growth (Stewart, 2014).

   d. Shake formula container well. Cleanse top of canned formula with alcohol swab before opening it. Fill container with formula (see illustration). Open roller clamp on tubing and fill with formula to remove air. Reclamp tubing. Hang on intravenous (IV) pole.

Filling tubing with formula prevents excess air from entering GI tract.

STEP	RATIONALE
4. For intermittent feeding have syringe ready and be sure that formula is at room temperature.	Cold formula causes gastric cramping.

IMPLEMENTATION

STEP	RATIONALE
1. Place patient in high-Fowler's position or elevate head of bed at least 30 (preferably 45) degrees. For patients forced to remain supine, place in reverse Trendelenburg's position.	Elevated head helps prevent aspiration (Kenny and Goodman, 2010).
2. Verify tube placement: (see Skill 45-2)	
a. *Nasogastric tube* (see Box 45-14): Attach syringe and aspirate 5 mL of gastric contents. Observe appearance of aspirate and note pH.	Verifies if tip of feeding tube is in stomach or intestine. Feedings instilled in misplaced tube can cause serious injury or death. Gastric fluid of patient who has fasted for at least 4 hours usually has a pH of 5 or less, especially when patient is not receiving gastric-acid inhibitor. Continuous administration of tube feedings elevates pH (Stewart, 2014). A pH greater than 6 indicates intestinal or pulmonary placement. (Bourgault et al., 2015).
b. *Gastrostomy tube:* Attach syringe and aspirate 5 mL of gastric contents. Observe appearance of aspirate and note pH.	
c. *Jejunostomy tube:* Aspirate intestinal secretions, observe their appearance, and check pH.	Presence of intestinal fluid indicates that end of tube is in small intestine.

> **CLINICAL DECISION:** *Auscultation of insufflated air is not a reliable method for verification of placement of a tube because a tube inadvertently placed in lungs, pharynx, or esophagus transmits sound similar to that of air entering the stomach (Kenny and Goodman, 2010; Stewart, 2014).*

STEP	RATIONALE
3. Check for gastric residual volume (GRV) before each feeding for bolus and intermittent feedings, every 4 hours in critically ill patients, and every 4 to 6 hours in non–critically ill patients for continuous feedings.	GRV indicates if there is delayed gastric emptying.
a. Draw up 10 to 30 mL of air into syringe. Connect to end of feeding tube. Flush tube with air. Pull back slowly to aspirate total amount of gastric contents and measure (see illustration).	
b. Return aspirated contents to stomach unless volume exceeds 250 mL (check agency policy). Some questions exist regarding safety of returning high volumes of fluid into the stomach (Delegge, 2011; Stewart, 2014).	Return of aspirate prevents fluid and electrolyte imbalance (Stewart, 2014).

> **CLINICAL DECISION:** *Numerous factors affect measurement accuracy of GRV, including size of gastric tube, position of the tube port in the gastric atrium, patient's position, and whether tube location is near the gastroesophageal junction. Best evidence suggests that a single high GRV should be monitored for the following hour but that the enteral feeding should not be stopped or withheld for an isolated high GRV (Makic et al., 2011).*

STEP 3d Pour formula into feeding container.

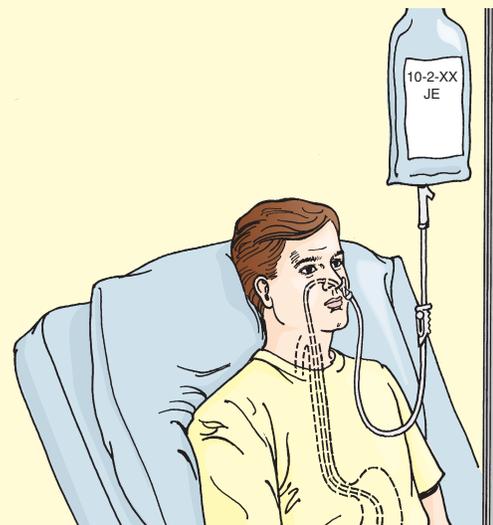
STEP 3a Check for gastric residual (small-bore tube).

SKILL 45-3	ADMINISTERING ENTERAL FEEDINGS VIA NASOENTERIC, GASTROSTOMY, OR JEJUNOSTOMY TUBES—cont'd

STEP	RATIONALE
c. Do not administer feeding when a single GRV exceeds 500 mL or when two consecutive measurements (taken 1 hour apart) each exceed 250 mL (Stewart, 2014; Yantis and Velander, 2011) (check agency policy).	Some controversy exists regarding ability of elevated GRVs to identify risk for pulmonary aspiration. However, frequent interruptions of feeding on the basis of GRV levels is a well-recognized reason for failure to meet nutritional goals (Delegge, 2011; Metheny et al., 2012; Stewart, 2014).
d. GRV in the range of 250 to 500 mL should raise concern and lead to implementation of measures to reduce aspiration risk. Automatic cessation of feeding should not occur for GRV less than 500 mL in the absence of other signs of intolerance (McCarthy et al., 2015).	Raising the cutoff value for GRV from a lower number to a higher number does not increase the risk for aspiration or pneumonia. Elevated GRV should raise concern and lead to measures to reduce the risk of aspiration.
4. Flush tubing with 30 mL water. Before attaching feeding administration set to feeding tube, trace tube to origin and label "Tube feeding only."	Ensures that tube is clear and patent (Metheny et al., 2012). Usually patients receive enteral feedings continuously. Avoids misconnections (Stewart, 2014). However, they often receive initial feedings by bolus to assess formula tolerance. See Box 45-12 for guidelines to advance enteral feedings.
5. Initiate feeding:	
a. Syringe for intermittent feeding	
(1) Pinch proximal end of feeding tube.	Prevents excessive air from entering patient's stomach/intestine or leaking of contents.
(2) Remove plunger from syringe and attach tip of syringe to end of tube.	
(3) Fill syringe with measured amount of formula (see illustration). Release tube, elevate syringe to no more than 45 cm (18 inches) above insertion site, and allow it to empty gradually by gravity. Repeat Steps (1) to (3) until you have delivered prescribed amount to patient.	Height of syringe allows for safe, slow, gravity drainage of formula. This gradual emptying of tube feeding by gravity reduces risk of abdominal discomfort, vomiting, or diarrhea induced by bolus or too-rapid infusion of tube feedings.
b. Feeding bag for intermittent feeding	

CLINICAL DECISION: *Before attaching feeding administration set to a feeding tube, trace the tube to its point of origin. Label the administration set "Tube Feeding Only." This prevents misconnections between feeding set and intravenous systems or other medical tubing or devices (Stewart, 2014).*

(1) Pinch proximal end of feeding tube and remove bag. Connect distal end of administration set tubing to end of feeding tube. Set rate by adjusting roller clamp on tubing or placing on feeding pump.	Prevents excess air from entering stomach and leakage of gastric contents.
(2) Allow bag to empty gradually over 30 to 45 minutes (see illustration). Label bag with tube-feeding type, strength, and amount (include date, time, and initials). Change bag every 24 hours.	Gradual emptying of tube feeding by gravity reduces risk for abdominal discomfort, vomiting, or diarrhea induced by bolus or too-rapid infusion of tube feedings. Helps decrease bacterial colonization.
(3) Immediately follow feeding with water (per health care provider's order). Cover end of bag with cap.	Cleans bag and feeding tube, prevents tube from clogging, and provides patient with adequate water.
(4) Keep bag as clean as possible, and change bag every 24 hours.	Helps decrease bacterial growth in feeding tube system.

STEP 5a(3) Fill syringe with formula.


STEP 5b(2) Administer intermittent feeding.

STEP	RATIONALE
c. Continuous-drip method	
(1) Remove cap and connect feeding tube to distal end of administration set tubing.	Prevents excess air from entering stomach and leakage of gastric contents.
(2) Insert tubing through infusion pump and set rate (see illustration). Use pump designated for tube feeding and not one for IV fluids.	Delivers continuous feeding at steady rate and pressure. Pump alarms for increased resistance.
6. Advance rate of tube feeding gradually as ordered (see Box 45-12).	Advancing tube feedings gradually helps prevent diarrhea and gastric intolerance to formula.
7. Flush with 30 mL water every 4 hours during continuous feeding, before and after an intermittent feeding (check agency policy). Collaborate with registered dietitian and health care provider regarding recommended total free water requirement per day and obtain order.	Clears tubing of formula and prevents clogging of tube (Stewart, 2014). Also provides water source for patient to help maintain fluid and electrolyte balance.

CLINICAL DECISION: *Flush tube with 30 mL sterile water in immunocompromised or critically ill patients (Stewart, 2014).*

STEP	RATIONALE
8. When patient is receiving intermittent tube feeding, cap or clamp proximal end of feeding tube when not in use.	Prevents air from entering stomach between feedings.
9. Rinse bag and tubing with warm water whenever feedings are interrupted.	Clears old tube feedings and reduces bacterial growth.
10. Change bag and use new administration set every 24 hours.	Reduces patient's exposure to bacterial growth occurring in bag and tubing.
11. For abdominally placed feeding tubes, clean insertion site daily and as needed. A small breathable dressing may be used to protect the insertion site. However, the site is usually left open to air.	Decreases risk for infection.
12. Dispose of supplies and perform hand hygiene.	Reduces transmission of microorganisms.

EVALUATION

1. Measure GRV per agency policy, usually every 4 to 6 hours. Ask patient if nausea is present.	Evaluates tolerance of tube feeding.
2. Monitor fingerstick blood glucose every 6 hours until patient reaches maximum administration rate and maintains it for 24 hours (see Skill 45-4).	Alerts nurse to patient's tolerance of glucose. If blood glucose levels are elevated, glucose testing will continue.
3. Monitor intake and output every 8 hours and calculate daily totals every 24 hours.	Intake and output are indications of fluid balance, fluid volume excess or deficit.
4. Weigh patient daily until maximum administration rate is reached and maintained for 24 hours; then weigh patient 3 times per week at same time using same scale.	Weight gain is indicator of improved nutritional status; however, sudden gain of more than 2 lbs in 24 hours usually indicates fluid retention.
5. Monitor laboratory values.	Improving laboratory values (e.g., albumin, transferrin, and prealbumin) indicate an improved nutritional status (Stewart, 2014).

STEP 5c(2) Connect tubing through infusion pump.

SKILL 45-3	ADMINISTERING ENTERAL FEEDINGS VIA NASOENTERIC, GASTROSTOMY, OR JEJUNOSTOMY TUBES—cont'd

STEP	RATIONALE
6. Observe patient's respiratory status.	Change in respiratory status (e.g., increased rate, declining SpO_2) may indicate aspiration of tube feeding.
7. Examine abdomen and auscultate bowel sounds.	Evaluates GI function.
8. Observe nasoenteral tube insertion site for impaired skin integrity. For tubes placed through abdominal wall, inspect insertion site for signs of impaired skin integrity and signs of infection, injury, or tightness of tube.	Enteral tubes often cause pressure and excoriation at insertion site. Gastric secretions also cause irritation to skin.
9. Use *Teach Back* to determine patient's and family's understanding about tube feedings. State, "I want to be sure I explained why we are giving tube feedings. Can you explain to me why tube feedings are necessary?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient and family are able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS (IN ADDITION TO THOSE IN SKILL 45-1)

1. Feeding tube is clogged.
   - Attempt to flush the tube with water
   - Special products, such as pancreatic enzymes, are available for unclogging feeding tubes.
   - Hold feeding and notify health care provider.
   - Maintain patient in semi-Fowler's position.
2. GRV exceeds 250 mL for each of two consecutive assessments (see agency policy).
   - Hold feeding and notify health care provider.
   - Maintain patient in upright position in chair/bed or elevate head of bed at least 30 (preferably 45) degrees.
   - Recheck residual in 1 hour.
3. Patient develops diarrhea 3 times or more in 24 hours.
   - Notify health care provider.
   - Confer with dietitian.
   - Institute skin-care measures.
   - Consider change in antibiotics, only for patients receiving antibiotics.
4. Patient develops nausea, vomits, and aspirates formula when gastric emptying is delayed or formula is administered too rapidly and produces vomiting.
   - Position patient in side-lying position.
   - Suction airway.
   - Notify health care provider.
   - Obtain chest x-ray film.
   - Check patency of tube.
   - Aspirate for GRV.

RECORDING AND REPORTING

- Record amount and type of feeding instilled, patient's response to tube feeding, patency of tube, condition of naris or skin at tube site for tubes placed in abdominal wall, and any side effects.
- Report patient's tolerance and adverse effects.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- Teach patient or family caregiver how to determine correct placement of feeding tube.
- Inform patient or family caregiver of signs associated with pulmonary aspiration, delayed gastric emptying.
- Reinforce signs and symptoms associated with feeding tube complications and when to call health care provider.
- Explain and demonstrate how to do skin care around gastrostomy or jejunostomy tube and explain signs and symptoms of infection at the insertion site.

SKILL 45-4	BLOOD GLUCOSE MONITORING

DELEGATION CONSIDERATIONS

When the patient is stable, the skill of measuring blood glucose level can be delegated to nursing assistive personnel (NAP). When the patient's condition changes frequently, you should not delegate this skill to NAP. The nurse directs the NAP by:

- Explaining appropriate sites to use for puncture and when to obtain glucose levels.
- Reviewing expected level and when to report unexpected glucose levels to the nurse.

EQUIPMENT

- Antiseptic swab
- Cotton ball
- Sterile lancet or blood-letting device
- Paper towel
- Blood glucose meter (e.g., OneTouch, Freestyle) (Figure 45-10)
- Blood glucose reagent strips (brand determined by meter used)
- Clean gloves

STEP	RATIONALE

ASSESSMENT

1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.

   Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).

2. Assess patient's understanding of procedure and purpose of glucose monitoring. Determine if patient with diabetes mellitus performs test at home and, if so, confirm his or her competency.

   Data set guidelines for nurse to develop teaching plan.

3. Determine if specific conditions need to be met before or after sample collection (e.g., with fasting, after meals, after certain medications, before insulin doses).

   Dietary intake of carbohydrates and ingestion of concentrated glucose preparations alter blood glucose levels.

4. Determine if risks exist for performing skin puncture (e.g., low platelet count, anticoagulant therapy, bleeding disorders).

   Abnormal clotting mechanisms increase risk for local ecchymosis and bleeding.

5. Assess area of skin that you will use as puncture site (e.g., fingers or heel). Alternative sites are palm, arm, or thigh. Avoid areas of bruising and open lesions.

   Sides of fingers and heels are commonly selected because they have fewer nerve endings. If the patient has diabetes mellitus, do not do a heelstick.

   Measurements from alternative sites are meter specific and may differ from traditional sites (ADA, 2012). Puncture site should not be edematous, inflamed, or recently punctured because these factors cause increased interstitial fluid and blood to mix and increase risk for infection.

6. Review health care provider's order for time of frequency of measurement.

   Health care provider determines test schedule on basis of patient's physiological status and risk for glucose imbalance.

7. For patient with diabetes who performs test at home, assess knowledge about procedure and ability to handle skin-puncturing device. If patient chooses, he or she may wish to continue self-testing while in hospital.

   Patient's physical health may change (e.g., vision disturbance, fatigue, pain, disease process), preventing him or her from performing test.

PLANNING

1. Explain procedure and purpose to inexperienced or uninformed patient and/or family. Offer patient and family opportunity to practice testing procedures. Provide resources/teaching aids for patient.

   Promotes understanding and cooperation.

IMPLEMENTATION

1. Perform hand hygiene.

   Reduces transfer of microorganisms.

2. Instruct adult to perform hand hygiene with soap and warm water. Rinse and dry.

   Reduces presence of microorganisms and any food residue on patient's hand. Food residue can contaminate blood drop and cause a false reading. Warmth promotes vasodilation at selected puncture site. Handwashing establishes practice for patient when performing test at home.

3. Position patient comfortably in chair or in semi-Fowler's position in bed.

   Ensures easy accessibility to puncture site. Patient assumes position when self-testing.

FIGURE 45-10 Blood glucose monitor. (Courtesy LifeScan, Inc., Milpitas, Calif.)

SKILL 45-4	BLOOD GLUCOSE MONITORING—cont'd

STEP	RATIONALE
4. Remove reagent strip from container; tightly seal cap. Check code on test strip vial.	Protects strips from accidental discoloration caused by exposure to air or light. Code on test strip vial must match code entered into glucose meter.
5. Turn on glucose meter if necessary.	Activates meter.

CLINICAL DECISION: *Some monitors activate when the reagent strip is inserted and therefore do not have a specific on/off switch.*

STEP	RATIONALE
6. Insert reagent strip into glucose meter (refer to manufacturer directions) and make necessary adjustments (see illustration).	Some machines need calibration; others require zeroing of timer. Each meter is adjusted differently.
7. Apply clean gloves.	Reduces risk for contamination by blood.
8. Choose puncture site. Puncture site should be vascular. In stable adults select lateral side of finger; be sure to avoid central tip of finger, which has more dense nerve supply.	Ensures free flow of blood following puncture. Lateral sides of fingers are less sensitive to pain.
9. Hold area to be punctured in dependent position. Do not milk or massage site.	Increases blood flow to area before puncture. Milking or messaging may hemolyze specimen and introduce excess tissue fluid, causing inaccurate readings (Pagana et al., 2015).
10. Wipe site with antiseptic swab and *allow it to dry completely.*	Removes resident microorganisms. Too much alcohol can cause blood to hemolyze.
11. Remove cover of lancet or bloodletting device. Hold lancet perpendicular to puncture site and pierce finger or heel quickly in one continuous motion (do not force lancet).	Placement ensures that lancet enters skin properly.
12. Some agencies use lancet devices with an automatic blade retraction system. This reduces possibility of self-sticks, preventing exposure to bloodborne pathogens. Place bloodletting device firmly against side of finger and push release button, causing needle to pierce skin (see illustration).	Bloodletting devices pierce skin to specific depth, ensuring adequate blood flow. Perpendicular position ensures proper skin penetration.
13. Wipe away first drop of blood with cotton ball. (See manufacturer directions for meter used.)	First drop of blood may contain more serous fluid than blood cells.
14. Lightly squeeze puncture site (without touching) until large drop of blood has formed (see illustration). Repuncturing is necessary if large-enough drop does not form to ensure accurate test results. (See manufacturer directions regarding how blood is applied.)	You need an adequate-size drop to activate monitor and obtain accurate results. Excessive squeezing of tissues during blood sample collection may contribute to pain, bruising, scarring, and hematoma formation.

CLINICAL DECISION: *Patients with diabetes frequently have peripheral vascular disease, making it difficult to produce a large drop of blood after a fingerstick. Be sure to hold finger in dependent position before puncturing to improve blood flow.*

STEP	RATIONALE
15. Obtain test results.	Exposure of blood to test strip for prescribed time ensures proper results.

CLINICAL DECISION: *Some meters (e.g., OneTouch [LifeScan]) require application of blood sample to a test strip already in the meter. Once the drop of blood is applied, the meter automatically calculates the reading.*

STEP 6 Load test strip into meter. (Courtesy of the manufacturer.)

STEP 12 Prick side of finger with lancet.

STEP 14 Squeeze puncture site until large droplet of blood forms.

STEP	**RATIONALE**
a. Be sure that meter is still powered on. Bring test strip in meter to drop of blood. The blood is wicked onto test strip (see manufacturer instructions).	Blood enters strip, and glucose device shows message on screen to signal that you have obtained enough blood.

CLINICAL DECISION: *Do not scrape blood onto the test strips or apply it to the wrong side of the test strip. This prevents accurate glucose measurement.*

b. Blood glucose test result appears on screen (see illustration). Some devices "beep" when completed.	
16. Turn off meter. Dispose of test strip, lancet, and gloves in proper receptacles. Perform hand hygiene.	Meter is battery powered. Proper disposal reduces risk for needlestick injury and spread of infection.
17. Discuss test results with patient.	Promotes participation and compliance with therapy.

EVALUATION

1. Observe puncture site for bleeding or tissue injury.	Site is a possible source of discomfort and infection.
2. Compare glucose meter reading with normal blood glucose levels and previous test results.	Determines if glucose level is normal.
3. Ask patient to explain test results.	Results of test may cause anxiety. Patient needs to understand range of glucose values to maintain blood glucose management.
4. Use **Teach Back** to determine patient's and family's understanding of how to monitor blood glucose. State, "It is important that you understand how to monitor your blood glucose. Can you explain why you need to monitor blood glucose? Can you explain to me the steps in performing a fingerstick?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient and family are able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Puncture site continues to bleed or bruised.
- Apply pressure to site.
- Notify health care provider if bleeding lasts more than 5 minutes.

2. Glucose meter malfunctions.
- Repeat test, following directions.
- Follow manufacturer directions for malfunctions.

3. Blood glucose level is above or below target range.
- Check medical record to see if there is a medication order for deviations in glucose level; if not, notify health care provider.
- Continue to monitor patient.
- Follow agency protocol for laboratory confirmation testing of very high or very low results. Generally laboratory testing is considered more accurate.
- Administer insulin or carbohydrate source as ordered (depending on glucose level).
- Notify health care provider of patient's response.

RECORDING AND REPORTING

- Record glucose results on flow sheet or nurses' notes in EHR or chart, including presence or absence of pain or excessive oozing of blood at puncture site.
- Document your evaluation of patient learning.
- Report blood glucose levels out of target range and take appropriate action for hypoglycemia or hyperglycemia.

STEP 15b Results appear on meter screen. (Courtesy of the manufacturer.)

KEY POINTS

- Ingestion of a diet balanced with carbohydrates, fats, proteins, vitamin, and minerals provides the essential nutrients to carry out the normal physiological functioning of the body throughout the life span.
- Through digestion food is broken down into its simplest form for absorption. Digestion and absorption occur mainly in the small intestine.
- Guidelines for dietary change recommend reduced fat, saturated fat, sodium, refined sugar, and cholesterol and increased intake of complex carbohydrates and fiber.
- Because improper nutrition affects all body systems, nutritional assessment includes a review of total physical assessment.
- Enteral feedings are for patients who are unable to ingest food but are able to digest and absorb food in the gastrointestinal tract.
- EN protects intestinal structure and function and enhances immunity.
- TPN supplies essential nutrients in appropriate amounts to support life through the administration of a concentrated nutrient solution into the superior vena cava near the right atrium of the heart.
- MNT is a recognized treatment modality for both acute and chronic disease states.
- One of the most important responsibilities of a nurse administering enteral feedings is to take precautions to prevent patients from aspirating feeding formula.
- Special diets alter the composition, texture, digestibility, and residue of foods to suit the patient's particular needs.

CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

1. Knowing that Mrs. Cooper is on a fixed income, you need to develop a plan to help her decrease her risk for complicating her present disease processes. Using your knowledge of medical nutrition therapy (MNT), summarize three points that you will include in a plan to help her meet her nutritional needs while living on a budget.
2. Six months later, Mrs. Cooper is admitted to the hospital for an exacerbation of her heart failure. She is diagnosed with a viral infection. She has increased weight gain because of fluid retention and decreased urinary output because her kidneys are starting to fail. Her appetite is poor; she has frequent nausea and vomiting. Her abdomen is soft and nontender, and bowel sounds are present. The health care provider orders the starting of enteral feedings.
   a. Which type of tube would be most appropriate for you to select?
   b. How would you verify tube placement?
   c. Which measures would you take to make sure that the tube stays in the correct position?
   d. Which tube-feeding complications would be appropriate for you to include in your patient assessment?

ⓔ *Answers to Clinical Application Questions can be found on the Evolve website.*

REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. The nurse is caring for a patient with pneumonia who has severe malnutrition. The nurse recognizes that, because of the nutritional status, the patient is at increased risk for: (Select all that apply.)
   1. Heart disease.
   2. Sepsis.
   3. Pleural effusion.
   4. Cardiac arrhythmias.
   5. Diarrhea.
2. The nurse evaluates which laboratory values to assess a patient's potential for wound healing?
   1. Fluid status
   2. Potassium
   3. Lipids
   4. Nitrogen balance
3. The nurse is caring for a patient with dysphagia and is feeding her a pureed chicken diet when she begins to choke. What is the priority nursing intervention?
   1. Suction her mouth and throat
   2. Turn her on their side
   3. Put on oxygen at 2-L nasal cannula
   4. Stop feeding her and place on NPO
4. A patient who is receiving parenteral nutrition (PN) through a central venous catheter (CVC) has an air embolus. What would the nurse do first?
   1. Have the patient perform a Valsalva maneuver
   2. Clamp the intravenous (IV) tubing to prevent more air from entering the line
   3. Have the patient take a deep breath and hold it
   4. Notify the health care provider immediately
5. A patient is receiving both parenteral (PN) and enteral nutrition (EN). When would the nurse collaborate with the health care provider and request discontinuing parenteral nutrition?
   1. When 25% of the patient's nutritional needs are met by the tube feedings
   2. When bowel sounds return
   3. When central line has been in for 10 days
   4. When 75% of the patient's nutritional needs are met by the tube feedings
6. The nurse is educating the patient and his family about the parenteral nutrition. Which aspect related to this form of nutrition would be appropriate to include? (Select all that apply.)
   1. The purpose of the fat emulsion in parenteral nutrition is to prevent a deficiency in essential fatty acids.
   2. We can give you parenteral nutrition through your peripheral intravenous line to prevent further infection.
   3. The fat emulsion will help control hyperglycemia during periods of stress.
   4. The parenteral nutrition will help your wounds heal.
   5. Since we just started the parenteral nutrition, we will only infuse it at 50% of your daily needs for the next 6 hours.
7. The nurse is inserting a small-bore nasoenteric tube before starting enteral feedings. Place the following steps in order to perform this procedure.
   1. Place patient in high-Fowler's position.
   2. Have patient flex head toward chest.
   3. Assess patient's gag reflex.
   4. Determine length of the tube to be inserted.
   5. Obtain radiological confirmation of tube placement.
   6. Check pH of gastric aspirate for verifying placement.
   7. Identify patient with two identifiers.
8. A patient's gastric residual volume was 250 mL at 0800 and 350 mL at 0900. What is the appropriate nursing action?
   1. Assess bowel sounds
   2. Raise the head of the bed to at least 45 degrees

3. Position the patient on his or her right side to promote stomach emptying
4. Do not reinstall aspirate and hold the feeding until you talk to the primary care provider

9. The nurse would delegate which of the following to nursing assistive personnel (NAP)? (Select all that apply.)
   1. Repositioning and retaping a patient's nasogastric tube
   2. Performing glucose monitoring every 6 hours on a patient
   3. Documenting PO intake on a patient who is on a calorie count for 72 hours
   4. Administering enteral feeding bolus after tube placement has been verified
   5. Hanging a new bag of enteral feeding

10. The patient's blood glucose level is 330 mg/dL. What is the priority nursing intervention?
    1. Recheck by performing another blood glucose test.
    2. Call the primary health care provider.
    3. Check the medical record to see if there is a medication order for abnormal glucose levels.
    4. Monitor and recheck in 2 hours.

11. Which statement made by a patient of a 2-month-old infant requires further education?
    1. I'll continue to use formula for the baby until he is a least a year old.
    2. I'll make sure that I purchase iron-fortified formula.
    3. I'll start feeding the baby cereal at 4 months.
    4. I'm going to alternate formula with whole milk starting next month.

12. The nurse is teaching a program on healthy nutrition at the senior community center. Which points should be included in the program for older adults? (Select all that apply.)
    1. Avoid grapefruit and grapefruit juice, which impair drug absorption.
    2. Increase the amount of carbohydrates for energy.
    3. Take a multivitamin that includes vitamin D for bone health.

4. Cheese and eggs are good sources of protein.
5. Limit fluids to decrease the risk of edema.

13. The nurse sees the nursing assistive personnel (NAP) perform the following intervention for a patient receiving continuous enteral feedings. Which action would require immediate attention?
    1. Fastening tube to the gown with new tape
    2. Placing patient supine while giving a bath
    3. Hanging a new container of enteral feeding
    4. Ambulating patient with enteral feedings still infusing

14. A patient is receiving total parenteral nutrition (TPN). What is the primary intervention the nurse should follow to prevent a central line infection?
    1. Institute isolation precautions
    2. Clean the central line port through which the TPN is infusing with antiseptic
    3. Change the TPN tubing every 24 hours
    4. Monitor glucose levels to watch and assess for glucose intolerance

15. Which patients are at high risk for nutritional deficits? (Select all that apply.)
    1. The divorced computer programmer who eats precooked food from the local restaurant
    2. The middle-age female with celiac disease who does not follow her gluten-free diet
    3. The 45-year-old patient with type II diabetes who monitors her carbohydrate intake and exercises regularly
    4. The 25-year-old patient with Crohn's disease who follows a strict diet but does not take vitamins or iron supplements
    5. The 65-year-old patient with gallbladder disease whose electrolyte, albumin, and protein levels are normal

Answers: 1. 2, 3, 4; **2.** 4; **3.** 4; **4.** 1; **5.** 4; **6.** 1, 3, 4; **7.** 1, 3, 4, 5, 6; **8.** 4; **9.** 2, 3; **10.** 3; **11.** 4; **12.** 1, 3, 4; **13.** 2; **14.** 2; **15.** 2, 4.

Urinary Elimination

OBJECTIVES

- Explain the function and role of urinary system structures in urine formation and elimination.
- Identify factors that commonly impact urinary elimination.
- Compare and contrast common alterations associated with urinary elimination.
- Obtain a nursing history from a patient with an alteration in urinary elimination.
- Perform a physical assessment focused on urinary elimination.
- Describe characteristics of normal and abnormal urine.
- Describe nursing implications of common diagnostic tests of the urinary system.

- Identify nursing diagnoses associated with alterations in urinary elimination.
- Discuss nursing measures to promote normal micturition and improve bladder control.
- Discuss nursing measures to reduce risk for urinary tract infections.
- Apply an external catheter and insert a urinary catheter.
- Perform closed catheter irrigation correctly.
- Measure postvoid residual with a bladder scanner.

A basic human function is urinary elimination. This function can be compromised by a wide variety of illnesses and conditions. Nurses are key members of the health care team when treating patients with urinary problems. It is your role to assess patients' urinary tract function and provide support for bladder emptying. During acute illness a patient may require urinary catheterization for close monitoring of urine output or to facilitate bladder emptying when bladder function is compromised. Some patients require long-term indwelling catheters, urethral or suprapubic, when the bladder fails to empty effectively. You also implement measures to minimize risk for infection when bladder function is impaired or urinary drainage tubes are required. Nurses in all health care settings play an important role in teaching patients about bladder health and supporting them to improve or obtain continence.

SCIENTIFIC KNOWLEDGE BASE

Urinary elimination is the last step in the removal and elimination of excess water and by-products of body metabolism. Adequate elimination depends on the coordinated function of the kidneys, ureters, bladder, and urethra (Figure 46-1). The kidneys filter waste products of metabolism from the blood. The ureters transport urine from the kidneys to the bladder. The bladder holds urine until the volume in the bladder triggers a sensation of urge, indicating the need to pass urine. **Micturition** occurs when the brain gives the bladder permission to empty, the bladder contracts, the urinary sphincter relaxes, and urine leaves the body through the urethra.

Kidneys

The kidneys lie on either side of the vertebral column behind the peritoneum and against the deep muscles of the back. Normally the left kidney is higher than the right because of the anatomical position of the liver.

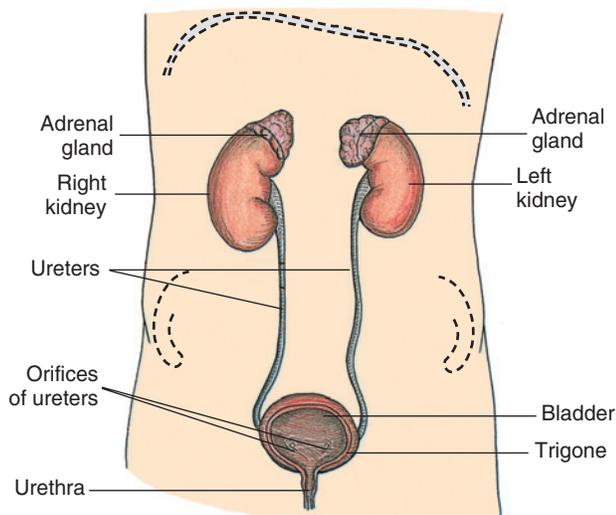
Nephrons, the functional unit of the kidneys, remove waste products from the blood and play a major role in the regulation of fluid and electrolyte balance. Each nephron contains a cluster of capillaries called the *glomerulus*. The glomerulus filters water, glucose, amino acids, urea, uric acid, creatinine, and major electrolytes. Large proteins


FIGURE 46-1 Organs of urinary system.

and blood cells do not normally filter through the glomerulus. When protein (proteinuria) or blood (**hematuria**) is found in the urine, glomerular injury is suspected.

Not all glomerular filtrate is excreted as urine. Approximately 99% is resorbed into the plasma by the proximal convoluted tubule of the nephron, the loop of Henle, and the distal tubule. The remaining 1% is excreted as urine. It is in the resorption process that the delicate balance of fluid and electrolytes is maintained (Huether and McCance, 2012). The normal range of urine production is 1 to 2 L/day (Huether and McCance, 2012). Many factors can influence the production of urine such as fluid intake and body temperature (Box 46-1).

The kidneys have essential functions other than elimination of body wastes. Erythropoietin, produced by the kidneys, stimulates red blood cell production and maturation in bone marrow. Patients with chronic kidney conditions cannot produce sufficient quantities of this hormone; therefore they are prone to anemia.

The kidneys play a major role in blood pressure control via the renin-angiotensin system (i.e., release of aldosterone and prostacyclin) (Huether and McCance, 2012). In times of renal ischemia (decreased blood supply), **renin** is released from juxtaglomerular cells. Renin

---

BOX 46-1   Factors Influencing Urinary Elimination

Growth and Development
- Children cannot voluntarily control voiding until 18 to 24 months.
- Readiness for toilet training includes the ability to recognize the feeling of bladder fullness, hold urine for 1 to 2 hours, and communicate the sense of urgency.
- Older adults may experience a decrease in bladder capacity, increased bladder irritability, and an increased frequency of bladder contractions during bladder filling.
- In older adults the ability to hold urine between the initial desire to void and an urgent need to void decreases.
- Older adults are at increased risk for urinary incontinence because of chronic illnesses and factors that interfere with mobility, cognition, and manual dexterity.

Sociocultural Factors
- Cultural and gender norms vary. North Americans expect toilet facilities to be private, whereas some cultures accept communal toilet facilities.
- Religious or cultural norms may dictate who is acceptable to help with elimination practices.
- Social expectations (e.g., school recesses, work breaks) can interfere with timely voiding.

Psychological Factors
- Anxiety and stress sometimes affect a sense of urgency and increase the frequency of voiding.
- Anxiety can impact bladder emptying because of inadequate relaxation of the pelvic floor muscles and urinary sphincter.
- Depression can decrease the desire for urinary continence.

Personal Habits
- The need for privacy and adequate time to void can influence the ability to empty the bladder adequately.

Fluid Intake
- If fluids, electrolytes, and solutes are balanced, increased fluid intake increases urine production.
- Alcohol decreases the release of antidiuretic hormones, thus increasing urine production.

- Fluids containing caffeine and other bladder irritants can prompt unsolicited bladder contractions, resulting in frequency, urgency, and incontinence.

Pathological Conditions
- Diabetes mellitus, multiple sclerosis, and stroke can alter bladder contractility and the ability to sense bladder filling. Patients experience either bladder overactivity or deficient bladder emptying.
- Arthritis, Parkinson's disease, dementia, and chronic pain syndromes can interfere with timely access to a toilet.
- Spinal cord injury or intervertebral disk disease (above S-1) can cause the loss of urine control because of bladder overactivity and impaired coordination between the contracting bladder and urinary sphincter.
- Prostatic enlargement (e.g., benign prostatic hyperplasia [BPH]) can cause obstruction of the bladder outlet, causing urinary retention.

Surgical Procedures
- Local trauma during lower abdominal and pelvic surgery sometimes obstructs urine flow, requiring temporary use of an indwelling urinary catheter.
- Anesthetic agents and other agents given during surgery can decrease bladder contractility and/or sensation of bladder fullness, causing urinary retention (Elsamara and Ellsworth, 2012).

Medications
- Diuretics increase urinary output by preventing resorption of water and certain electrolytes.
- Some drugs change the color of urine (e.g., phenazopyridine-orange, riboflavin–intense yellow).
- Aniticholinergics (e.g., atropine, overactive agents) may increase the risk for urinary retention by inhibiting bladder contractility (Burchum and Rosenthal, 2016).
- Hypnotics and sedatives (e.g., analgesics, antianxiety agents) may reduce the ability to recognize and act on the urge to void.

Diagnostic Examinations
- Cystoscopy may cause localized trauma of the urethra, resulting in transient (1 to 2 days) dysuria and hematuria.
- Whenever the sterile urinary tract is catheterized, there is a risk for infection.

functions as an enzyme to convert angiotensinogen (a substance synthesized by the liver) into angiotensin I. Angiotensin I is converted to angiotensin II in the lungs. Angiotensin II causes vasoconstriction and stimulates aldosterone release from the adrenal cortex. Aldosterone causes retention of water, which increases blood volume. The kidneys also produce prostaglandin E_2 and prostacyclin, which help maintain renal blood flow through vasodilation. These mechanisms increase arterial blood pressure and renal blood flow (Huether and McCance, 2012).

The kidneys affect calcium and phosphate regulation by producing a substance that converts vitamin D into its active form. Patients with kidney impairment can have problems such as anemia, hypertension, and electrolyte imbalances.

Ureters

A ureter is attached to each kidney pelvis and carries urinary waste to the bladder. Urine draining from the ureters to the bladder is sterile. Peristaltic waves cause the urine to enter the bladder in spurts rather than steadily. Contractions of the bladder during micturition compress the lower part of the ureters to prevent urine from backflowing into the ureters (Huether and McCance, 2012). Obstruction of urine flow through the ureters such as by a kidney stone can cause a backflow of urine (urinary reflux) into the ureters and pelvis of the kidney, causing distention (hydroureter/hydronephrosis) and in some cases permanent damage to sensitive kidney structures and function.

Bladder

The urinary bladder is a hollow, distensible, muscular organ that holds urine. When empty, the bladder lies in the pelvic cavity behind the symphysis pubis. In males the bladder rests against the rectum, and in females it rests against the anterior wall of the uterus and vagina. The bladder has two parts, a fixed base called the *trigone* and a distensible body called the *detrusor*. The bladder expands as it fills with urine. Normally the pressure in the bladder during filling remains low, and this prevents the dangerous backward flow of urine into the ureters and kidneys. Backflow can cause infection. In a pregnant woman the developing fetus pushes against the bladder, reducing capacity and causing a feeling of fullness.

Urethra

Urine travels from the bladder through the urethra and passes to the outside of the body through the urethral meatus. The urethra passes through a thick layer of skeletal muscles called the *pelvic floor muscles.* These muscles stabilize the urethra and contribute to urinary continence. The external urethral sphincter, made up of striated muscles, contributes to voluntary control over the flow of urine (Huether and McCance, 2012). The female urethra is approximately 3 to 4 cm (1 to 1.5 inch) long, and the male urethra is about 18 to 20 cm (7 to 8 inches) long (Huether and McCance, 2012). The shorter length of the female urethra increases risk for urinary tract infection (UTI) because of close access to the bacteria-contaminated perineal area.

Act of Urination

Urination, micturition, and voiding are all terms that describe the process of bladder emptying. Micturition is a complex interaction among the bladder, urinary sphincter, and central nervous system. Several areas in the brain are involved in bladder control: cerebral cortex, thalamus, hypothalamus, and brainstem. There are two micturition centers in the spinal cord: one that coordinates inhibition of bladder contraction, and the other that coordinates bladder contractility. As the bladder fills and stretches, bladder contractions are inhibited by sympathetic stimulation from the thoracic micturition center.

When the bladder fills to approximately 400 to 600 mL, most people experience a strong sensation of urgency. When in the appropriate place to void, the central nervous system sends a message to the micturition centers, stopping sympathetic stimulation and starting parasympathetic stimulation from the sacral micturition center. The urinary sphincter relaxes, and the bladder contracts. When the time and place are inappropriate, the brain sends messages to the micturition centers to contract the urinary sphincter and relax the bladder muscle.

Factors Influencing Urination.   Physiological factors, psychosocial conditions, and diagnostic or treatment-induced factors can all affect normal urinary elimination (see Box 46-1). Knowledge of these factors enables you to anticipate possible elimination problems and intervene when problems develop.

Common Urinary Elimination Problems.   The most common urinary elimination problems involve the inability to store urine or fully empty urine from the bladder. Problems can result from infection; irritable or overactive bladder; obstruction of urine flow; impaired bladder contractility; or issues that impair innervation to the bladder, resulting in sensory or motor dysfunction.

Urinary Retention.   **Urinary retention** is the inability to partially or completely empty the bladder. Acute or rapid-onset urinary retention stretches the bladder, causing feelings of pressure, discomfort/pain, tenderness over the symphysis pubis, restlessness, and sometimes diaphoresis. Patients may have no urine output over several hours and in some cases experience frequency, urgency, small-volume voiding, or incontinence of small volumes of urine. Chronic urinary retention has a slow, gradual onset during which patients may experience a decrease in voiding volumes, straining to void, frequency, urgency, incontinence, and sensations of incomplete emptying. **Postvoid residual (PVR)** is the amount of urine left in the bladder after voiding and is measured either by ultrasound or straight catheterization. Incontinence caused by urinary retention is called *overflow incontinence* or *incontinence associated with chronic retention of urine*. The pressure in the bladder exceeds the ability of the sphincter to prevent the passage of urine, and the patient will dribble urine (see Table 46-1).

Urinary Tract Infections.   UTIs are one of the most common health care–acquired infections, with almost all caused by instrumentation of the urinary tract (CDC, 2015). *Escherichia coli,* a bacterium commonly found in the colon, is the most common causative pathogen (Gupta and Hooton, 2011; Nicolle, 2014). The risk for a UTI increases in the presence of an indwelling catheter, any instrumentation of the urinary tract, urinary retention, urinary and fecal incontinence, and poor perineal hygiene practices.

UTIs are characterized by location (i.e., upper urinary tract [kidney] or lower urinary tract [bladder, urethra]) and have signs and symptoms of infection. **Bacteriuria**, or bacteria in the urine, does not always mean that there is a UTI. In the absence of symptoms, the presence of bacteria in the urine as found on a urine culture is called *asymptomatic bacteriuria* and is not considered an infection and should not be treated with antibiotics (Mody and Juthani-Mehta, 2014). Symptomatic infection of the bladder can lead to a serious upper UTI (**pyelonephritis**) and life-threatening bloodstream infection (**bacteremia** or urosepsis) and should be treated with antibiotics. Symptoms of a lower UTI (bladder) can include burning or pain with urination (**dysuria**); irritation of the bladder (**cystitis**) characterized by urgency, frequency, incontinence, suprapubic tenderness; and foul-smelling cloudy urine. Older adults may experience a change in mental status called *delirium*. In some cases there will be obvious blood in the urine (hematuria). If infection spreads to the upper urinary tract (pyelonephritis), patients

TABLE 46-1 Urinary Incontinence

Definition	Characteristics	Selected Nursing Interventions
Transient Incontinence		
Incontinence caused by medical conditions that in many cases are treatable and reversible	Common reversible causes include: • Delirium and/or acute confusion. • Inflammation (e.g., urinary tract infection [UTI], urethritis). • Medications (e.g., diuretics) (Hall et al., 2012). • Excessive urine output (e.g., hyperglycemia, congestive heart failure). • Mobility impairment from any cause. • Fecal impaction. • Depression. • Acute urinary retention.	With new-onset or increased incontinence look for reversible causes. Notify health care provider of any suspected reversible causes.
Functional Incontinence		
Loss of continence because of causes outside the urinary tract Usually related to functional deficits such as altered mobility and manual dexterity, cognitive impairment, poor motivation, or environmental barriers Direct result of caregivers not responding in a timely manner to requests for help with toileting	Toilet access restricted by: • Sensory impairments (e.g., vision). • Cognitive impairments (e.g., delirium, dementia, severe retardation). • Altered mobility (e.g., hip fracture, arthritis, chronic pain, spastic paralysis associated with multiple sclerosis, slow movements associated with Parkinson's disease, hemiparesis). • Altered manual dexterity (e.g., arthritis, upper extremity fracture) • Environmental barriers (e.g., caregiver not available to help with transfers, pathway to bathroom not maneuverable with a walker, tight clothing that is difficult to remove, incontinence briefs).	Adequate lighting in the bathroom Individualized toileting program designed for the degree of cognitive impairment: habit training program, scheduled toileting program, prompted voiding program Mobility aides (e.g., raised toilet seats, toilet grab bars) Toilet area cleared to allow access for a walker or wheelchair Elastic-waist pants without buttons or zippers Call bell always within reach Use of incontinence containment product patient can easily remove such as a pull-up–type pant or a pad that can be moved aside easily for voiding
Urinary Incontinence Associated with Chronic Retention of Urine (Overflow Urinary Incontinence)		
Involuntary loss of urine caused by an overdistended bladder often related to bladder outlet obstruction or poor bladder emptying because of weak or absent bladder contractions	Distended bladder on palpation High postvoid residual Frequency Involuntary leakage of small volumes of urine Nocturia	Interventions are individualized related to the severity of the urinary retention, ability of bladder to contract, existing kidney damage. Mild retention with some bladder function: • Timed voiding • Double voiding • Monitor postvoid residual per health care provider's direction • Intermittent catheterization Severe retention, no bladder function: • Intermittent catheterization • Indwelling catheterization
Stress Urinary Incontinence		
Involuntary leakage of small volumes of urine associated with increased intraabdominal pressure related to either urethral hypermobility or an incompetent urinary sphincter (e.g., weak pelvic floor muscles, trauma after childbirth, radical prostatectomy) Result of weakness or injury to the urinary sphincter or pelvic floor muscles Underlying result: urethra cannot stay closed as pressure increases in the bladder as a result of increased abdominal pressure (e.g., a sneeze or cough)	Small-volume loss of urine with coughing, laughing, exercise, walking, getting up from a chair Usually does not leak urine at night when sleeping	As directed by the health care provider, instruct patient in pelvic muscle exercises.

TABLE 46-1   Urinary Incontinence—cont'd

Definition	Characteristics	Selected Nursing Interventions
Urge or Urgency Urinary Incontinence		
Involuntary passage of urine often associated with strong sense of urgency related to an overactive bladder caused by neurological problems, bladder inflammation, or bladder outlet obstruction In many cases bladder overactivity is idiopathic; cause is not known Caused by involuntary contractions of the bladder associated with an urge to void that causes leakage of urine	May experience one or all of the following symptoms: • Urgency • Frequency • Nocturia • Difficulty or unable to hold urine once the urge to void occurs • Leaks on the way to the bathroom • Leaks larger volumes of urine, sometimes enough to wet outer clothing • Dribbles small amounts on the way to the bathroom • Strong urge/leaks when one hears water running, washes hands, drinks fluids	Ask patient about symptoms of a UTI Avoid bladder irritants (e.g., caffeine, artificial sweeteners, alcohol). As directed by the health care provider, instruct patient in pelvic muscle exercises, in urge-inhibition exercises, and/or in bladder training. If ordered by the health care provider, monitor patient symptoms and for the presence of side effects of antimuscarinic medications.
Reflex Urinary Incontinence		
Involuntary loss of urine occurring at somewhat predictable intervals when patient reaches specific bladder volume related to spinal cord damage between C1 to S2	Diminished or absent awareness of bladder filling and the urge to void Leakage of urine without awareness May not completely empty the bladder because of dyssynergia of the urinary sphincter; inappropriate contraction of the sphincter when the bladder contracts, causing obstruction to urine flow **CAUTION:** At risk for developing autonomic dysreflexia, a life-threatening condition that causes severe elevation of blood pressure and pulse rate and diaphoresis	Follow the prescribed schedule for emptying the bladder either through voiding or by intermittent catheterization. Supply urine-containment products: condom catheter, undergarments, pads, briefs. Monitor for signs and symptoms of urinary retention and UTI. Monitor for autonomic dysreflexia; this is a medical emergency requiring immediate intervention. Notify the health care provider immediately.

may also experience fever, chills, diaphoresis, and flank pain (Schaeffer and Schaeffer, 2012).

Catheter-associated UTIs (CAUTIs) are an ongoing problem for hospitals because they are associated with increased hospitalizations, increased morbidity and mortality, longer hospital stays, and increased hospital costs (Gould et al., 2009; Hooton and Bradley, 2010). Because a CAUTI is common, costly, and believed to be reasonably preventable, as of October 1, 2008, the Centers for Medicare and Medicaid Services (CMS) chose it as one of the complications for which hospitals no longer receive additional payment to compensate for the extra cost of treatment. Consequently there has been a shift in clinical care practices from the traditional focus on early recognition and prompt treatment to one of prevention. CAUTI needs to be defined with some caution. Urine sampling for a microbiological workup needs to be done carefully to avoid contamination. For critically ill patients, urine sampling must be done either routinely once a week or at the beginning of a new episode of sepsis. CAUTI is usually deemed present if at least 10^3 colony-forming units (CFU)/mL of 1 or 2 microorganisms are identified by urine culture (Maki and Tambyah, 2001; Mnatzaganian et al., 2005).

Urinary Incontinence. Urinary incontinence (UI) is defined as the "complaint of any involuntary loss of urine" (Staskin et al., 2013) (Table 46-1). UI is a common problem affecting 27% of men and 43% women over the age of 40 (Coyne and Kvasz, 2012), 20% to 40% of older adults (Aguilar-Navarro et al., 2012), and over 70% of elderly nursing home patients (Coyne and Wein, 2014). Common forms of UI are urge or urgency UI (involuntary leakage associated with urgency) and stress UI (involuntary loss of urine associated with effort or exertion on sneezing or coughing (Staskin et al., 2013). Mixed UI is when stress- and urgency-type symptoms are both present. Overactive bladder is defined as urinary urgency, often accompanied by increased urinary frequency and nocturia that may or may not be associated with urgency incontinence and is present without obvious bladder pathology or infection (Staskin et al., 2013). UI associated with chronic retention of urine (formally called *overflow UI*) is urine leakage caused by an overfull bladder (Staskin et al., 2013). Functional UI is caused by factors that prohibit or interfere with a patient's access to the toilet or other acceptable receptacle for urine. In most cases there is no bladder pathology. It is a significant problem for older adults who experience problems with mobility or the dexterity to manage their clothing and toileting behaviors. Patients with other types of incontinence can also have a functional aspect to their incontinence. A recently added category of incontinence is identified as multifactorial incontinence. This describes incontinence that has multiple interacting risk factors, some within the urinary tract and others not, such as multiple chronic illnesses, medications, age-related factors, and environmental factors (Staskin et al., 2013).

Urinary Diversions. Patients who have had the bladder removed (cystectomy) because of cancer or significant bladder dysfunction related to radiation injury or neurogenic dysfunction with frequent UTI require surgical procedures that divert urine to the outside of the body through an opening in the abdominal wall called a *stoma*. Urinary diversions are constructed from a section of intestine to create a storage reservoir or conduit for urine. Diversions can be temporary or permanent, continent or incontinent.

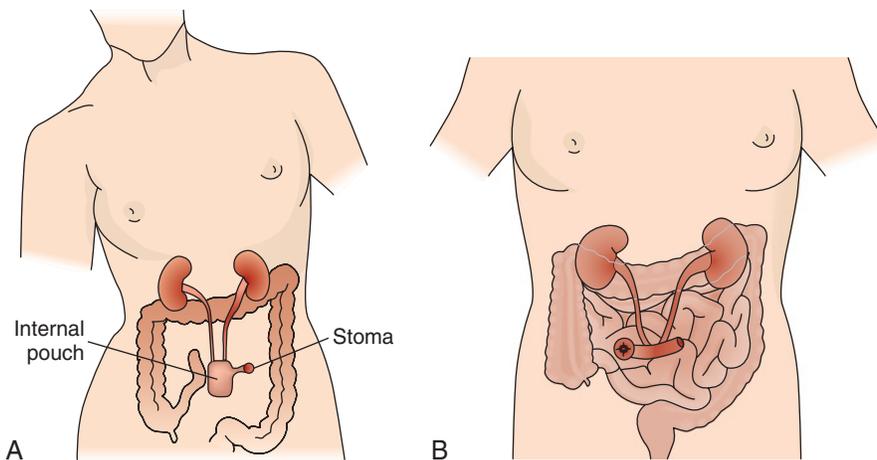
There are two types of continent urinary diversions. The first is called a *continent urinary reservoir* (Figure 46-2, *A*) which is created from a distal part of the ileum and proximal part of the colon. The ureters are embedded into the reservoir. This reservoir is situated under the abdominal wall and has a narrow ileal segment brought out


FIGURE 46-2 Types of urinary diversions. **A,** Continent urinary reservoir. **B,** Urostomy (ileal conduit).
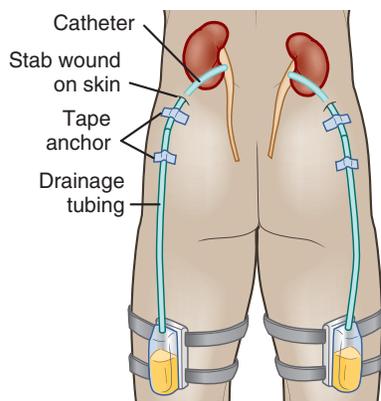

Bilateral nephrostomy tubes inserted into renal pelvis; catheters exit through an incision on each flank, or there may be just one kidney

FIGURE 46-3 Nephrostomy tubes. (From Lewis SL et al: *Medical-surgical nursing,* ed 9, St Louis, 2014, Mosby.)

through the abdominal wall to form a small stoma. The ileocecal valve creates a one-way valve in the pouch through which a catheter is inserted through the stoma to empty the urine from the pouch. Patients must be willing and able to catheterize the pouch 4 to 6 times a day for the rest of their lives.

The second type of continent urinary diversion is called an *orthotopic neobladder,* which uses an ileal pouch to replace the bladder. Anatomically the pouch is in the same position as the bladder was before removal, allowing a patient to void through the urethra using a Valsalva technique.

A **ureterostomy** or ileal conduit is a permanent incontinent urinary diversion created by transplanting the ureters into a closed-off part of the intestinal ileum and bringing the other end out onto the abdominal wall forming a stoma (Figure 46-2, *B*). The patient has no sensation or control over the continuous flow of urine through the ileal conduit, requiring the effluent (drainage) to be collected in a pouch.

Nephrostomy tubes are small tubes that are tunneled through the skin into the renal pelvis. These tubes are placed to drain the renal pelvis when the ureter is obstructed. Patients do go home with these tubes and need careful teaching about site care and signs of infection (Figure 46-3).

NURSING KNOWLEDGE BASE

Urinary elimination is a basic body function and carries with it a variety of psychological and physiological needs. When illness or disability interferes with meeting these needs, nursing care that addresses both the physiological and the psychological is essential. You need an understanding beyond anatomy and physiology of the urinary system to give appropriate care.

Infection Control and Hygiene

The urinary tract is sterile. Use infection control principles to help prevent the development and spread of UTIs. You need to follow the principles of medical asepsis when carrying out procedures involving the urinary tract or external genitalia. Perineal hygiene is an essential component of care (see Chapter 40) when there is an alteration in the usual pattern of urinary elimination. Perineal care or examination of the genitalia requires medical asepsis, including proper hand hygiene. Any invasive procedure such as catheterization requires sterile aseptic technique.

Growth and Development

It is important to apply knowledge of normal growth and development when caring for the patient with urinary problems. A patient's ability to control micturition changes during the life span. The neurological system is not well developed until 2 to 3 years of age. Until this stage of development, the small child is not able to associate the sensation of filling and urge with urination. When the child recognizes feelings of urge, can hold urine for 1 to 2 hour, and is able to communicate his or her needs, toilet training becomes successful. Continence starts during daytime hours. Children who wet the bed at night without waking from sleep have what is called *nocturnal enuresis.* In some cases they can experience this nighttime incontinence until late in childhood. Infants and young children cannot effectively concentrate urine. Their urine appears light yellow or clear. In relation to their small body size, infants and children excrete large volumes of urine. For example, a 6-month-old infant who weighs 13 to 18 lbs (6 to 8 kg) excretes 400 to 500 mL of urine daily.

Pregnancy causes many changes in the body, including the urinary tract. In early and late pregnancy urinary frequency is common. Hormonal changes and the pressure of the growing fetus on the bladder cause increased urine production and shrinking bladder capacity.

Normal aging causes changes in the urinary tract and the rest of the body. These changes are not the cause of bladder dysfunction, but age does increase risk and incidence (Box 46-2).

FOCUS ON OLDER ADULTS

Urinary Incontinence

A number of normal aging changes impact urinary continence. Prostatic enlargement in older men can cause obstruction of urine flow from the bladder, resulting in incomplete bladder emptying, urgency, frequency, urinary tract infections, and damage to the upper urinary tract from urinary retention. Patterns of urine production may change as a result of a shift in circadian rhythm of water secretion, causing increased urine production at night and nocturia (Varilla et al., 2011). Nocturia disturbs sleep and increases risk for falls (Foley et al., 2012; Gomelsky and Dmochowski, 2011). Older adults have a decreased ability to delay voiding; an increased incidence of overactive bladder; and possibly a loss of bladder contractility, increasing the risk for urinary retention. Older women have a decrease in estrogenization of perineal tissue that increases the risk of urinary tract infection (Mody and Juthani-Mehta, 2014).

Advancing age is associated with increased prevalence of chronic illnesses such as stroke, diabetes, degenerative joint disease, Parkinson's disease, heart disease, and voiding dysfunction (Harris and Smith, 2010; Nobili et al., 2011). These illnesses and the problems associated with them such as cognitive impairment, mobility limitation, and other functional impairments can impact continence and increase the risk for urinary incontinence (Erekson et al., 2015; Gomelsky and Dmochowski, 2011). The use of multiple medications, called *polypharmacology,* is more common in older adults (Touhy and Jett, 2014). Many of these medications have the potential to impact normal elimination by affecting the ability of the bladder to hold urine or adequately empty (antihypertensives, cholinesterase inhibitors, antidepressants, sedatives) (Burchum and Rosenthal, 2016).

Implications for Practice
- Older adults with cognitive impairment may need to be reminded to void more frequently to improve continence.
- Evaluate all possible causes of new-onset incontinence, which should include taking note of any new medications that might impact cognition, alertness, mobility, or voiding.
- Older adults newly started on an antimuscarinic medication should be assessed carefully for mental status changes. This class of medications has the potential to cause cognitive impairment in older adults (American Geriatrics Society, 2012).
- Older adults with impaired mobility and incontinence should have interventions put in place to maximize self-care and continence (e.g., toileting program, mobility aids, help with hygiene).
- Teach older women with stress incontinence about pelvic muscle exercises. There is no age limit on their effectiveness.
- The sensation of thirst decreases with aging. Adequate hydration promotes bladder health. Older adults may need to be reminded to drink adequate amounts of water (Touhy and Jett, 2014).
- To decrease nocturia, instruct patients to restrict fluid intake for the 2 hours before bedtime.
- Older men with voiding pattern changes (e.g., urgency, frequency, slow stream, decreased output, dribbling) should be assessed for urinary retention because of age-related prostate enlargement.

Psychosocial Implications

Self-concept, culture, and sexuality are all closely related concepts that are affected when patients have elimination problems. Self-concept changes over one's life span and includes body image; self-esteem, roles, and identity (see Chapters 34 and 35). When children begin to achieve bladder control and learn the appropriate toileting skills, they sometimes resist urinating on the toilet and associate their urine and feces as extensions of self and thus do not want to flush them away.

The process of micturition is often a culturally private event and requires you to be sensitive to a need for privacy. Incontinence can be devastating to self-image and self-esteem. When your patient asks for help for such a private and personal activity, it can be perceived as embarrassing or being treated like a child, or it may threaten the patient's sense of self-determination. When a patient has a urinary diversion, it will influence his or her sense of body image, resulting in a perceived threat in being able to maintain a healthy sexual relationship with a partner. As a nurse, be aware of how elimination disorders affect patients psychosocially so that you can understand the full impact of the patient's elimination problem.

CRITICAL THINKING

Successful critical thinking requires synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require you to anticipate and collect necessary information, analyze the data, and make decisions regarding your patient's care.

When applying the nursing process, take into consideration the knowledge you have learned about the urinary system. Integrate the knowledge from nursing and other disciplines, previous experiences, and patients to understand the process of urinary elimination and the impact on a patient and family. The urinary system is affected by many factors, both as part of or outside the urinary tract. As a result you are able to identify the unique impact of these problems on patients and families. For example, men after prostate cancer surgery may experience stress UI because of trauma to the urinary sphincter, people with high caffeine intake or those who take a diuretic may experience increased urinary urgency and frequency, and patients who are normally continent and become immobile may become incontinent.

Urinary elimination problems are common in all health care settings. Reflect on previous and personal experiences to help you determine a patient's elimination needs. If you have personally had a UTI, the experience helps you to understand a patient's frustration and embarrassment as a result of frequency, urgency, and dysuria. Caring for other older adults with functional disabilities helps you to anticipate patient needs related to toileting.

In addition, use critical thinking attitudes such as perseverance to find a plan of care to provide successful management of urinary elimination problems. Professional standards also provide valuable directions. You are in a key position to serve as a patient advocate by suggesting noninvasive alternatives to catheterization use (e.g., the use of a bladder scanner to evaluate urine volume without invasive instrumentation or implementation of a voiding schedule for the incontinent patient).

Practice standards and guidelines prepared by nursing specialty organizations and those developed by national and international professional organizations are valuable tools to use when critically assessing patient problems and developing a plan of care. Box 46-3 lists some of these resources. The professional nurse incorporates such evidence-based guidelines into the plan of care. There are two nursing organizations, the Society for Urological Nurses and Associates (http://www.suna.org) and the Wound, Ostomy, Continence Nurses Society (http://www.wocn.org), that offer many resources related to continence care. Both organizations have specialty certification agencies offering entry level and advanced practice specialty certification

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in the care of patients. The nursing process provides a clinical

decision-making approach for you to develop and implement an individualized plan of care.

◆ **Assessment**

During the assessment process, critically analyze assessment findings to ensure that you make patient-centered clinical decisions required for safe nursing care (Figure 46-4).

Through the Patient's Eyes. Throughout the nursing assessment it is important for you to consider a patient's frame of reference related to his or her illness or urinary problem. Assess the patient's understanding of the urinary problem and expectations of treatment. Because urination is a private matter, some patients find it difficult to talk about their voiding habits. Approach patients in a professional manner and assure them that their problems will be kept confidential. Postoperative patients or patients receiving medications that affect bladder function may become concerned that something is wrong when you assess voiding amount and frequency. Patients receiving intravenous (IV) fluids do not always realize that they have an increased need for urination. Sensitivity to patient misconceptions will allow you to quickly identify areas for patient education. Always ask what he or she expects from care. For example, does the patient expect that the UTI will be resolved? Does the patient expect the colostomy to be only temporary?

Self-Care Ability. It is very important to thoroughly assess patients' ability to perform necessary behaviors associated with voiding. Investigate their expectations of what the nurses will do and what they can do independently. Do not assume that because a patient has a diagnosis of cognitive impairment that he or she cannot understand or participate in care. Balancing patient safety and supporting self-care are sometimes challenges and should be discussed with the patient. For example, a patient with poor balance will need nursing assistance with transfers to a toilet and may need continued nursing supervision while on the toilet, something the patient may find embarrassing or demeaning.

Cultural Considerations. Be aware of cultural and gender differences related to the very private act of voiding and how they affect nursing assessment and care. Be sensitive and ask questions in a straightforward manner. Be aware of gender preferences in positioning

Knowledge
- Physiology of fluid balance
- Anatomy and physiology of normal urine production and urination
- Pathophysiology of selected urinary alterations
- Factors affecting urination
- Principles of communication used to address issues related to self-concept and sexuality

Experience
- Caring for patients with alterations in urinary elimination
- Caring for patients at risk for urinary infection
- Personal experience with changes in urinary elimination

ASSESSMENT
- Gather nursing history for the patient's urination pattern, symptoms, and factors affecting urination
- Conduct physical assessment of the patient's body systems potentially affected by urinary change
- Assess characteristics of urine
- Assess the patient's perception of urinary problems as it affects self-concept and sexuality
- Gather relevant laboratory and diagnostic test data

Standards
- Maintain the patient's privacy and dignity
- Apply intellectual standards to ensure patient history and assessment are complete and in depth
- Apply professional standards of care from professional organizations such as ANA, International Continence Society (ICS), United Ostomy Associations of America

Attitudes
- Display humility in recognizing limitations in knowledge
- Establish trust with the patient to reveal full picture of this potentially sensitive area of assessment

FIGURE 46-4 Critical thinking model for urinary elimination assessment. *ANA*, American Nurses Association.

for urination: many men stand to void, whereas women sit. There are gender-linked urinary alterations such as prostate enlargement in men and pelvic organ prolapse in women. Culture often dictates gender-specific roles when it comes to care of elimination issues. It may be inappropriate for a male to touch or even talk about elimination matters with a woman (Box 46-4).

Health Literacy. When taking a nursing history, you should be careful to assess a patient's understanding of his or her urinary tract problem. Urinary tract problems are not common topics of conversation in families and other settings. Limited knowledge of basic anatomy and how the urinary tract functions can contribute to poor understanding and outcomes of treatment (Anger et al., 2012). Assess

⊕ BOX 46-4   CULTURAL ASPECTS OF CARE

Urinary Elimination

Urinary elimination is a private human activity. It is important when caring for patients from diverse cultures and religions to incorporate into the plan of care sensitivity and awareness of factors that may impact care when dealing with urinary elimination problems. Many cultures have specific beliefs and practices related to elimination, privacy, and gender-specific care. Because of the personal nature of the problem and cultural practices surrounding elimination, urinary problems such as incontinence often are not discussed with medical professionals (Beji et al., 2010; Gemmill and Wells, 2010). Variations within a cultural group are common; thus each patient must be assessed and cared for as an individual.

Implications for Patient-Centered Care

- Each patient is unique. As a professional nurse you must determine the extent to which a patient's cultural background, such as age-group, geographic location, ethnicity, or race, affect their elimination problems.
- Whenever possible, provide for a same-gender caregiver for individuals whose cultural preferences emphasize female modesty and prohibit non-related males and females from touching (Beji et al., 2010). Patients from the Iranian, Jewish Orthodox, Korean, Hindu, and Vietnamese cultures may prefer same-gender care.
- Privacy is important in many cultures; thus careful attention to closing doors, bedside curtains, and draping is important.
- Pay special attention that the patient understands instructions and patient education when English is not the primary language (see Chapter 10). If available, provide written materials in patient's primary language. Provide a professional interpreter as needed.
- Certain cultures such as Hindus and Muslims observe meticulous hygiene practices that designate the left hand to perform unclean procedures such as genitourinary hygiene. Perform hand hygiene before touching the patient and use your right hand when possible. Use the left hand to handle the urinal and/or secretions.
- Some cultures (e.g., African, Western, and Southeastern Asia) continue to practice female genital cutting or female genital circumcision, which can include removal of all or part of the clitoris and part or complete removal of the labia minora or, in its most severe form, the total removal of the clitoris and labia and sewing together the labia majora, leaving only a small opening for urine and menses (American Academy of Pediatrics, 2010). Some long-term consequences include recurrent urinary tract infections, incontinence, pelvic infections, fistulas, scarring, and sexual dysfunction (Odemerho and Baier, 2012).
- Cultural practices dictate the level of involvement of family in a patient's care. This source of strength is important to the health of the patient, and family must be included in the plan of care.

BOX 46-5   Nursing Assessment Questions

Nature of the Problem
- Which problems are you having with passing urine?

Signs and Symptoms
- Does it hurt or burn when you pass your urine?
- Are you having abdominal pain/flank pain/fevers/chills?
- Has there been a change in the color or odor of your urine? Please describe that change.
- Do you feel like you are emptying your bladder completely?
- Are you passing urine more frequently than normal during the day?
- Do you need to strain and/or wait before your urine stream starts?
- Do you need to get up at night to pass urine?
- Do you leak urine when feeling a strong desire to void?
- Do you ever leak urine when you cough, sneeze, and/or exercise?
- Are you ever wet with urine and do not know when it happened?
- Do you dribble urine before you void, after you void, or at other times?

Onset and Duration
- When did you first notice a problem?
- How long has this problem lasted?

Severity
- How many times a day do you pass urine?
- How many times a day and how many times at night do you leak urine?
- How many times are you wet/need to change a pad in a day and at night?
- How often are you awakened with the urge to void and get up to use the bathroom?
- How does this pattern compare with the pattern you last remember?

Predisposing Factors
- Have you noticed any patterns to your urinary problem?
- Tell me what you usually eat/drink in a day. Does it include such things as caffeinated beverages, chocolate, citrus, or alcohol?
- Which medicines do you take routinely, and have any recently changed?
- Have you been hospitalized or diagnosed with a new medical problem recently?

Effect on Patient
- How have these symptoms affected your life?
- Does your urinary problem interfere with any of your usual activities?
- Have you ever tried any treatment for this problem (self-help, complementary therapies, over-the-counter remedies, medical professional, and specialist)?

---

the patient's health literacy level before engaging in education (see Chapter 25).

Nursing History. The nursing history includes a review of the patient's elimination patterns, symptoms of urinary alterations, and assessment of factors that are affecting the ability to urinate normally. Box 46-5 lists nursing history questions that will help direct the patient to focus on urinary problems.

Pattern of Urination. Ask the patient about daily voiding patterns, including frequency and times of day, normal volume at each voiding, and history of recent changes. Frequency of voiding varies among individuals depending on fluid intake, medications such as diuretics, and the intake of bladder irritants such as caffeine or other caffeinated

beverages. The common times for urination are on awakening, after meals, and before bedtime. Most people void an average of 5 or more times a day. Be sure to ask if the patient is awakened from sleep with an urge to void and how many times this occurs. It is normal for patients who wake at night because of noise, pain, or nighttime treatments to experience an urge to void. Information about the pattern of urination is necessary to establish a baseline for comparison.

Symptoms of Urinary Alterations. Certain symptoms specific to urinary alterations may occur in more than one type of disorder. During assessment ask the patient about the presence of symptoms related to urination (Table 46-2). Also determine whether the patient is aware of conditions or factors that precipitate or aggravate the symptoms and determine what he or she does if any of these symptoms occur.

TABLE 46-2   Common Symptoms of Urinary Alterations

Description	Common Causes	Description	Common Causes
Urgency An immediate and strong desire to void that is not easily deferred	Full bladder Urinary tract infection Inflammation or irritation of the bladder Overactive bladder	**Nocturia** Awakened from sleep because of the urge to void	Excess intake of fluids (especially coffee or alcohol before bedtime) Bladder outlet obstruction (e.g., prostate enlargement) Overactive bladder Medications (e.g., diuretic taken in the evening) Cardiovascular disease (e.g., hypertension) Urinary tract infection
Dysuria Pain or discomfort associated with voiding	Urinary tract infection Inflammation of the prostate Urethritis Trauma to the lower urinary tract Urinary tract tumors	**Dribbling** Leakage of small amounts of urine despite voluntary control of micturition	Bladder outlet obstruction (e.g., prostatic enlargement) Incomplete bladder emptying Stress incontinence
Frequency Voiding more than 8 times during waking hours and/or at decreased intervals such as less than every 2 hours.	High volumes of fluid intake Bladder irritants (e.g., caffeine) Urinary tract infection Increased pressure on bladder (e.g., pregnancy) Bladder outlet obstruction (e.g., prostate enlargement, pelvic organ prolapse) Overactive bladder	**Hematuria** Presence of blood in urine Gross hematuria (blood is easily seen in urine) Microscopic hematuria (blood not visualized but measured on urinalysis)	Tumors (e.g., kidney, bladder) Infection (e.g., glomerular nephritis, cystitis) Urinary tract calculi Trauma to the urinary tract
Hesitancy Delay in start of urinary stream when voiding	Anxiety (e.g., voiding in public restroom) Bladder outlet obstruction (e.g., prostate enlargement, urethral stricture)	**Retention** Acute retention: Suddenly unable to void when bladder is adequately full or overfull Chronic retention: Bladder does not empty completely during voiding, and urine is retained in the bladder	Bladder outlet obstruction (e.g., prostatic enlargement, urethral obstruction) Absent or weak bladder contractility (e.g., neurological dysfunction such as caused by diabetes, multiple sclerosis, lower spinal cord injury) Side effects of certain medications (e.g., anesthesia, anticholinergics, antispasmodics, antidepressants)
Polyuria Voiding excessive amounts of urine	High volumes of fluid intake Uncontrolled diabetes mellitus Diabetes insipidus Diuretic therapy		
Oliguria Diminished urinary output in relation to fluid intake	Fluid and electrolyte imbalance (e.g., dehydration) Kidney dysfunction or failure Increased secretion of antidiuretic hormone (ADH) Urinary tract obstruction		

Physical Assessment. A physical examination (see Chapter 31) provides you with data to determine the presence and severity of urinary elimination problems. The primary areas to assess include the kidneys, bladder, external genitalia, urethral meatus, and perineal skin. Fluid intake and the pattern and amounts provides additional objective data.

Kidneys. When the kidneys become infected or inflamed, they can become tender, resulting in flank pain. You assess for tenderness by gently percussing the costovertebral angle (the angle formed by the spine and twelfth rib). Auscultation is sometimes performed to detect the presence of a renal artery bruit (sound resulting from turbulent blood flow through a narrowed artery), but this skill is usually performed by an advanced practice nurse.

Bladder. In adults the bladder rests below the symphysis pubis. When distended with urine, the bladder will rise above the symphysis pubis along the midline of the abdomen. A very full bladder can extend as far as the umbilicus. On inspection you may observe a swelling or convex curvature of the lower abdomen. On gentle palpation of the lower abdomen, a full bladder may be felt as a smooth and rounded mass. When a full bladder is palpated, patients report a sensation of urinary urge tenderness or even pain. If an overfull bladder is suspected, further assessment with an ultrasound device or a bladder scanner is recommended if available.

External Genitalia and Urethral Meatus. Careful and sensitive inspection of the external genitalia and urethral meatus yield important data that may indicate inflammation and infection. Normally there should be no drainage or inflammation. To best examine the female patient, position her in the dorsal recumbent position to provide full exposure of the genitalia. Observe the labia majora for swelling, redness, tenderness, rashes, lesions, or evidence of scratching. Using a gloved hand, retract the labial folds. The labia minora is normally pink and moist. The urethral meatus will appear as an irregular

or slitlike opening below the clitoris and above the vaginal orifice. Look for drainage and lesions and ask the patient if there is discomfort. If there is drainage, note the color and consistency and any odor. The vaginal tissue of a postmenopausal woman may be dryer and less pink than that of younger women.

Examine the penis. Look for any redness or irritation. If the man is uncircumcised, retract the foreskin or ask the patient to do so. The foreskin should move back easily to expose the glans penis. In some cases the foreskin will become tight and cannot be retracted (phimosis), increasing risk for inflammation and infection. The urethral meatus is a slitlike opening just below the tip of the penis. Inspect the glans penis and meatus for discharge, lesions, and inflammation. Following inspection, return the foreskin to the unretracted position. Retracted foreskins can cause dangerous swelling (paraphimosis) of the penis (Ball and Dains, 2015).

All patients with an indwelling catheter should have the urinary meatus assessed for catheter-related damage and for the presence of inflammation and discharge that can indicate infection. Pulling and traction on catheters can damage the urinary meatus by creating pressure on the urethra and meatus. In some severe cases the catheter will erode through the meatus to the vagina or in men through the glans and shaft of the penis. Early detection of trauma means that a plan of prevention for further damage can be implemented.

Perineal Skin. Assessment of skin exposed to moisture, especially urine, needs to occur at least daily (and more often if incontinence is ongoing) to pick up early signs of skin damage related to the moisture. Observe for erythema in areas exposed to moisture, skin erosion, and patient complaints of a burning itching pain (Gray et al., 2012).

Assessment of Urine. The assessment of urine includes measuring the patient's fluid intake and urinary output (I&O) and observing the characteristics of the urine.

Intake and Output. Assessment of I&O is a way to evaluate bladder emptying, renal function, and fluid and electrolyte balance. Although often written as part of a health care provider's order, placing a patient on I&O is also a nursing judgment. Obtaining accurate I&O measurement often requires cooperation and assistance from the patient and family. Intake measurements need to include all oral liquids and semi-liquids, enteral feedings, and any parenteral fluids (see Chapter 42). Output measurement includes not only urine but any fluid that leaves the body that can be measured such as vomitus, gastric drainage tubes, and wound drains.

Urinary output is a key indicator of kidney and bladder function. A change in urine volume can be a significant indicator of fluid imbalance, kidney dysfunction, or decreased blood volume. For example, a postoperative catheterized patient's hourly urinary output provides an indirect measure of circulating blood volume. If the urinary output falls below 30 mL/hr, the nurse should immediately assess for signs of blood loss and notify the health care provider. Urinary output is also an indicator of bladder function. Patients who have not voided for longer than 3 to 6 hours and have had fluid intake recorded should be evaluated for urinary retention. Just helping some patients to a normal position to void prompts voiding. Assess for any extreme increase or decrease in urine volume. Urine output less than 30 mL per hour for more than two consecutive hours or excessive urine output (polyuria) is a cause for concern and should prompt further assessment and notification of the health care provider.

Urine volume is measured using receptacles with volume-measurement markings. After a patient voids in a bedside commode, bedpan, or urinal, or when urine is emptied from a catheter drainage bag, urine can be measured using a graduated measuring container. For patients who void in a toilet, a urine hat (Figure 46-5) collects

FIGURE 46-5 Urine hat.

FIGURE 46-6 Urometer. (Courtesy Michael Gallager, RN, BSN, OSF Saint Francis Medical Center, Peoria, IL.)

urine, allowing for patient privacy in the bathroom. Catheterized patients may have a specialized drainage bag with a urometer (Figure 46-6) attached between the drainage tubing and drainage bag that allows for accurate hourly urine measurement. When emptying catheter drainage bags, follow Standard Precautions (Chapter 29) and make sure that the drainage tube is reclamped and secured. Each patient needs to have a graduated receptacle for individual use to prevent potential cross-contamination. Label each container with the patient's name. The container needs to be rinsed after each use to minimize odor and bacterial growth.

Characteristics of Urine. Inspect the patient's urine for color, clarity, and odor. Monitor and document any changes.

Color. Normal urine ranges in color from a pale straw color to amber, depending on its concentration. Urine is usually more concentrated in the morning or with fluid volume deficits. As the patient drinks more fluids, urine becomes less concentrated, and the color lightens. Patients taking diuretics commonly void dilute urine while the medication is active.

TABLE 46-3	Urine Testing
Collection Type/Use of Specimen	**Nursing Considerations**
Random (routine urinalysis) Includes a number of tests that are used for screening and are diagnostic for fluid and electrolyte disturbances, urinary tract infection, presence of blood and other metabolic problems	Collect during normal voiding or from an indwelling catheter or urinary diversion collection bag. Do not collect from an indwelling catheter drainage bag (urine is not freshly voided). Use a clean specimen cup. In some health care settings you may be responsible for testing urine with reagent strips. Follow manufacturer instructions when performing and reading the strips. Dip the reagent strip into fresh urine, then observe color changes on the strip. Compare the color on the strip with the color chart on the reagent strip container. Each color is examined at the exact time indicated on the container.
Clean-voided or midstream (culture and sensitivity)	Urine may be collected by the patient after detailed instruction on proper cleansing and collection technique (see Skill 46-1 on pp. 1128-1131). Always use a sterile specimen cup.
Sterile specimen for culture and sensitivity Determines the presence of bacteria and to which antibiotic the bacteria are sensitive	If the patient has an indwelling catheter, collect a specimen by using sterile aseptic technique through the special sampling port (see Figure 46-12) found on the side of the catheter. Never collect the specimen from the drainage bag. Clamp the tubing below the port, allowing fresh, uncontaminated urine to collect in the tube. After wiping the port with an antimicrobial swab, insert a sterile syringe hub and withdraw at least 3 to 5 mL of urine (check agency policy). Using sterile aseptic technique, transfer the urine to a sterile container (see Chapter 28). Patients with a urinary diversion need to have the stoma catheterized to obtain an accurate specimen. A preliminary report will be available in 24 hours; but usually 48 to 72 hours are needed for bacterial growth and sensitivity testing.
Timed urine specimens Measure bodily substances that may be excreted at higher levels at specific times of the day or over a specific time period	Requires urine collection and testing either at specific time of day or urine collected over a specific time period (e.g., 2-, 12-, or 24-hour collections). The timed period begins after the patient urinates and ends with a final voiding at the end of the time period. In most 24-hour specimen collections discard the first voided specimen and then start collecting urine. Patient voids into a clean receptacle; and the urine is transferred to the special collection container, which often contains special preservatives. Depending on the test, the urine container may need to be kept cool by setting it in a container of ice. Each specimen must be free of feces and toilet tissue. Missed specimens make the whole collection inaccurate. Check with agency policy and the laboratory for specific instructions. Patients' education should include an explanation of the test, an emphasis on the need to collect all urine voided during the prescribed time period, and urine collection procedure.

Blood in the urine (hematuria) is never a normal finding. Bleeding from the kidneys or ureters usually causes urine to become dark red; bleeding from the bladder or urethra usually causes bright red urine. Hematuria and blood clots are a common cause of urinary catheter blockage.

Various medications and foods change the color of the urine. For example, patients taking phenazopyridine, a urinary analgesic, void urine that is bright orange. Eating beets, rhubarb, and blackberries causes red urine. The kidneys excrete special dyes used in IV diagnostic studies, and this discolors the urine. Dark amber urine is the result of high concentrations of bilirubin (urobilinogen) in patients with liver disease. Report unexpected color changes to the health care provider.

Clarity. Normal urine appears transparent at the time of voiding. Urine that stands several minutes in a container becomes cloudy. In patients with renal disease, freshly voided urine appears cloudy because of protein concentration. Urine may also appear thick and cloudy as a result of bacteria and white blood cells. Early-morning voided urine may be cloudy because of urine held in the bladder overnight but will be clear on the next voiding.

Odor. Urine has a characteristic ammonia odor. The more concentrated the urine, the stronger the odor. As urine remains standing (e.g., in a collection device), more ammonia breakdown occurs, and the odor becomes stronger. A foul odor may indicate a UTI. Some foods such as asparagus and garlic can change the odor of urine.

Laboratory and Diagnostic Testing. You are often responsible for collecting urine specimens for laboratory testing. The type of test determines the method of collection. Label all specimens with the patient's name, date, time, and type of collection. Most urine specimens need to reach the laboratory within 2 hours of collection or must be preserved according to the laboratory protocol (Pagana and Pagana, 2013). Urine that stands in a container at room temperature without the required preservative will grow bacteria resulting in changes that will affect the accuracy of the test. Agency infection control policies require the adherence to standard precautions during the handling of urine specimens (see Chapter 29). To obtain urine that is fresh or new you need to ask the patient to double void. The second voided specimen is the one sent to the laboratory. To obtain urine as free of bacterial contamination as possible, a midstream clean-catch urine specimen may be required. Table 46-3 describes nursing considerations for a variety of common tests. Table 46-4 describes the components of the most common of the urinary tests, urinalysis.

Diagnostic Examinations. The urinary system is one of the few organ systems accessible to accurate diagnostic study by radiographic techniques. Studies can be simple and noninvasive or complex and invasive. See Table 46-5 for a review of some common diagnostic testing of the urinary tract.

TABLE 46-4   Routine Urinalysis

Measurement (Normal Value)	Interpretation
pH (4.6 to 8.0)	pH level indicates acid-base balance. Acid pH helps protect against bacterial growth. Urine that stands for several hours becomes alkaline from bacterial growth.
Protein (up to 8 mg/100 mL)	Protein is normally not present in urine. The presence of protein is a very sensitive indicator of kidney function. Damage to the glomerular membrane (such as in glomerulonephritis) allows for the filtration of larger molecules such as protein to seep through.
Glucose (not normally present)	Patients with poorly controlled diabetes have glucose in the urine because of inability of tubules to resorb high serum glucose concentrations (>180 mg/100 mL). Ingestion of high concentrations of glucose causes some to appear in urine of healthy people.
Ketones (not normally present)	With poor control of diabetes, patients experience breakdown of fatty acids. End products of fatty acid metabolism are ketones. Patients with dehydration, starvation, or excessive aspirin ingestion also have ketonuria.
Blood	A positive test for occult blood occurs when intact erythrocytes, hemoglobin, or myoglobin is present. Damage to the glomerulus or tubules causes blood cells to enter urine. Trauma or disease of the lower urinary tract also causes hematuria.
Specific gravity (1.0053 to 1.030)	Specific gravity tests measure concentration of particles in urine. High specific gravity reflects concentrated urine, and low specific gravity reflects diluted urine. Dehydration, reduced renal blood flow, and increase in ADH secretion elevate specific gravity. Overhydration, early renal disease, and inadequate ADH secretion reduce specific gravity.
Microscopic examination RBC (up to 2)	Damage to glomeruli or tubules allows RBCs to enter the urine. Trauma, disease, presence of urethral catheters, or surgery of the lower urinary tract also causes RBCs to be present.
WBCs (0-4 per low-power field)	Elevated numbers indicate inflammation or infection.
Bacteria (not normally present)	Bacteria in the urine can mean infection or colonization (if the patient shows no symptoms).
Casts (cylindrical bodies not normally present, the shapes of which take on the likeness of objects within the renal tubule)	Types include hyaline, WBCs, RBCs, granular cells, and epithelial cells. Their presence indicates renal disease.
Crystals (not normally present)	Crystals indicate increased risk for the development of renal calculi (stone). Patients with high uric acid levels (gout) may develop uric acid crystals.

Data from Pagana KD, Pagana TJ: *Mosby's diagnostic and laboratory test reference*, ed 11, St Louis, 2013, Mosby.
ADH, Antidiuretic hormone; *RBC,* red blood cell; *WBC,* white blood cell.

Many of the nursing responsibilities related to diagnostic testing of the urinary tract are common to most studies. Those responsibilities before testing include the following:

- Ensure that a signed consent is completed (check agency policy).
- Assess the patient for any allergies and if he or she has experienced a previous reaction to a contrast agent (Pagana and Pagana, 2013).
- Administer bowel-cleansing agents as ordered (check agency policy).
- Ensure that the patient adheres to the appropriate pretest diet (clear liquids) or nothing by mouth (NPO).
- Responsibilities after testing include:
  - Assessing I&O.
  - Assessing voiding and urine (color, clarity, presence of blood, dysuria, problems emptying.)
- Encouraging fluid intake, especially if using radiopaque dye.

◆ Nursing Diagnosis

A thorough assessment of a patient's urinary elimination function reveals patterns of data that allow a nurse to make relevant and accurate nursing diagnoses. Use critical thinking to reflect on knowledge of previous patients, apply knowledge of urinary function and the effects of disorders, review defining characteristics, and make a specific nursing diagnosis. Data from questions about the urinary system are important in identifying nursing diagnoses. The diagnosis focuses on a specific urinary elimination alteration or an associated problem such as *Impaired Skin Integrity related to UI.* Identification of defining characteristics leads to selection of an appropriate problem-focused diagnosis. Identification of risk factors leads to section of a risk diagnosis (see Chapter 17).

An important part of formulating problem-focused nursing diagnoses is identifying the relevant causative or related factor. In the case of risk diagnoses, you select correct risk factors. You will choose interventions that treat or modify the related factor or risk factor for the diagnosis to be resolved. Specifying related factors for a diagnosis allows selection of individualized nursing interventions (Ackley and Ladwig, 2011). For example, *Toileting Self-Care Deficit related to impaired transfer ability* or *impaired mobility* status guides the selection of nursing interventions that remove barriers to toilet access. *Toileting Self-Care Deficit related to cognitive impairment* guides the selection of nursing interventions such as a prompted voiding program or habit training program. Box 46-6 provides an example of diagnostic reasoning. Some nursing diagnoses common to patients with urinary elimination problems include the following:

- *Functional Urinary Incontinence*
- *Stress Urinary Incontinence*
- *Urge Urinary Incontinence*
- *Reflex Incontinence*
- *Risk For Infection*
- *Toileting Self-Care Deficit*

TABLE 46-5	Common Diagnostic Tests of Urinary Tract	
Procedure	**Description**	**Special Nursing Considerations**
Noninvasive Procedures		
Abdominal roentgenogram (plain film; kidney, ureter, bladder (KUB) or flat plate)	X-ray film of the abdomen to determine the size, shape, symmetry, and location of the structures of the lower urinary tract Common uses: Detect and measure the size of urinary calculi	No special preparation
Computerized axial tomography (CT) scan	Detailed imagery of the abdominal structures provided by computerized reconstruction of cross-sectional images. Common uses: Identify anatomical abnormalities, renal tumors and cysts, calculi, and obstruction of the ureters	Preparation: Cleanse bowel (see agency or health care provider protocol). Assess for presence of any allergies and previous reaction to contrast media. All patients with allergies are at increased risk for anaphylactoid reactions to radiocontrast. Adverse reactions to contrast media are anaphylactoid, not true allergies (Kaufman et al., 2013). **NOTE:** The myth that anyone allergic to contrast media is allergic to shellfish or iodine is untrue. Iodine is an essential trace element and not an allergen (Schabelman and Witting, 2010). The allergens in shellfish are proteins that do not contain iodine. Restrict food and fluid up to 4 hours before test (see agency or health care provider protocol). After procedure: Encourage fluids to promote dye excretion. Assess for delayed hypersensitivity reaction to the contrast media. Patient teaching: Explain that he or she will be placed on a special bed that will move through a tunnel-like imaging chamber. He or she will need to lie still when instructed by the technician; some patients may feel claustrophobic.
Intravenous pyelogram (IVP)	Imaging of the urinary tract that views the collecting ducts and renal pelvis and outlines the ureters, bladder, and urethra (After intravenous injection of contrast media [iodine based that converts to a dye], a series of x-ray films are taken to observe the passage of urine from the renal pelvis to the bladder.) Common uses: Detect and measure urinary calculi, tumors, hematuria, obstruction of the urinary tract	Preparation: Assess for allergies. Assess for dehydration. Cleanse bowel (see agency or health care provider protocol). Restrict food and fluid up to 4 hours before test (see agency or health care provider protocol). After procedure: Assess for delayed hypersensitivity to the contrast media. Encourage fluids after the test to dilute and flush dye from the patient. Assess urine output. Less than 30/mL hr increases risk for contrast-induced nephropathy. Patient teaching: Facial flushing is a normal response during dye injection, and patients may feel dizzy or warm or feel some nausea.
Ultrasound: Renal bladder	Imaging of the kidneys, ureters, and bladder using sound waves Identifies gross structural abnormalities and estimates the volume of urine in the bladder Common uses: Detect masses, obstruction, presence of hydronephrosis or hydroureter, abnormalities of the bladder wall, and calculi; measure postvoid residual	Patients need to come to the study with a full bladder.
Invasive Procedures		
Endoscopy-cystoscopy	Introduction of a cystoscope through the urethra into the bladder to provide direct visualization, specimen collection, and/or treatment of the bladder and urethra (In most cases the procedure is performed using local anesthesia, but under certain circumstances general anesthesia or conscious sedation may be used.) Common uses: Microscopic hematuria, detect bladder tumors and obstruction of the bladder outlet and urethra	When applicable, follow agency protocol for preoperative preparation (see Chapter 39). Patient teaching: Urine may be pink tinged after the test; signs and symptoms of urinary tract infection.

BOX 46-6   Nursing Diagnostic Process

Urge Urinary Incontinence Related to Bladder infection

Assessment Activities	Defining Characteristics
Ask patient to describe voiding problems/incontinence.	Patient complains of urine leakage associated with a strong urge to void.
Assess patient's voiding pattern.	Bladder record shows episodes of urinary incontinence.
	Patient describes or is observed to leak urine on the way to or at the toilet.
	Patient describes or is observed to rush or hurry to the toilet.

- *Impaired Skin Integrity*
- *Impaired Urinary Elimination*
- *Urinary Retention*

◆ Planning

During planning integrate the knowledge from assessment and information about available resources and therapies to develop an individualized plan of care (see the Nursing Care Plan). Match the patient's needs with clinical and professional standards recommended in the literature (Figure 46-7). Building a relationship of trust with patients is important because the implementation of care involves interaction of a very personal nature.

Goals and Outcomes. The plan of care for urinary elimination alterations must include realistic and individualized goals along with relevant outcomes. The nurse and the patient need to collaborate in setting goals and outcomes and ultimately in choosing nursing interventions. A general goal is often normal urinary elimination; but sometimes the individual goal differs, depending on the problem. The goals are short or long term.

For example, a realistic short-term goal for a patient with *Toileting Self-Care Deficit related to impaired mobility status* would be that the patient will be able to independently use the toilet. An appropriate outcome would be that the "patient is observed to safely transfer to the toilet." To achieve this outcome you identify a number of interventions such as ensuring that the call bell is within reach, providing assistive devices such as a raised toilet seat, and providing easy access to the urinal when in bed. Conversely, the patient with stress incontinence often has a long-term goal that depends on weeks of pelvic floor muscle exercise to improve urinary control: Patient will experience normal continence. An outcome for this goal would be to "decrease the number of incontinence pads by 1 to 2 within 8 weeks after start of Kegel exercise program." Interventions will include daily Kegel exercises. Make sure that goals and outcomes are reasonably achievable and relevant to the patient's situation (see Box 46-8).

Setting Priorities. It is important to establish priorities of care on the basis of a patient's immediate physical and safety needs, patient expectations, and readiness to perform some self-care activities. Establish a relationship with the patient that allows discussion and intervention. While you are collaborating with the patient, priorities become apparent, enhancing patient understanding of all the goals. When a patient has multiple nursing diagnoses (Figure 46-8), it is important to recognize the primary health problem and its influence on other problems. For example, a patient with a long-term indwelling

Knowledge
- Importance of caring in maintenance of the patient's self-esteem
- Role other health professionals might provide in the care of the patient with urinary elimination alterations
- Adult learning principles to apply when educating the patient and family
- Services of community-based resources
- Nursing interventions effective in maintaining normal urinary elimination

Experience
- Previous patient responses to planned nursing interventions to promote urinary elimination

PLANNING
- Reinforce adherence to good hygiene practices
- Select interventions that promote normal physiology of micturition
- Involve the family in learning knowledge and skills for the patient's care in the home
- Refer the patient to appropriate health care professionals and/or community agencies

Standards
- Individualize interventions to adapt to a normal urination pattern
- Apply standards of care from the agency and professional organizations such as ANA, ICS, and United Ostomy Associations of America in planning care

Attitudes
- Use risk taking and creativity in trying alternatives in care (e.g., skin care, ostomy management)

FIGURE 46-7 Critical thinking model for urinary elimination planning. *ANA,* American Nurses Association; *ICS,* International Continence Society.

catheter is admitted to acute care with a severe UTI. The patient expects to resume self-care of the catheter. However, because of the severity of the infection and the patient's condition, the nurse needs to perform all care for the patient's catheter. In this case the priorities are to treat the infection, prevent reinfection, and teach the patient how to resume care of the catheter using techniques to prevent infection.

Teamwork and Collaboration. When planning individualized care, it is essential to use the expertise of the health care team and incorporate them into the plan. For example, when planning care for a patient with urge UI, incorporate the expertise of a continence nurse

◎ **NURSING CARE PLAN**

Stress Urinary Incontinence

ASSESSMENT

Mrs. Kay, the nurse, is caring for Mrs. Grayson, a 75-year-old woman, who has recently been seen in the emergency department for a urinary tract infection. Mrs. Grayson shares with Mrs. Kay her concerns over her incontinence. Medical history includes: postmenopausal, has a history of three vaginal births, is "overweight," and has type 2 diabetes managed well with oral medication and diet. She lives with her husband, and her three grown children live nearby. Mrs. Grayson volunteers at a local food bank but had not gone recently because of her incontinence. She confides to the nurse that her uncontrollable urine leakage has affected her life. The patient's primary care provider has prescribed for Mrs. Grayson pelvic muscle exercise and lifestyle modifications to treat her incontinence. Mrs. Kay's assessment includes a discussion of Mrs. Grayson's current health status with emphasis on her urinary concerns.

Assessment Activities	*Findings/Defining Characteristics**
Ask Mrs. Grayson about the effects of her urinary symptoms on her daily life.	She responds, "I find myself being embarrassed and frustrated for **losing control.** I **dribble** when I'm on the way to the bathroom. I'm afraid to cough, sneeze, or laugh because I **leak urine.** I don't go places and try to avoid being close to other people because I'm afraid I might have an odor."
Ask her what she has been doing about her condition.	She states, "I've been wearing a pad and will go to the bathroom every hour just in case. I try to limit the amount of water I drink so I will not have to go to the bathroom."
Ask Mrs. Grayson about any other effects caused by her leakage.	She begins to cry and states, "I don't even like to go to the movies or visit my grandchildren. It's safer to stay home."
Observe Mrs. Grayson's behavior.	She appears anxious and sad.
Take a focused nursing history addressing urinary leakage and other lower urinary tract symptoms.	Mrs. Grayson's report of **urine leakage on physical exertion, sneezing, and laughing** and leakage on the way to the bathroom increases the likelihood of a diagnosis of mixed incontinence. Her risk factors for this condition include a **history of type 2 diabetes, three pregnancies,** being **postmenopausal,** and being **overweight.** The history helps to define the proper interventions.
Have Mrs. Grayson complete a 3-day bladder diary.	The bladder diary provides objective verification of fluid intake, urine elimination pattern, and patterns of urine leakage. The record also is a baseline for evaluation of the effectiveness of the treatment plan.

*Defining characteristics** are shown in bold type.

NURSING DIAGNOSIS: Stress urinary incontinence related to weakened pelvic musculature

PLANNING

Goals	*Expected Outcomes (NOC)*[†]
	Urinary Continence
Mrs. Grayson will have reduced episodes of urine leakage (incontinence) between voiding within 6 to 8 weeks.	Patient reports fewer than two episodes of daily incontinence following the start of daily pelvic muscle–strengthening exercises (Kegel) and urge-suppression strategies.
	Patient states decreased anxiety about her incontinence.
	Urinary Elimination
Mrs. Grayson will have improved urinary elimination pattern within 2 months.	Patient remains free of urinary tract infection.
	Patient is able to resist the urge to void for 15 or more minutes without leaking.

[†]Outcome classification labels from Moorhead S et al: *Nursing outcomes classification (NOC)*, ed 5, St Louis, 2013, Mosby.

INTERVENTIONS (NIC)[‡]	**RATIONALE**
Urinary Incontinence Care	
Help Mrs. Grayson with supportive measures to reduce intraabdominal pressure by:	These measures reduce intraabdominal and bladder pressure, which increase leakage.
• Losing weight.	
• Avoiding heavy lifting.	
Teach Mrs. Grayson about how to keep her bladder healthy (see Box 46-7):	Fluids that contain caffeine and other irritants can prompt unwanted bladder contractions, resulting in frequency, urgency, and incontinence.
• Avoid bladder irritants.	
• Keep blood sugars controlled by adherence to her diabetic diet.	
• Drink adequate amounts of water; avoid drinking large amounts at one time.	
Pelvic Muscle Exercise	
Teach Mrs. Grayson how to perform pelvic muscle exercises (see Box 46-8):	Pelvic muscle training is effective in treating stress urinary incontinence (Dumoulin et al., 2011).
• Instruct her how to identify and contract the muscle.	
• Help her set up a daily schedule for performing the exercises.	
• Instruct her to squeeze the muscle immediately before coughing and sneezing.	
Bladder retraining (behavioral therapy)	Behavioral therapy that includes pelvic muscle training should be offered as first-line treatment for stress, urge, and mixed incontinence in women of all ages (Moore et al., 2013).
• Teach her how to inhibit strong sensations of urinary urgency by taking slow and deep breaths to relax and performing 5 to 6 quick, strong pelvic muscle exercises (flicks) in quick succession, followed by focusing the attention away from the bladder sensations.	
• Once successful with inhibiting the urge to void and avoiding incontinence, instruct her to gradually increase the time period between trips to the bathroom.	

[‡]Intervention classification labels from Bulechek GM et al: *Nursing interventions classifications (NIC)*, ed 6, St Louis, 2013, Mosby.

⊚ NURSING CARE PLAN

Stress Urinary Incontinence—cont'd

EVALUATION

Nursing Actions	Patient Response/Finding	Achievement of Outcomes
Ask Mrs. Grayson about frequency of incontinence since starting pelvic muscle exercises and urge-suppression strategies. Ask Mrs. Grayson to keep a 3-day bladder diary.	She responds, "I'm dry most of the time now. I'm now babysitting my grandchildren and have returned to my volunteer job." Bladder diary revealed one small-volume loss of urine with a strong cough and voiding every 3 to 4 hours.	Mrs. Grayson reports increasing success with bladder control and with this sense of increased control is less anxious and more socially active. Mrs. Grayson has been free of urinary tract infection. Mrs. Grayson is able to resist the urge to void for 15 or more minutes without leaking as seen in her ability to void every 3 to 4 hours.

CONCEPT MAP

Nursing diagnosis: Stress urinary incontinence related to weakened pelvic musculature
- Leakage of urine on the way to the bathroom
- Leakage of urine associated with sneezing and coughing
- Obese
- Three pregnancies

Interventions
- Encourage Mrs. Grayson to decrease intra-abdominal pressure: weight loss, avoid heavy lifting
- Avoid caffeine and other bladder irritants
- Encourage adequate hydration
- Teach Mrs. Grayson pelvic muscle exercises
- Initiate a bladder retraining

Nursing diagnosis: Risk for infection
- Recent UTI
- Urinary incontinence
- Diabetes

Interventions
- Instruct Mrs. Grayson to maintain adequate fluid intake
- Teach good perineal hygiene
- Reinforce teaching related to type 2 diabetes to maintain normal blood sugars (diet, take medication as ordered)
- Teach about signs and symptoms of UTI

Primary health problem: Stress urinary incontinence
Priority assessments: Voiding patterns, bladder diary, skin integrity

Nursing diagnosis: Risk for impaired skin integrity
- Wet skin due to dribbling/incontinence
- 75 years old with diabetes

Interventions
- Teach Mrs. Grayson to change pads frequently
- Teach Mrs. Grayson to inspect skin daily
- Instruct Mrs. Grayson to gently cleanse after each incontinent episode
- Teach Mrs. Grayson to apply moisture barrier product as needed

Nursing diagnosis: Deficient knowledge—treatment of urinary incontinence
- Lifestyle modifications
- Pelvic muscle exercises
- Bladder retraining

Interventions
- Use written and verbal instructions
- Use pictures to teach about pelvic anatomy
- Evaluate learning

——— Link between medical diagnosis and nursing diagnosis   - - - - Link between nursing diagnoses

FIGURE 46-8 Concept map for Mrs. Grayson.

BOX 46-7   Health Promotion/Restoration: Patient Education for a Healthy Bladder

1. Maintain adequate hydration.
   - Drink six to eight glasses of water a day. Spread it out evenly throughout the day.
   - Avoid or limit drinking beverages that contain caffeine (coffee, tea, chocolate drinks, soft drinks).
   - To decrease nocturia, avoid drinking fluids 2 hours before bedtime.
   - Do not limit fluids if you experience incontinence. Concentrated urine may irritate the bladder and increase bladder symptoms.
2. Keep good voiding habits,
   - Women: sit well back on the toilet seat, avoid "hovering over the toilet," and make sure that the feet are flat on the floor.
   - Void at regular intervals, usually every 3 to 4 hours, depending on fluid intake.
   - Avoid straining when voiding or moving the bowels.
   - Take enough time to empty the bladder completely.
3. Keep the bowels regular. A rectum full of stool may irritate the bladder, causing urgency and frequency.
4. Prevent urinary tract infections.
   - Women: Cleanse the perineum from front to back after each voiding and bowel movement; wear cotton undergarments
   - Drink enough water to pass pale yellow urine.
   - Shower or bathe regularly
5. Stop smoking to reduce your risk for bladder cancer and reduce risk of developing a cough which can contribute to stress urinary incontinence.
6. Report to your health care provider any changes in bladder habits, frequency, urgency, pain when voiding, or blood in the urine.

BOX 46-8   PATIENT TEACHING

Teaching Patients About Pelvic Muscle Exercises (Kegel Exercises)

Objective
- Patient will verbalize and/or demonstrate how to perform pelvic muscle exercises (Kegel exercises).

Teaching Strategies
- Use pictures and plain language to teach the patient pelvic anatomy and the location of the pelvic muscles (see Fig 46-16).
- Teach patient how to identify and contract the correct muscle.
  - Women: Instruct the patient to squeeze the anus as if to hold in gas or to insert a finger into the vagina and feel the muscle squeeze around her finger. The woman can also observe the perineum pulling in by using a mirror.
  - Men: Instruct the patient to stand in front of a mirror, squeeze the anus as if to hold in gas, and watch to see if the penis moves up and down as he contracts the pelvic floor muscles.
  - Instruct to not contract the abdomen, buttocks, or thighs when contracting the pelvic muscles.
- Teach patients pelvic muscle contraction exercises.
  - Quick flicks: Squeeze the muscle for 2 to 3 seconds and relax.
  - Sustained contractions: Squeeze the muscle for 10 seconds and relax after each contraction for 10 seconds.
  - Counting out loud prevents breath holding during exercises.
- Teach patient to maintain a daily exercise schedule.
  - Perform three to five quick flicks followed by 10 sustained contractions.
  - Do these exercises 3 to 4 times a day.

Evaluation
- Use open-ended questions to determine level of learning.
- Ask the patient to describe how to correctly identify the pelvic floor muscles.
- Ask the patient to demonstrate and/or explain how to perform pelvic muscle exercises.

---

specialist to help the patient learn techniques to inhibit the urinary urge, strengthen pelvic floor muscles, and learn fluid and food modifications; the occupational therapist to help the patient learn efficient and safe toilet transfers; the physical therapist to help with strengthening exercises of the lower extremities; and the social worker to facilitate obtaining assistive devices in the home that are covered by insurance. The family caregiver is included in planning when applicable. When a patient requires an indwelling urinary catheter because of acute illness and a need to measure accurate urinary output, the nurse is a key member of the team by monitoring patient progress and ensuring that the catheter is removed in a timely manner. Your active and thoughtful role in planning these interventions will result in the patient's progress toward improved urinary elimination.

◆ Implementation

Complete independent and collaborative interventions to help the patient achieve the desired outcomes and goals. The independent activities are those in which nurses use their own judgment. An example of this is teaching self-care activities to the patient. Collaborative activities are those prescribed by the health care provider and carried out by the nurse such as medication administration.

Health Promotion. Health promotion helps the patient understand and participate in self-care practices to preserve and protect healthy urinary system function (Box 46-7). You can achieve this focus using several means.

Patient Education. Success of therapies aimed at eliminating or minimizing urinary elimination problems depends in part on successful patient education (see Box 46-7). Although many patients need to learn about all aspects of healthy urinary elimination, it is best to

focus on a specific elimination problem first. For example, a patient who has a UTI would greatly benefit from learning about the significance of symptoms that might indicate another UTI and learning to seek early treatment, which potentially can prevent serious illness. You can easily incorporate teaching when giving nursing care. For example, teach about common bladder irritants such as caffeine when helping a patient with his or her meal. Include in your teaching sensitivity to the patient's health literacy. Pictures are helpful when teaching about urinary tract anatomy and the relationship with UTI. If a patient speaks a different language, involve a professional interpreter.

Promoting Normal Micturition. Maintaining normal urinary elimination helps to prevent many problems. Many measures that promote normal voiding are independent nursing interventions.

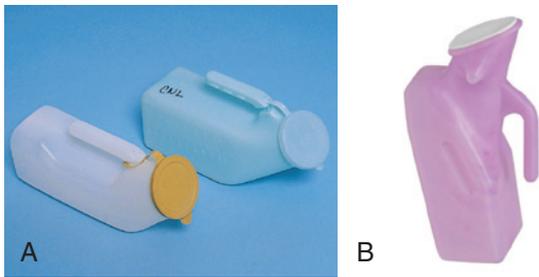
Maintaining Elimination Habits. Many patients follow routines to promote normal voiding. When in a hospital or long-term care facility, institutional routines often conflict with those of the patient. Integrating the patient's habits into the care plan fosters a more normal voiding pattern. Elimination is a very private act. Create as much privacy as possible by closing the door and bedside curtain; asking visitors to leave a room when a bedside commode, bedpan or urinal is used; and masking the sounds of voiding with running water. Respond to requests for help with toileting as quickly as possible. Embarrassing accidents are easily avoided when help comes in time. Avoid the use of


FIGURE 46-9 Types of male **(A)** and female **(B)** urinals. (**B** Courtesy Briggs Medical Service Co.)

incontinence-containment products unless needed for uncontrolled urine leakage. Some containment products may be difficult to remove and interfere with prompt toilet access.

Maintaining Adequate Fluid Intake. A simple method to promote normal micturition is maintaining optimal fluid intake. A patient with normal renal function who does not have heart disease or alterations requiring fluid restriction should have approximately 30 mL/kg of body weight or 0.5 ounces/lb/day (Gray, 2011). Adequate fluid intake will help flush out solutes or particles that collect in the urinary system and decrease bladder irritability. Help patients change their fluid intake by teaching the importance of adequate hydration. If a patient needs to increase fluid intake, set a schedule for drinking extra fluids, identify fluid preferences, increase high fluid foods such as fruits, and encourage fluid intake in small volumes frequently. Excessive fluid intake should be avoided. To prevent nocturia, suggest that the patient avoid drinking fluids 2 hours before bedtime.

Promoting Complete Bladder Emptying. It is normal for a small volume of urine to remain in the bladder after micturition. When the bladder does not empty completely and residual urine volumes are high, there is risk for incontinence and dangerous urinary retention. Urinary retention increases the risk for UTI and damage to the kidneys. Adequate bladder emptying depends on feeling an urge to urinate, contraction of the bladder, and the ability to relax the urethral sphincter. A strategy to promote relaxation and stimulate bladder contractions is to help patients assume the normal position for voiding. The normal anatomical position for female voiding is in the squatting position. Women empty the bladder better when sitting on the toilet or bedside commode with the feet on the floor. If the patient cannot use a toilet, position her on a bedpan (see Chapter 47). After bedpan use help the patient perform perineal hygiene (see Chapter 40). A man voids more easily in the standing position. If the patient is unable to reach a toilet, have him stand at the bedside and void into a urinal (a plastic or metal receptacle for urine) (Figure 46-9, *A*). Always assess mobility status and determine if he can stand safely. At times it is necessary for one or more nurses to help a male patient stand. If the patient is unable to stand at the bedside, you will need to help him use the urinal in bed. Some patients need the nurse to position the penis completely within the urinal and hold the urinal in place or help them hold the urinal. Once the patient has finished voiding, carefully remove the urinal and perform perineal hygiene (see Chapter 40). Most urinals are used by men, but there are specially designed urinals for women (see Figure 46-9, *B*). The female urinal has a larger opening at the top with a defined rim, which helps position the urinal closely against the genitalia.

There are other measures that improve bladder emptying. To promote relaxation and stimulate bladder contractions, use sensory stimuli (e.g., turning on running water, putting a patient's hand in a pan of warm water) and provide privacy. In addition, bladder exercises help to improve pelvic muscles, which reduces stress incontinence and

improves bladder emptying (Box 46-8). To improve bladder emptying, encourage patients to wait until the urine flow completely stops when voiding and encourage them to attempt a second void (double voiding). Timed voiding is voiding according to the clock, not the urge to void, and is a helpful strategy when the bladder does not fully empty. The Credé method or manual compression of the bladder (i.e., placing the hands over the bladder and compressing it to help in emptying) should not be implemented until consultation with the health care provider. In the presence of high PVRs or a complete inability of the bladder to empty, urinary catheterization, either intermittent or indwelling, is needed.

Preventing Infection. UTIs are one of the most common bacterial infections encountered by health care providers (Gupta and Hooton 2011; Schaeffer and Schaeffer, 2012). Nurses play a key role in implementing evidence-based practices to avoid this common and potentially dangerous infection. Some key interventions include promoting adequate fluid intake, promoting perineal hygiene, and having patients void at regular intervals. Encourage women to wipe front to back after voiding and defecation and teach them to avoid perfumed perineal washes and sprays, bubble baths, and tight clothing. If a patient has a problem with urine leakage, hygiene should be especially stressed. Patients should use containment products that are designed for urine and wick wetness away from the body. Prolonged periods of urine wetness should be avoided.

Acute Care. Patients with acute illness, surgery, or impaired function of the urinary tract may require more invasive interventions that support urinary elimination.

Catheterization. Urinary **catheterization** is the placement of a tube through the urethra into the bladder to drain urine. This is an invasive procedure that requires a medical order and, in institutional settings, aseptic technique (Gould et al., 2009; Lo et al., 2014). Skill 46-2 on pp. 1131-1140 lists steps for performing female and male urethral catheterization.

Urinary catheterization can be intermittent (one-time catheterization for bladder emptying) or indwelling (remains in place over a period of time). Indwelling catheterization may be short term (2 weeks or less) or long term (more than 1 month) (Cottenden et al., 2013). Conditions requiring the use of a short- or long-term urinary catheter include the need for accurate monitoring of urine output either perioperative or postoperative after urologic or gynecological procedures and when the bladder inadequately empties because of obstruction or a neurological condition. Excessive accumulation of urine in the bladder is painful for a patient; increases the risk for UTI; and can cause backward flow of urine up the ureters, increasing risk for kidney damage. UI may require indwelling catheterization if the leaking urine interferes with wound healing or in the presence of terminal illness when incontinence care is overly burdensome for the patient (Cottenden et al., 2013). Intermittent catheterization is used to measure PVR when ultrasound or a bladder scanner is not available or as a way to manage chronic urinary retention.

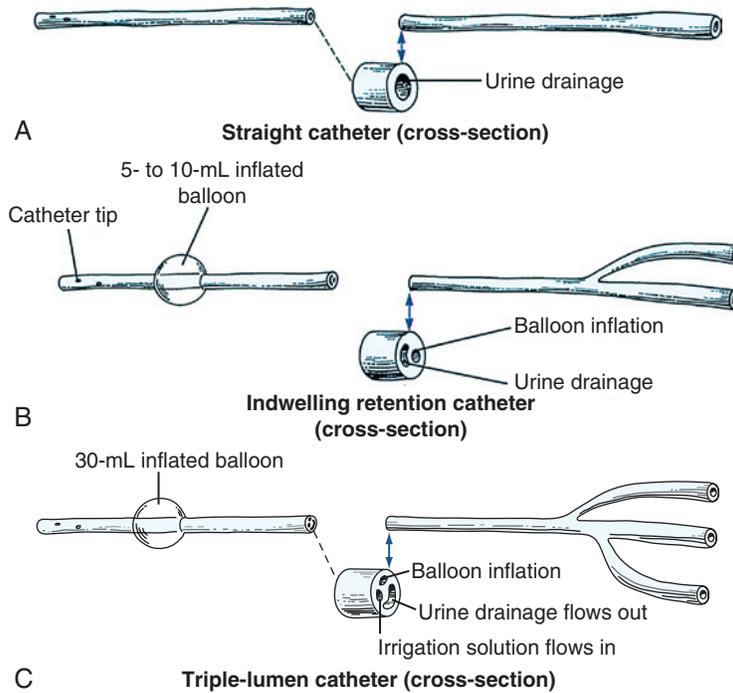
Types of Catheters. The difference among urinary catheters is related to the number of catheter lumens, the presence of a balloon to keep the indwelling catheter in place, the shape of the catheter, and a closed drainage system. Urinary catheters are made with one to three lumens (Figure 46-10). Single-lumen catheters (see Figure 46-10, *A*) are used for intermittent/straight catheterization. Double-lumen catheters, designed for indwelling catheters, provides one lumen for urinary drainage while a second lumen is used to inflate a balloon that keeps the catheter in place (see Figure 46-10, *B*). Triple-lumen catheters (see Figure 46-10, *C*) are used for continuous bladder irrigation (CBI) or when it becomes necessary to instill medications into the bladder.


FIGURE 46-10 **A,** Straight catheter (cross-section). **B,** Indwelling (Foley) retention catheter (cross-section). **C,** Triple-lumen catheter (cross-section.)

One lumen drains the bladder, a second lumen is used to inflate the balloon, and a third lumen delivers irrigation fluid into the bladder.

A health care provider chooses a catheter on the basis of factors such as latex allergy, history of catheter encrustation, anatomical factors, and susceptibility to infection. Indwelling catheters are made of latex or silicone. Latex catheters with special coatings reduce urethral irritation (Cottenden et al., 2013). All silicone catheters have a larger internal diameter and may be helpful in patients who require frequent catheter changes as a result of encrustation. Intermittent/straight catheters are made of rubber (softer and more flexible) or polyvinyl chloride (PVC). Patients who self-catheterize have a large selection of catheters, some with special coatings that do not require lubrication and others that are self-contained systems consisting of a prelubricated catheter and packaged with a preconnected drainage bag. Catheter shape can differ; shape chosen is based on anatomical differences in patients. One such catheter is a coudé-tip catheter. This catheter has a curvature at the end that helps it maneuver through the prostatic urethra in the presence of a large prostate. Nurses need special training to use this type of catheter.

Catheter Sizes. The size of a urinary catheter is based on the French (FR) scale, which reflects the internal diameter of the catheter. Most adults with an indwelling catheter should use a size 14 to 16 Fr to minimize trauma and risk for infection. Larger catheter diameters increase the risk for urethral trauma (Cottenden et al., 2013). However, larger sizes are used in special circumstances such as after urological surgery or in the presence of gross hematuria. Smaller sizes are needed for children such as a 5 to 6 Fr for infants, 8 to 10 Fr for children, and 12 Fr for young girls.

Indwelling catheters come in a variety of balloon sizes from 3 mL (for a child) to 30 mL for CBI. The size of the balloon is usually printed on the catheter port (Figure 46-11). The recommended balloon size for an adult is a 10-mL balloon (the balloon is 5 ml and requires 10 mL to fill completely). Long-term use of larger balloons (30 mL) has been associated with increased patient discomfort, irritation and trauma to the urethra, increased risk of catheter expulsion, and incomplete

FIGURE 46-11 Size of catheter and balloon printed on catheter.

emptying of the bladder resulting from urine that pools below the level of the catheter drainage eyes (Cottenden et al., 2013).

Catheter Drainage Systems. An indwelling catheter is attached to a urinary drainage bag to collect the continuous flow of urine. The drainage system should not be separated unless absolutely necessary to avoid introducing pathogens. In patients with indwelling catheters specimens are collected without opening the drainage system using a special port in the tubing (Figure 46-12). Always hang the drainage bag below the level of the bladder on the bedframe or a chair so urine will drain down out of the bladder. The bag should never touch the floor to prevent accidental contamination during emptying. When a patient ambulates, carry the bag below the level of the patient's bladder. Ambulatory patients may use a leg bag. This is a bag that attaches to the leg with straps. Leg bags are usually worn during the day and replaced at night with a standard drainage bag. The only drainage bag that does not need to be kept dependent to the bladder is a specially

FIGURE 46-12 Urine specimen collection: aspiration from a collection port in drainage tubing of indwelling catheter (needleless technique). (Courtesy and © Becton, Dickinson and Company.)

designed drainage bag (belly bag) that is worn across the abdomen. A one-way valve prevents the back flow of urine into the bladder. To keep the drainage system patent, check for kinks or bends in the tubing, avoid positioning the patient on drainage tubing, prevent tubing from becoming dependent, and observe for clots or sediment that may block the catheter or tubing.

Routine Catheter Care. Patients with indwelling catheters require regular perineal hygiene, especially after a bowel movement, to reduce the risk for catheter-associated UTI (CAUTI) (Gould et al., 2009; Lo et al., 2014). In many institutions patients receive catheter care every 8 hours as the minimal standard of care. See Chapter 40 for routine perineal care and Skill 46-3 on pp. 1140-1142 for catheter care. Empty drainage bags when ½ full (Figure 46-13). An overfull drainage bag can create tension and pulling on the catheter, resulting in trauma to the urethra and/or urinary meatus, and increase risk for CAUTI (Cipa-Tatum and Kelly-Signs, 2011; Rassin and Markovski, 2013). Expect continuous drainage of urine into the drainage bag. In the presence of no urine drainage, first check to make sure that there are no kinks or obvious occlusion of the drainage tubing or catheter.

Preventing Catheter-Associated Infection. A critical part of routine catheter care is reducing the risk for CAUTI (Box 46-9). Box 46-10 includes some important interventions included in the CDC *Guideline for Prevention of Catheter-Associated Urinary Tract Infections* (Gould et al., 2009; Lo et al., 2014). A key intervention to prevent infection is maintaining a closed urinary drainage system. Portals for entry of bacteria into the system are illustrated in Figure 46-14. Another key intervention is prevention of urine backflow from the tubing and bag into the bladder. Many urine drainage systems are equipped with an antireflux valve, but the nurse should monitor the system to prevent pooling of urine within the tubing and to keep the drainage bag below the level of the bladder.

QSEN QSEN: BUILDING COMPETENCY IN EVIDENCE-BASED PRACTICE A nursing unit is experiencing an increase in catheter-associated urinary tract infection (CAUTIs). A team of staff nurses are investigating this problem and discover that some nurses are resistant to implementing new evidence-based practice (EBP) guidelines in CAUTI prevention. What can you do to decrease resistance and enhance EBP care on this unit?

ⓔ *Answers to QSEN Activities can be found on the Evolve website.*

FIGURE 46-13 Urine drainage bag.

Catheter Irrigations and Instillations. To maintain the patency of indwelling urinary catheters, it is sometimes necessary to irrigate or flush a catheter with sterile solution. However, irrigation poses the risk for causing a UTI and thus must be done maintaining a closed urinary drainage system. Generally, if a catheter becomes occluded, it is best to change it rather than risk flushing debris into the bladder. In some instances the health care provider will determine that irrigations are needed to keep a catheter patent such as after genitourinary surgery when there is high risk for catheter occlusion from blood clots. Bladder instillations are used to instill medication into the bladder. Refer to specific instructions for these medications in terms of how long the medication needs to stay in the bladder.

Closed catheter irrigation provides intermittent or continuous irrigation of a urinary catheter without disrupting the sterile connection between the catheter and the drainage system (see Skill 46-4 on pp. 1142-1145). CBI is an example of a continuous infusion of a sterile solution into the bladder, usually using a three-way irrigation closed system with a triple-lumen catheter. CBI is frequently used following genitourinary surgery to keep the bladder clear and free of blood clots or sediment.

Removal of Indwelling Catheter. Prompt removal of an indwelling catheter after it is no longer needed is a key intervention that has proven to decrease the incidence and prevalence of hospital-acquired UTIs (HAUTIs), one of the "never events" identified by the Centers for Medicare and Medicaid Services (CMS) (APIC, 2014) (see Skill 46-2). All patients should have their voiding monitored after catheter removal for at least 24 to 48 hours by using a voiding record or bladder diary. The bladder diary should record the time and amount of each voiding, including any incontinence. The use of ultrasound or a bladder scanner can monitor bladder function by measuring PVR (Box 46-11). The first few times a patient voids after catheter removal may be accompanied by some discomfort, but continued complaints of painful urination indicate possible infection. Abdominal pain and

BOX 46-9 EVIDENCE-BASED PRACTICE

Factors to Decrease Urinary Tract Infections

PICO Question: Which factors decrease the risk of urinary tract infections (UTIs) in hospitalized patients with indwelling urinary catheters?

Evidence Summary

Catheter-associated UTI (CAUTI) is responsible for 30% or more infections in the acute care setting, with increased length of hospital stay, morbidity, mortality, and cost (Bernard et al., 2012). In 2009 the Centers for Disease Control and Prevention (CDC) published a long-awaited update for their Guideline for Prevention of Catheter-Associated Urinary Tract Infections (Gould et al., 2009). Measures to reduce CAUTI are organized into: criteria for appropriate use, proper insertion and maintenance techniques, quality improvement programs, and ongoing surveillance for CAUTI and related causative factors. Current research continues to reinforce the validity of these guidelines and successful reduction in CAUTI when implemented in the acute care setting. A review of current evidence found that nurse-led interventions reduced the duration of indwelling catheter use and incidence of CAUTI (Bernard et al., 2012). Oman et al. (2012) showed how a hospital-wide strategy that included reeducation of nurses about CAUTI prevention and infusing best practice into current practice nursing care also decreased CAUTI rates. Purvis et al. (2014) showed that a nurse-managed program that included evidence-based best practices, staff education, data reporting, and using an icon in the electronic health record as a catheter reminder decreased the CAUTI rate in an academic medical center. A systematic review and meta-analysis of studies regarding measures to use to reduce catheter use and decrease CAUTI showed that CAUTI rates can be reduced when reminders to evaluate catheter need and stop orders are in place (Meddings et al., 2014). Nurses play a key role in this strategy of catheter awareness.

Application to Nursing Practice

- Become familiar with guidelines related to CAUTI prevention and care.
- Be aware of indications for catheter insertion and be prepared to advocate for the patient if the indications do not meet accepted guidelines.
- Collaborate with health care providers to remove catheters early when medical indications no longer exist.
- Become a patient advocate in your institution through careful adherence to CAUTI preventive practices.

BOX 46-10 Preventing Catheter-Associated Urinary Tract Infection (CAUTI)

- Prevention of CAUTI often requires use of an evidence based "bundle" to perform all elements of care at one time along with completion of a checklist to ensure that each element is included in that care. Know the policies of your institution to determine which components are in a care bundle.
- Patients in acute care hospital should have urinary catheters inserted using aseptic technique with sterile equipment.
- Secure indwelling catheters to prevent movement and pulling on the catheter.
- Maintain a closed urinary drainage system.
- Maintain an unobstructed flow of urine through the catheter, drainage tubing, and drainage bag.
- Keep the urinary drainage bag below the level of the bladder at all times.
- Avoid dependent loops in urinary drainage tubing.
- Prevent the urinary drainage bag from touching or dragging on the floor.
- When emptying the urinary drainage bag, use a separate measuring receptacle for each patient. Do not let the drainage spigot touch the receptacle.
- Before transfers or activity, drain all urine from the tubing into bag and empty the drainage bag.
- Empty the drainage bag when $\frac{1}{2}$ full.
- Perform routine perineal hygiene daily and after soiling using antiseptic wipes. Be sure to use a wipe to clean the length of the exposed catheter.
- Obtain urine samples using the sampling port. Cleanse the port with disinfectant. Use a sterile syringe/cannula.
- Quality improvement programs should be in place that alert providers that a catheter is in place and include regular educational programming about catheter care.

Data from Gould CV et al: *Guideline for prevention of catheter-associated urinary tract infections,* 2009, http://www.cdc.gov/hicpac/cauti/001_cauti.html. Accessed October 4, 2014.

distention, a sensation of incomplete emptying, incontinence, constant dribbling of urine, and voiding in very small amounts can indicate inadequate bladder emptying requiring intervention.

The risk of UTI increases with the use of an indwelling catheter (APIC, 2014; Lo et al., 2014). Symptoms of infection can develop 2 to 3 or more days after catheter removal. Patients need to be informed of the risk for infection, prevention measures, and signs and symptoms that need to be reported to the nurse and health care provider.

Alternative to Catheterization. To avoid the risks associated with urethral catheters, two alternatives are available for urinary drainage.

Suprapubic Catheterization. A **suprapubic catheter** is a urinary drainage tube inserted surgically into the bladder through the abdominal wall above the symphysis pubis (Figure 46-15). The catheter may be sutured to the skin, secured with an adhesive material, or retained in the bladder with a fluid-filled balloon similar to an indwelling catheter. Suprapubic catheters are placed when there is blockage of the urethra (e.g., enlarged prostate, urethral stricture, after urological surgery) and in situations when a long-term urethral catheter causes irritation or discomfort or interferes with sexual functioning.

FIGURE 46-14 Potential sites for introduction of infectious organisms into urinary drainage system.

BOX 46-11   PROCEDURAL GUIDELINES

Using a Bladder Scanner to Measure Postvoid Residual

Delegation Considerations

The skill of measuring bladder volume by bladder scan can be delegated to nursing assistive personnel (NAP). However, it is important to establish competency in bladder scan measurements because reliability between different care provider readings can be poor. An RN must first determine the timing and frequency of the bladder scan measurement and interpret the measurements obtained. The nurse is also responsible for assessing the patient's ability to toilet before measurement of postvoid residual (PVR) and assessing the abdomen for distention if urinary retention is suspected. The nurse directs the NAP to:

- Follow manufacturer recommendations for the use of the device.
- Measure PVR volumes 10 minutes after helping the patient to void.
- Report and record bladder scan volumes.

Equipment

Bladder scanner, ultrasound gel, cleaning agent for scanner head such as an alcohol pad, clean gloves (optional)

Steps

1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number, according to agency policy) (TJC, 2016).
2. Perform hand hygiene. Discuss procedure with patient. If the measurement is for PVR, ask him or her to void and measure and record voided urine volume. (apply gloves if patient requires assistance with voiding). The scan measurement should be within 10 minutes of voiding.
3. Help patient to the supine position with the head slightly elevated. Raise bed to appropriate working height. If side rails are raised, lower side rail on working side.
4. Expose patient's lower abdomen.
5. Turn on the scanner per manufacturer guidelines.
6. Set the gender designation per manufacturer guidelines. Women who have had a hysterectomy should be designated as male.
7. Wipe the scanner head with an alcohol pad or other cleanser and allow to air dry.
8. Palpate the patient's symphysis pubis (pubic bone). Apply a generous amount of ultrasound gel (or if available a bladder scan gel pad) to the midline abdomen 2.5 to 4 cm (1 to 1.5 inches) above the symphysis pubis. The ultrasound gel ensures adequate transmission and thus accurate measurement.
9. Place the scanner head on the gel, ensuring that the scanner head is oriented per manufacturer guidelines (see illustration).

STEP 9 Point scanner head slightly downward toward bladder.

10. Apply light pressure, keep the scanner head steady, and point it slightly downward toward the bladder. Press and release the scan button.
11. Verify accurate aim (refer to manufacturer guidelines). Complete the scan and print the image (if needed) (see illustration).

STEP 11 Bladder scan image. (Courtesy Verathon Inc.)

12. Remove ultrasound gel from patient's abdomen with a paper towel.
13. Remove ultrasound gel from scanner head and wipe with alcohol pad or other cleanser; let air dry.
14. Help patient to a comfortable position. Lower bed and place side rails accordingly.
15. Dispose of soiled towels and pad. Perform hand hygiene.

FIGURE 46-15 A, Placement of suprapubic catheter above symphysis pubis. **B**, Suprapubic catheter without a dressing.

Care of a suprapubic catheter involves daily cleansing of the insertion site and catheter. The same care for the tubing and drainage bag for a urethral catheter applies to a suprapubic catheter. The insertion site should be assessed for signs of inflammation and the growth of overgranulation tissue. If insertion is new, slight inflammation may be expected as part of normal wound healing, but it can also indicate infection. Overgranulation tissue can develop at the insertion site as a reaction to the catheter. In some instances intervention may be needed. Site care applies principles of applying a dry dressing, and institutional policy will indicate if aseptic or sterile technique is required (see Chapter 48).

External Catheter. The external catheter, also called a *condom catheter* or *penile sheath,* is a soft, pliable condom-like sheath that fits over the penis, providing a safe and noninvasive way to contain urine. Most external catheters are made of soft silicone that aids in reducing friction and are clear to allow for easy visualization of skin under the catheter. Latex catheters are still available and used by some patients. It is important to verify that a patient does not have a latex allergy before applying this type of catheter. Condom-type external catheters are held in place by an adhesive coating of the internal lining of the sheath, a double-sided self-adhesive strip, brush-on adhesive applied to the penile shaft, or in rare cases an external strap or tape. They may be attached to a small-volume (leg) drainage bag or a large-volume (bedside) urinary drainage bag, both of which need to be kept lower than the level of the bladder. The condom-type external catheter is suitable for incontinent patients who have complete and spontaneous bladder emptying. Condom-type external catheters come in a variety of styles and sizes. For the best fit and correct application it is important to refer to manufacturer guidelines. See Box 46-12 for the steps in applying a condom catheter. Condom-type external catheters are associated with less risk for UTI than indwelling catheters; thus they are an excellent option for the male with UI. For men who cannot be fitted for a condom-type external catheter, there are other externally applied catheters. One type attaches to the glans penis using hydrocolloid strips that stay in place for multiple days and allow intermittent/straight catheterization (Kyle, 2011). Another available option is a reusable condom-like device that is held in place by specially designed underwear.

Urinary Diversions. Immediately after surgery the patient with an incontinent urinary diversion must wear a pouch to collect the effluent (drainage). The pouch will keep the patient clean and dry, protect the skin from damage, and provide a barrier against odor. Urinary pouches with an antireflux flap can be opaque or clear, drainable one-piece or two-piece pouches, with cut-to-fit or precut wafers. The pouch should be changed every 4 to 6 days. Each pouch may be connected to a bedside drainage bag for use at night.

When changing a pouch, gently cleanse the skin surrounding the stoma with warm tap water using a washcloth and pat dry. Do not use soap because it can leave a residue on the skin. Measure the stoma and cut the opening in the pouch. Then apply the pouch after removing the protective backing from the adhesive surface. Press firmly into place over the stoma. Observe the appearance of the stoma and surrounding skin. The stoma is normally red and moist and is located in the right lower quadrant of the abdomen. It is important for the patient to have the correct type and fit of an ostomy pouch. A specialty ostomy nurse is an essential resource when selecting the right appliance so the pouch fits snugly against the surface of the skin around the stoma, preventing damaging leakage of urine (see Chapter 47).

Patients with continent urinary diversions do not have to wear an external pouch. However, if the patient has a continent urinary reservoir, he or she must be taught how to intermittently catheterize the pouch. Patients need to be able and willing to do this 4 to 6 times a day for the rest of their lives. After creation of an orthopic neobladder, patients will have frequent episodes of incontinence until the neobladder slowly stretches and the urinary sphincter is strong enough to contain the urine. To achieve continence the patient will need to follow a bladder-training schedule and perform pelvic muscle exercises (Geng et al., 2010). The postoperative care of patients having continent urinary diversions varies widely with the surgical techniques used, and it is important to learn the surgeon's preferred routine or health care facility procedures before caring for these patients.

Medications. A small number of medications are used to treat urgency, frequency, nocturia, and urgency UI. Antimuscarinics include darifenacin, oxybutynin, solifenacin, fesoterodine, tolterodine, and tropsium and one that is not an antimuscarinic, mirabegron (Qaseem and Dallas, 2014). The most common adverse effects of the antimuscarinics are dry mouth, constipation, and blurred vision. In some cases these medications can cause a change in mental status in older adults (Burchum and Rosenthal, 2016). Patients taking mirabegron should have their blood pressure monitored because of possible

BOX 46-12   PROCEDURAL GUIDELINES

Applying a Condom Catheter

Delegation Considerations

The skill of applying condom catheters can be delegated to nursing assistive personnel (NAP). Before delegation instruct the NAP to:

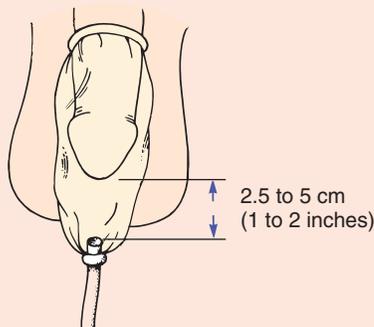
- Inform the nurse if there is any redness, swelling, or skin irritations or breakdown of glans penis or penile shaft.
- Be sensitive to privacy needs of patients.
- Follow manufacturer directions for applying the condom catheter and securing the device.

Equipment

Condom catheter (includes securing device such as internal adhesive, strap, or tape), collection bag, basin with warm water, towel and washcloth, clean gloves, scissors, hair guard or paper towel, bath blanket and sheet

Steps

1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number, according to agency policy) (TJC, 2016).
2. Perform hand hygiene.
3. Assess urinary elimination patterns, patient's ability to empty bladder effectively, and degree of continence.
4. Assess patient's mental status, knowledge about the procedure, and ability to self-apply device. Explain procedure.
5. Provide for privacy by closing room door or bedside curtain. Raise bed to working height and lower side rail on working side.
6. Prepare condom catheter (prescribed size and type), drainage bag, and tubing (see manufacturer directions). Most manufacturers provide a measuring guide and instructions.
7. Help patient to a supine or sitting position. Place bath blanket over upper torso; fold a sheet over lower torso so only penis is exposed.
8. Apply clean gloves; provide perineal care (see Chapter 40), and dry thoroughly. If patient is uncircumcised, ensure that the foreskin is in the normal nonretracted position. Do not apply barrier cream and make sure that any remaining adhesive is removed (Cottenden et al., 2013).
9. Assess penis for erythema, rashes, and/or open areas. Condom catheters can only be applied to intact skin.
10. Clip hair at base of penile shaft as necessary. Do not shave the pubic area. Some manufacturers provide a hair guard, which is placed over the penis before applying the device. An alternative to a hair guard is to tear a hole in a paper towel, place it over the penis, and remove after application of the device (Cottenden et al., 2013; Kyle, 2011).
11. Apply condom catheter. With nondominant hand, grasp penis along shaft. With dominant hand, hold condom sheath at tip of penis and smoothly roll sheath onto penis. Allow 2.5 to 5 cm (1 to 2 inches) of space between tip of penis and end of catheter (see illustration).

2.5 to 5 cm
(1 to 2 inches)


STEP 11 Distance between end of penis and tip of condom.

12. Secure condom catheter according to manufacturer directions:
   a. Outer-securing strip-type catheter: Spiral wrap the penile shaft with supplied elastic adhesive. Strip should not overlap. The elastic

strip should be snug, not tight (see illustration). **NOTE: Never use adhesive tape.**

Elastic adhesive

STEP 12a Apply elastic adhesive in spiral fashion to secure condom catheter to penis.

   b. For self-adhesive catheter, apply gentle pressure on penile shaft for 10 to 15 seconds to secure.
13. Connect drainage tubing to end of condom catheter. Be sure that condom is not twisted. Connect catheter to large-volume drainage bag or leg (see illustration).

STEP 13 Attach condom catheter to leg bag.

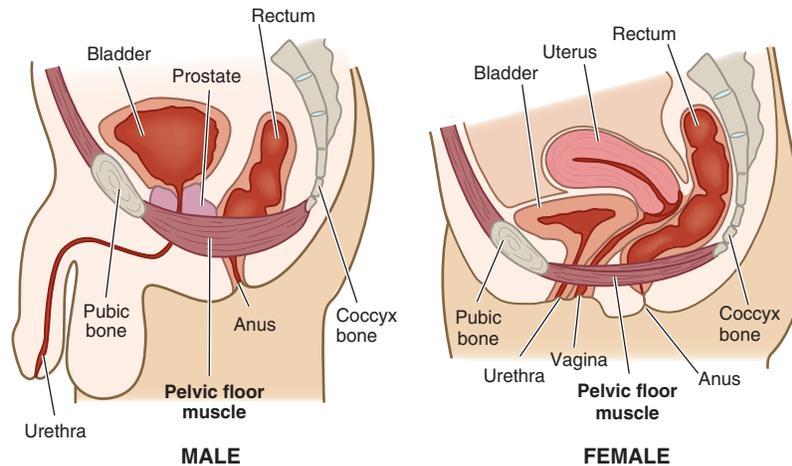
14. Help patient to a safe, comfortable position, lower bed, and place side rails accordingly.
15. Dispose of contaminated supplies, remove gloves, and perform hand hygiene.
16. Inspect penis with condom catheter in place within 15 to 30 minutes after application for any swelling, discoloration, or discomfort. Observe for patency of urinary drainage system, characteristics of urine, condition of penis, and proper placement of condom catheter.
17. Remove and reapply daily following the previous steps unless an extended-wear device is used. For removal, wash the penis with warm, soapy water and gently roll the sheathe and adhesive off the penile shaft (Kyle, 2011).
18. Perform *Teach Back* to determine patient's understanding about the catheter. State, "We talked about what you need to do to prevent the drainage tube from blocking urine flow. Can you tell me what you need to do?"


FIGURE 46-16 Pelvic floor muscles. (From Lewis S et al: *Medical-surgical nursing: assessment and management of clinical problems*, ed 9, St Louis, 2014, Mosby.)

increases. There are no medications, other than off-label use of vaginal estrogen in postmenopausal women, to treat stress UI (Shamliyan et al., 2012). Urinary retention is sometimes treated with bethanechol, and men with outlet obstruction caused by an enlarged prostate are treated with agents that relax the smooth muscle of the prostatic urethra such as tamsulosin and silodosin and agents that shrink the prostate such as finasteride and dutasteride. Know the medications and indications for all medications your patient is taking.

When a patient is newly started on an antimuscarinic, monitor for effectiveness, watching for a decrease in symptoms such as urgency, frequency, and urgency UI episodes. A bladder diary is one of the best ways to do this. In addition, regularly assess the patient for side effects such as constipation by monitoring the bowel movement record. Watch for a decrease in bowel movement frequency, straining at bowel movements, and changes in stool consistency.

UTIs are treated with antibiotics. Patients with painful urination are sometimes prescribed urinary analgesics that act on the urethral and bladder mucosa (e.g., phenazopyridine). Patients taking drugs with phenazopyridine need to be aware that their urine will be orange. They must drink large amounts of fluids to prevent toxicity from the sulfonamides and maintain optimal flow through the urinary system (Burchum and Rosenthal, 2016).

Continuing and Restorative Care. There are techniques that can improve control over bladder emptying and restore some degree of urinary continence. These techniques are commonly referred to as behavioral therapy and are considered first-line treatment for stress, urge, and mixed incontinence (Gormley and Lightner, 2012). They include lifestyle changes, **pelvic floor muscle training** (PFMT), bladder retraining, and a variety of toileting schedules (see Table 46-1). In some cases, when the bladder does not empty, patients or caregivers learn to intermittently catheterize. Whenever there is a risk for urine leakage, skin care is an essential component of the plan of care. Adequate urine containment and skin protection promotes patient comfort and dignity.

Lifestyle Changes. A number of lifestyle modifications can improve bladder function and decrease incontinence. In addition to interventions listed earlier in this chapter under health promotion and in Box 46-7, you can teach patients about foods and fluids that cause bladder irritation and increase symptoms such as frequency, urgency, and incontinence. Teach patients to avoid common irritants such as artificial sweeteners, spicy foods, citrus products, and especially caffeine (Jura et al., 2011; Lohsiriwat, 2011). Discourage patients from

drinking large volumes of fluid at one time. Constipation can also impact bladder symptoms, and measures to promote bowel regularity should be implemented (see Chapter 47). Encourage patients with edema to elevate the feet for a minimum of a few hours in the afternoon to help diminish nighttime voiding frequency.

Pelvic Floor Muscle Training. Evidence has shown that patients with urgency, stress, and mixed UI experience improvement and can eventually achieve continence when treated with pelvic floor muscle training (Bettez et al., 2012 Lucas et al., 2013; Shamliyan et al., 2012). Pelvic floor muscle training involves teaching patients how to identify and contract the pelvic floor muscles in a structured exercise program. This exercise program is commonly called *Kegel exercises* and is based on therapy first developed by obstetrician gynecologist Dr. Arnold Kegel in the 1940s. The exercises work by increasing the pressure within the urethra by strengthening the pelvic floor muscles and inhibiting unwanted bladder contractions (Figure 46-16). Many patients benefit from verbal instructions on how to do the exercises (see Box 46-8). Patients who have difficulty correctly identifying and contracting the pelvic floor muscles can be sent to a continence specialist for biofeedback. Biofeedback involves intensive instruction augmented by computerized measurement of muscle activity that is displayed on a monitor. The visual feedback helps the patient learn to contract the muscles correctly.

Bladder Retraining. Bladder retraining is a behavioral therapy designed to help patients control bothersome urinary urgency and frequency. Patients are taught about their bladder and techniques to suppress urgency. They are given a schedule of toileting on the basis of their diary of voiding and leaking, and a schedule is designed to slowly increase the interval between voiding. Successful bladder retraining requires that patients get regular support and positive reinforcement. Patients are taught to inhibit the urge to void by taking slow, deep breaths to relax, performing five to six quick, strong pelvic muscle exercises (flicks) in quick succession, followed by distracting attention from bladder sensations. When the urge to void becomes less severe or subsides, only then should the patient start his or her trip to the bathroom. Only highly motivated and cognitively intact patients are candidates for this therapy. If a patient is in such a program, you can support him or her by reinforcing the schedule and providing emotional encouragement.

Toileting Schedules. A key component to any treatment plan for UI is regular toilet access. Toileting schedules should be individualized based on the type of incontinence and functional disability (e.g., cognitive impairment). Toileting can be implemented in any care

setting and should be the first plan of action when you assess a patient to be incontinent. Timed voiding or scheduled toileting is toileting based on a fixed schedule, not the patient's urge to void. The schedule may be set by a time interval, every 2 to 3 hours or at times of day such as before and after meals. It is very successful with moderate-to-severe cognitively- and mobility-impaired adults. Habit training is a toileting schedule based on the patient's usual voiding pattern. Using a bladder diary, the usual times a patient voids are identified. It is at these times that the patient is then toileted. Prompted voiding is a program of toileting designed for patients with mild or moderately cognitive impairment. Patients are toileted based on their usual voiding pattern. Caregivers ask the patient if they are wet or dry, give positive feedback for dryness, prompt the patient to toilet, and reward the patient for desired behavior. This is a very successful toileting program; but it does require a consistent motivated caregiver, a cooperative patient, and evidence that the patient will void when toileted at least 50% of the time or more.

Intermittent Catheterization. Some patients experience chronic inability to completely empty the bladder as a result of neuromuscular damage related to multiple sclerosis, diabetes, spinal cord injury, and urinary retention caused by outlet obstruction. To minimize the risk of UTI, patients or family caregivers are taught to catheterize the bladder. It is important they follow the principles of asepsis as discussed earlier in the chapter. Teach patients and caregivers about the importance of adequate fluid intake, signs of infection, and their individualized catheterization schedule. The goal for intermittent catheterization is drainage of 400 mL of urine with the schedule individualized to meet this goal.

Skin Care. Incontinence-associated dermatitis (IAD) is defined as "erythema and edema of the surface of the skin, sometimes accompanied by bullae with serous exudates, erosion or secondary cutaneous infection" (Gray et al., 2012). It is caused by irritation of the skin by urine caused by skin overhydration, increased pH, and friction injury during movement (Gray et al., 2012). Exposure to stool and urine increases the risk for skin injury. Key components for IAD prevention and treatment include gentle skin cleansing with a no-rinse pH balanced cleanser, using a skin moisturizer, and applying a moisture barrier product (Doughty et al., 2012). In some cases patients may develop a topical fungal infection that requires treatment with a steroid/antifungal cream or ointment. Typically these patients present with erythema with raised red spots located near the edge. Patients may complain of intense itchiness.

◆ **Evaluation**

Through the Patient's Eyes. The patient is the best source of evaluation of outcomes and responses to nursing care. Include patients in the planning of nursing care and revision of the plan based on their perception of its success. It is important to remember that urinary problems impact the patient not only physically but emotionally, psychologically, spiritually, and socially. Carefully assess the patient's self-image, social interactions, sexuality, and emotional status as impacted by the urinary problem (Figure 46-17).

Patient Outcomes. To evaluate the care plan use the expected outcomes developed during planning to determine whether interventions were effective. This evaluation process is dynamic. Information gathered is used to modify the plan of care to meet expected outcomes. Evaluate for changes in the patient's voiding pattern and/or presence of symptoms such as dysuria, urinary retention, and UI. If a behavioral plan is in effect, evaluate patient/caregiver compliance with the plan such as toileting according to the schedule or the number of incontinent episodes. Actual outcomes are compared with expected outcomes

Knowledge
- Clinical signs of normal micturition
- Characteristics of normal urine
- Behaviors that demonstrate learning

Experience
- Previous patient responses to planned nursing interventions to promote urinary elimination

EVALUATION
- Reassess the patient's urination pattern and signs and symptoms of alterations
- Inspect the character of the patient's urine
- Have the patient and family demonstrate any self-care skills
- Have the patient discuss feelings regarding any permanent changes in elimination
- Ask patient if expectations are being met

Standards
- Use expected outcomes established in patient's plan of care
- Use established expected outcomes from professional organizations such as ANA and AHCPR to evaluate the patient's response to care

Attitudes
- Be accountable and responsible for onset of any complications related to care
- Demonstrate perseverance when necessary because some interventions (e.g., pelvic floor exercises) may take weeks to months to effect any change
- Adapt and revise approaches if interventions are ineffective

FIGURE 46-17 Critical thinking model for urinary elimination evaluation. *AHCPR,* Agency for Health Care Policy and Research; *ANA,* American Nurses Association.

to determine success or partial success in achieving these outcomes. Examples of questions to ask for evaluation include:
- "Tell me, how frequently are you voiding now?"
- "How many times are you awakened from sleep with a strong urge to void?"
- "Do you continue to experience that sensation of urgency or need to rush to the toilet?"
- "How many episodes of urine leakage have you experienced over the past week?"
- "Do you have pain or burning when you pass urine?

Evaluation of an intervention may take place within a day or two, or it may take weeks or months to fully evaluate effectiveness. Evaluate initial compliance with dietary changes, understanding of instructions for pelvic muscle exercise, or effectiveness of antibiotic treatment for UTI in 1 to 2 days. Evaluation of the effectiveness of pelvic muscle exercises in decreasing urgency and incontinence will need to be weeks or months after therapy is started. Continuous evaluation, when possible, allows you to determine progress toward goals, encourage compliance, and revise the diagnosis and/or plan as needed.

SAFETY GUIDELINES FOR NURSING SKILLS

Ensuring patient safety is an essential role of the professional nurse. To ensure patient safety, communicate clearly with members of the health care team, assess and incorporate a patient's priorities of care and preferences, and use the best evidence when making decisions about your patient's care. When performing the skills in this chapter, remember to follow points to ensure safe, individualized care:

- Follow principles of surgical and medical asepsis as indicated when performing catheterizations, handling urine specimens, or helping patients with their toileting needs.

- Identify patients at risk for latex allergies (i.e., patient history of hay fever; asthma; and allergies to certain foods such as bananas, grapes, apricots, kiwi fruit, and hazelnuts).
- Identify patients with allergies to povidone-iodine (Betadine). Provide alternatives such as chlorhexidine.

SKILL 46-1   COLLECTING MIDSTREAM (CLEAN-VOIDED) URINE SPECIMEN

DELEGATION CONSIDERATIONS

The skill of collecting midstream (clean-voided) urine specimens can be delegated to nursing assistive personnel (NAP). If appropriate, you can instruct an alert patient who is physically able to collect the specimen. It is the nurse's responsibility to ensure that this specimen is obtained correctly and in a timely manner. Be knowledgeable about agency policy regarding specimen collection. Direct the NAP to:

- Consider patient's mobility restrictions and inform nurse when specimen is obtained.
- Inform nurse if patient is unable to initiate a stream or has pain or burning on urination.
- Inform nurse if collected specimen is dark, bloody, cloudy, or odorous or contains mucus.

EQUIPMENT

- Soap or cleaning solution, washcloth, and towel
- Commercial kit for clean-voided specimen (Figure 46-18) or individual supplies as listed
  - Antiseptic towelettes or
  - Antiseptic solution (e.g., chlorhexidine [Hibiclens] or povidone-iodine [Betadine]) and sterile cotton balls or sterile 2 × 2 or 4 × 4 gauze pads
  - Sterile specimen container
- Clean gloves
- Bedpan, bedside commode, or specimen hat
- Completed specimen label and laboratory requisition form with proper patient identifiers

---

STEP	RATIONALE

ASSESSMENT

1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.

2. Assess for patient allergy to cleansing agent.

3. Assess patient's cognitive status, developmental level, mobility, coordination, and physical limitations.

4. Assess patient's understanding of purpose of test and method of collection.

5. Assess perineal area for soiling.

Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).

If allergic to iodine, provide cleansing alternative such as chlorhexidine.

Identifies patient's needs for help and ability to cooperate during procedure

Allows you to clarify misunderstandings, promotes patient cooperation, and improves accuracy of specimen collection.

Cleansing of genitourinary and perianal areas can be completed before obtaining specimen.

FIGURE 46-18 Commercial midstream urine collection kit.

STEP	RATIONALE

PLANNING

1. Provide fluids to drink ½ hour before collection unless contraindicated (i.e., fluid restriction) if patient does not feel urge to void.

Improves likelihood of patient being able to void.

2. Explain procedure to patient:

Helps patient understand procedure.

    a. Reason midstream specimen is necessary

    b. Ways for patient and family to help

    c. Ways to obtain specimen free of feces

Feces change characteristics of urine and cause abnormal values.

    d. Use plain language and visual aids (if applicable) to explain procedure

Illustrations demonstrating midstream collection techniques help to clarify a complex procedure, especially with patients for whom English is a second language.

3. If female patient is menstruating, record this on laboratory requisition form.

IMPLEMENTATION

1. Perform hand hygiene and apply gloves.

Reduces transmissions of microorganisms.

2. Provide privacy for patient by closing door or bed curtain.

Privacy allows patient to relax and produce specimen more quickly.

3. Help patient as needed to toilet or onto bedpan or position the urinal. If on a bedpan, raise the head of the bed.

Semi-sitting position may ease voiding.

4. Prepare sterile specimen container.

    a. Remove lid from sterile urine cup and place lid with sterile inside surface up nearby. Do not touch inside of container

Maintains inside of container sterile.

    b. Open antiseptic towelette package or prepare cotton balls/gauze sponges with antiseptic solution.

    c. If helping patient, apply clean pair of gloves.

5. Collect specimen.

    a. Female

        (1) Spread labia with thumb and forefinger of nondominant hand.

Provides access to urethral meatus.

        (2) Clean area with towelette/cotton ball/gauze, moving from front (above urethral orifice) to back (toward anus). Using a fresh towelette/cotton ball/gauze each time, repeat front-to-back motion 3 times (begin with left side, then right side, then center) (see illustration).

Clean from area of least contamination to area of greatest contamination to decrease bacterial levels.

        (3) While continuing to hold labia apart, have patient initiate stream. After patient starts urine stream, pass container into stream and collect 30 to 60 mL (see illustration)

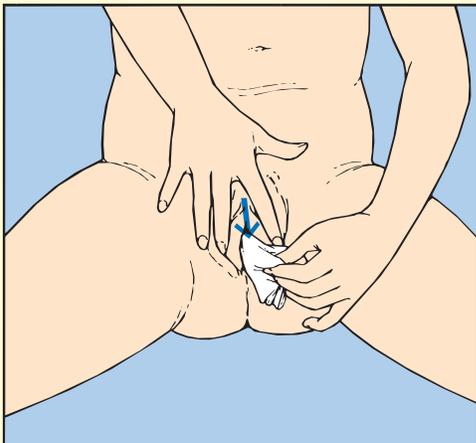
Initial stream flushes out microorganisms that accumulate at urethral meatus and prevents transfer into specimen.

    b. Male

        (1) Hold penis with one hand and cleanse glans penis using circular motion with antiseptic towelette/cotton ball/gauze; clean moving from center to outside (see illustration). In uncircumcised men retract foreskin before cleaning.

Clean from area of least contamination to area of greatest contamination to decrease bacterial levels.

        (2) After patient has initiated urine stream, pass specimen collection container into stream and collect 30 to 60 mL (see illustration).

Initial stream flushes out microorganisms that accumulate at urethral meatus and prevents transfer into specimen.


STEP 5a(2) Cleaning technique (female).

STEP 5a(3) Specimen collection (female).

SKILL 46-1	**COLLECTING MIDSTREAM (CLEAN-VOIDED) URINE SPECIMEN—cont'd**

STEP	**RATIONALE**
6. Remove specimen container before flow of urine stops and before releasing labia or penis. Patient finishes voiding in bedpan/toilet/urinal.	Prevents contamination of specimen with skin flora.

CLINICAL DECISION: *If foreskin was retracted for specimen collection, replace it over the glans. If foreskin is not replaced, swelling and constriction occur, causing pain and possible obstruction to urine flow.*

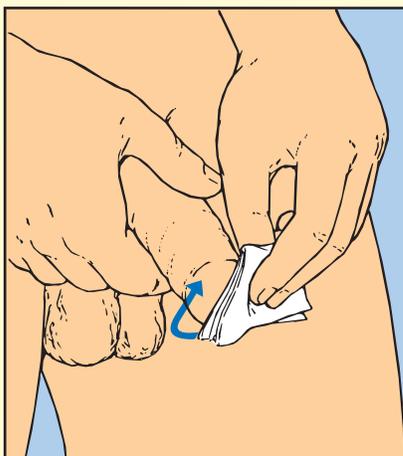
STEP	**RATIONALE**
7. Replace cap securely on specimen container (touch outside only).	Retains sterility of inside of container and prevents spillage of urine.
8. Clean any urine from exterior surface of container. Attach label on side of container (not lid) in front of patient. Be sure label is complete with two identifiers, specimen source, and date and time. Place in plastic specimen biohazard bag as required by agency.	Prevents transfer of microorganisms to others.
9. Remove and empty bedpan/urinal (if applicable) and help patient to comfortable position.	Promotes relaxing environment.
10. Attach laboratory requisition to specimen bag.	Prevents inaccurate identification and minimizes errors in diagnosis or treatment.
11. Remove gloves, dispose of them in proper receptacle, and perform hand hygiene.	Reduces transmission of infection.
12. Transport specimen to laboratory within 15 to 30 minutes or refrigerate immediately.	Because bacteria grow quickly in urine, urine not received by laboratory within 30 minutes should be refrigerated. However, refrigeration should not exceed 2 hours (Pagana and Pagana, 2013).

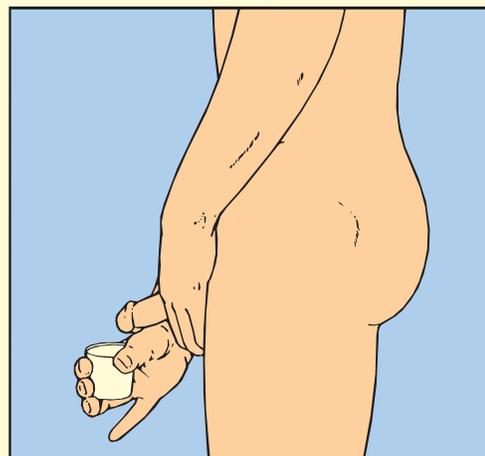
EVALUATION

1. Observe characteristics of urine and look for any contaminants such as feces.	Contaminants prevent specimen from being used.
2. Evaluate laboratory results of urine test.	Determines presence of bacteria and kidney function.
3. Use **Teach Back** to determine patient's and family's understanding about the correct steps in obtaining a clean-catch urine specimen. State, "I want to be sure I explained the steps in obtaining the urine specimen. Can you repeat those steps for me?" Revise your instruction now or develop a plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient and family are able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Urine specimen is contaminated with feces or toilet paper.
- Repeat instruction to patient or help patient obtain specimen.
- Obtain a new specimen.
- Request an order for using a straight catheterization to obtain specimen.

2. Specimen is spilled or accidentally discarded.
- Repeat specimen collection.


STEP 5b(1) Cleaning technique (male).


STEP 5b(2) Specimen collection (male).

RECORDING AND REPORTING

- Record date and time urine specimen was obtained in nurses' notes.
- Notify health care provider of any significant abnormalities.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- If patient is to collect specimen as outpatient, a clean technique may be used. Provide instruction for collection and appropriate equipment.
- Provide information about storing specimen until time for delivery to health care provider's office or hospital laboratory.

SKILL 46-2	**INSERTING AND REMOVING A STRAIGHT (INTERMITTENT) OR INDWELLING CATHETER**

DELEGATION CONSIDERATIONS

The skill of inserting a straight or an indwelling catheter cannot be delegated. The nurse is responsible for assessing the need for and evaluation of catheterization. The nurse directs nursing assistive personnel (NAP) to:

- Help with patient positioning, focus lighting for the procedure, empty urine from collection bag, and help with perineal care.
- Report postprocedure patient discomfort, fever, or catheter leakage to the nurse.
- Report abnormal color, odor, or amount of urine to the nurse.

EQUIPMENT

Catheter insertion

- Sterile drainage tubing and bag (if not included in the kit)
- Device to secure catheter (catheter strap or other device)
- Extra sterile gloves and catheter (optional)
- Bath blanket
- Waterproof absorbent pad
- Clean gloves, basin with warm water, soap or perineal cleanser, washcloth, and towel for perineal care
- Additional lighting as needed (such as a flashlight or procedure light)
- Measuring container for urine
- Bladder scanner (if available)
- Catheter kit containing the following sterile items: (Catheter kits vary; thus it is important to check the list of contents on the package.)

Straight/intermittent catheterization kit

- Single-lumen catheter (commonly 12-14 Fr)
- Drapes (one fenestrated—has an opening in the center)
- Sterile gloves
- Lubricant
- Cleansing solution incorporated in an applicator or to be added to cotton balls (forceps to pick up cotton balls)
- Specimen container

Indwelling catheterization kit

- Double-lumen catheter (Some kits contain a catheter with attached drainage bag; others contain only a catheter; others with no catheter.)
- Drapes (one fenestrated—has an opening in the center)
- Lubricant
- Cleansing solution incorporated in an applicator or to be added to cotton balls (forceps to pick up cotton balls)
- Prefilled syringe with sterile water for balloon inflation
- Sterile drainage tubing and bag (some kits come preconnected; others do not, and a separate package is required)
- Sterile gloves
- Specimen container

Catheter removal

- Clean gloves
- Waterproof pad
- Bath blanket
- Soap, washcloth, towel, and basin filled with warm water
- 10-mL or larger syringe without needle—information on balloon size (mL) is printed directly on balloon inflation valve (see Figure 46-11)
- Graduated cylinder to measure urine
- Toilet, bedside commode, urine "hat," urinal, or bedpan
- Bladder scanner (if available and indicated)

SKILL 46-2	INSERTING AND REMOVING A STRAIGHT (INTERMITTENT) OR INDWELLING CATHETER—cont'd

STEP	RATIONALE

ASSESSMENT

1. Review patient's medical record, including health care provider's order and nurses' notes. Note previous catheterizations, including catheter size, response of patient, and time of catheterization.	Identifies purpose of inserting catheter such as for measurement of residual urine or specimen collection, previous catheter size, and potential difficulty with catheter insertion.
2. Review medical record for any pathological condition that may impair passage of catheter (e.g., enlarged prostate gland in men, urethral strictures).	Obstruction of urethra may prevent passage of catheter into bladder. Men with enlarged prostates may require the use of a coudé-tip catheter.
3. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
4. Ask patient and check medical record for allergies.	Identifies allergy to components of catheterization kit and/or catheter (e.g., antiseptic, tape, latex).
5. Assess patient's weight, level of consciousness, developmental level, ability to cooperate, and mobility.	Determines positioning for catheterization and indicates how much help is needed to properly position patient, ability of patient to cooperate during procedure, and level of explanation needed.
6. Review patient's gender and age.	Determines catheter size.

CLINICAL DECISION: *Large catheters can damage the urethra and urinary meatus, increase bladder irritability, and cause urine to leak around the catheter because of spasm (Cottenden et al., 2013). Use the smallest size catheter possible to minimize trauma and patient discomfort (Gould et al., 2009).*

7. Assess bladder for fullness by palpation of bladder over symphysis pubis or by use of bladder scanner (if available).	Palpation of full bladder causes pain and/or urge to void, indicating full or overfull bladder.
8. Perform hand hygiene and apply clean gloves. Inspect the perineal area for anatomical landmarks, erythema, drainage or discharge, and odor. Remove gloves and perform hand hygiene.	Assessment of female perineum landmarks improves accuracy and speed of catheter insertion.
9. Assess patient's knowledge and prior experience with catheterization.	Reveals extent of instruction or support needed by patient.

PLANNING

1. Collect appropriate equipment.	
2. Arrange for extra nursing personnel to help as necessary.	More than one person is needed to help position patients who are weak, frail, obese, or confused.
3. Explain procedure to patient and why catheter is necessary. Describe sensations patient will feel (e.g., liquid cleansing of perineum, burning during catheter insertion).	Promotes cooperation and facilitates anxiety reduction.

IMPLEMENTATION

1. Perform hand hygiene.	Reduces transmission of microorganisms.
2. Provide privacy by closing room door and bedside curtain.	Protects patient confidentiality.
3. Raise bed to appropriate working height. If side rails in use, raise side rail on opposite side of bed and lower side rail on working side.	Promotes good body mechanics. Use of side rails in this manner promotes patient safety.
4. Place waterproof pad under patient.	Prevents soiling of bed linen.
5. Provide perineal hygiene if needed (apply clean gloves, complete cleansing, discard gloves and perform hand hygiene).	Hygiene before catheter insertion removes secretions, urine, and feces that could contaminate the sterile field and increase risk for catheter-associated urinary tract infection (CAUTI).

CLINICAL DECISION: *Obtain help to position and support weak, frail, or confused patients.*

STEP	RATIONALE

6. Position and drape patient:

   a. Female Patient

      (1) Help to dorsal recumbent position (supine with knees flexed). Ask patient to relax thighs to externally rotate hip joints (see illustration).

      (2) Alternate female position: Position side-lying (Sims') position with upper leg flexed at knee and hip. Ensure that rectal area is covered with drape to reduce risk of contamination. Support patient with pillows if necessary to maintain position.

   b. Male Patient

      (1) Position supine with legs extended and thighs slightly abducted.

   c. Drape Patient: Cover upper part of body with small sheet or blanket. Cover lower extremities with sheet or blanket, exposing only genitalia. In women it is helpful to place blanket diamond fashion over patient, with one corner at patient's neck, side corners over each arm and side, and last corner over perineum (see illustration).

7. Position light to illuminate genitals or have assistant available to hold light source to visualize urinary meatus.

8. Perform hand hygiene.

9. Open catheterization kit (some products have a double wrapping requiring removal of outer wrapper or plastic covering; others require peeling back a paper top). Place opened kit on clean bedside table or, if possible, between patient's open legs. Patient size and positioning will dictate exact placement.

10. If present, open inner sterile wrap covering box using sterile technique (see Chapter 29).

   a. Straight/intermittent catheterization: All needed supplies are in sterile tray. Tray that contains supplies can be used for urine collection.

   b. Indwelling catheterization open system: Open separate package containing drainage bag, check to make sure that clamp on drainage port is closed, and place drainage bag and tubing easily accessible. Open outer package of sterile catheter, maintaining sterility of inner wrapper.

Rationale column:

Provides good visualization of structures of perineum and decreases risk for fecal contamination.

Alternate position is more comfortable if patient cannot abduct leg at hip joint (e.g., patient has arthritic joints or contractures).

Comfortable position for patient that aids in visualization of penis.

Protects patient dignity by avoiding unnecessary exposure of body parts.

Adequate visualization of urinary meatus helps with speed and accuracy of catheter insertion.

Provides easy access to supplies during catheter insertion.

Inner sterile wrap serves as sterile field. Straight catheterization trays do not routinely come with double wrapping.

An open drainage bag system requires separate sterile packaging for sterile catheter, drainage bag, and tubing and insertion kit.

STEP 6a(1) Draping female for catheterization.

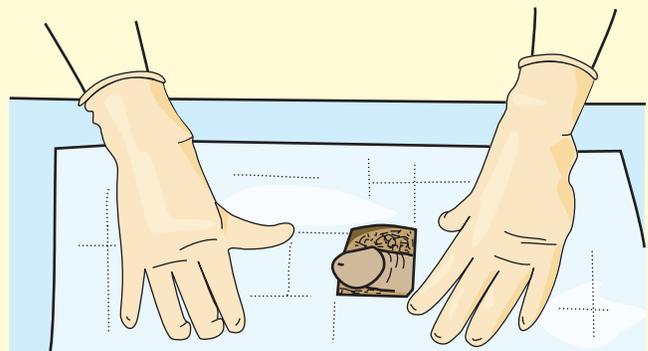
STEP 6c Draping male for catheterization.

SKILL 46-2	INSERTING AND REMOVING A STRAIGHT (INTERMITTENT) OR INDWELLING CATHETER—cont'd

STEP	RATIONALE

CLINICAL DECISION: *Some companies are now inserting CDC guidelines lists inside sterile packages to outline indications for indwelling catheterization. Simply discard after reviewing.*

STEP	RATIONALE
c. Indwelling catheterization closed system: All supplies are in sterile tray. Once sterile gloves are put on, check to make sure clamp on drainage bag is closed.	Closed drainage bag systems have catheter preattached to drainage tubing and bag.
11. Apply sterile gloves. Drape perineum, keeping gloves and working surface of drape sterile.	Sterile drapes provide sterile field over which nurse will work during catheterization.
a. Sterile Drape Female	
(1) Pick up square drape and allow unfolding without touching unsterile surfaces. Allow top edge of drape to form cuff over both hands. Place drape with shiny side down on bed between patient's thighs. Slip cuffed edge just under buttocks as you ask patient to lift hips. Take care not to touch contaminated surfaces with sterile gloves.	When creating cuff over sterile gloved hands, sterility of gloves and workspace is maintained. If gloves are contaminated, remove and apply new pair.
(2) Pick up fenestrated sterile drape. Allow drape to unfold without touching unsterile surfaces. Allow top edge of drape to form cuff over both hands. Drape over perineum, exposing labia (see illustration).	Opening in drape creates sterile field around labia.
b. Sterile Drape Male: Pick up square drape and allow unfolding without touching unsterile surfaces. Place over thighs with shiny side down, just below penis. Place fenestrated drape with opening centered over penis (see illustration).	
c. In some kits sterile gloves may be below square sterile drape. In this case, pick up the square drape from tray by edges and allow it to unfold without touching unsterile surfaces. The top edge is then folded away (sterile side up, hands on shiny underside) from patient to form cuff over both hands and carefully placed. Then put on sterile gloves and place fenestrated drape.	Sequence of supplies in kit varies. Use supplies in order to prevent contamination of underlying supplies.
12. Arrange supplies on sterile field, maintaining sterility of gloves. Place sterile tray with cleaning medium (premoistened swab sticks or cotton balls, forceps, and solution), lubricant, catheter, and prefilled balloon inflation syringe (indwelling catheterization only) on sterile drape.	Provides easy access to supplies during catheter insertion and helps to maintain aseptic technique. Appropriate placement is determined by size of patient and position during catheterization.
a. Open package of sterile antiseptic solution. Open end of package for easy access. Pour solution over sterile cotton balls. Some kits may contain a package of premoistened swab sticks or sticks that will be in the tray in which you pour antiseptic.	Use of sterile supplies and antiseptic solution will reduce risk of CAUTI (Geng et al., 2012; Gould et al., 2009).
b. Open sterile specimen container if urine specimen required.	Makes container accessible to receive urine from catheter if specimen is needed.

STEP 11a(2) Place sterile fenestrated drape (with opening in center) over perineum with labia exposed.


STEP 11b Draping male with fenestrated drape.

STEP	RATIONALE

c. Indwelling catheterization: Open inner sterile wrapper of catheter. If part of kit, remove tray with catheter and attached drainage bag and place on sterile drape. Make sure that clamp on drainage port of bag is closed.

d. Open packet of lubricant (some kit lubricant comes in a syringe) and squeeze out on sterile field. Lubricate catheter by dipping catheter into water-soluble gel 2.5 cm to 5 cm (1 to 2 inches) for women and 12.5 to 17.5 cm (5 to 7 inches) for men.

Lubrication minimizes trauma to urethra and discomfort during catheter insertion. Male catheter needs enough lubricant to cover length of catheter inserted.

CLINICAL DECISION: *It is essential to check manufacturer instructions before inserting an indwelling catheter. Some manufacturers do not recommend pretesting the inflation balloon. Pretesting by inflation/deflation of the balloon may lead to formation of ridges in the balloon, potentially causing trauma on insertion.*

---

13. Cleanse urethral meatus:

a. Female Patient

   (1) Gently separate labia with fingers of nondominant hand (now contaminated) to fully expose urinary meatus.

   (2) Maintain position of nondominant hand throughout remainder of procedure.

   (3) Use forceps to hold one cotton ball or hold one swab stick at a time. Clean labia and urinary meatus from clitoris toward anus. Use new cotton ball or swab for each area you cleanse. Cleanse by wiping far labial fold, near labial fold, and directly over center of urethral meatus (see illustration).

Optimal visualization of urethral meatus is possible. Closure of labia during cleansing means that area is now contaminated and requires cleaning procedure to be repeated.

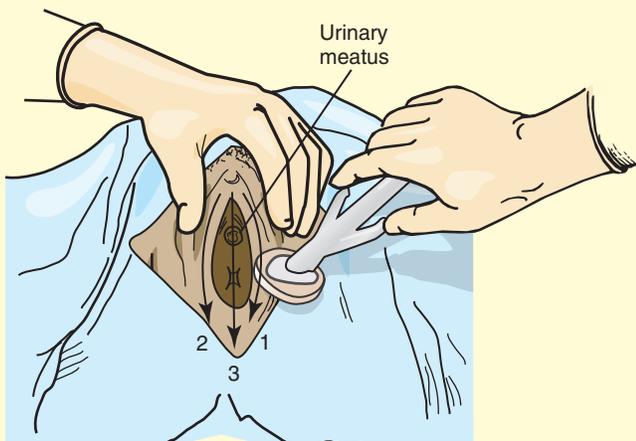
Front-to-back cleansing is cleaning from area of least contamination toward highly contaminated area (see Chapter 29). Dominant gloved hand remains sterile.

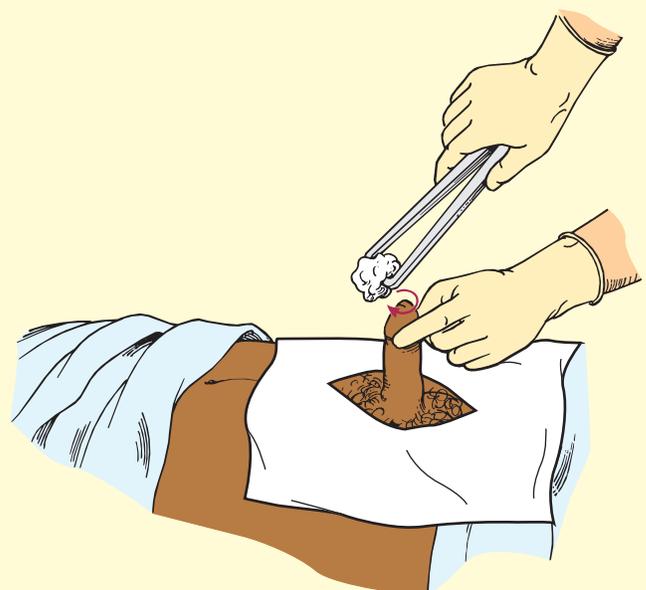
b. Male Patient

   (1) With nondominant hand (now contaminated) retract foreskin (if uncircumcised) and gently grasp penis at shaft just below glans. Hold shaft of penis at right angle to body. This hand remains in this position for remainder of procedure.

   (2) With uncontaminated dominant hand cleanse meatus with cotton balls/swab sticks, using circular strokes, beginning at meatus and working outward in spiral motion. Repeat 3 times using clean cotton ball/stick each time (see illustration).

When grasping shaft of penis, avoid pressure on dorsal surface to prevent compression of urethra. Positioning penis at this 90-degree angle to patient straightens out curvature of male urethra and eases insertion (Geng et al., 2012; Mendez-Probst et al., 2012).

Circular cleansing pattern follows principles of medical asepsis (see Chapter 29).


STEP 13a(3) Cleansing female perineum.


STEP 13b(2) Cleansing male urinary meatus.

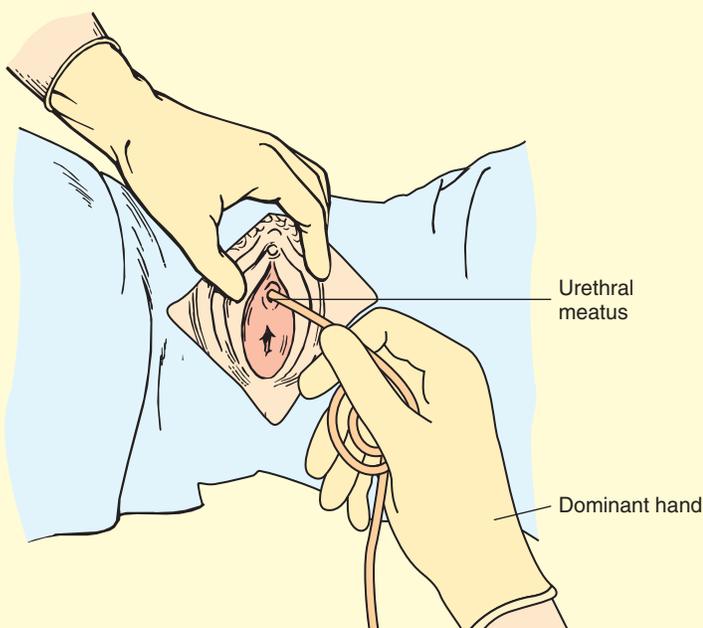
SKILL 46-2	INSERTING AND REMOVING A STRAIGHT (INTERMITTENT) OR INDWELLING CATHETER—cont'd

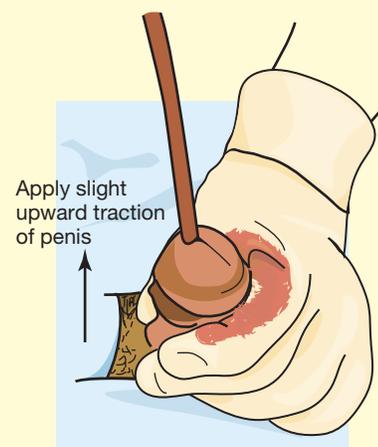
STEP	RATIONALE
14. Pick up and hold catheter 7.5 to 10 cm (3 to 4 inches) from catheter tip with catheter loosely coiled in palm of hand. If catheter is not attached to drainage bag, make sure to position urine tray so end of catheter can be placed there once insertion begins.	Holding catheter near tip allows for easier manipulation of catheter during insertion. Coiling catheter in palm prevents distal end from striking nonsterile surface.
15. Insert catheter:	
a. Female Patient	
(1) Ask patient to bear down gently and slowly insert catheter through urethral meatus (see illustration).	Bearing down may help visualize urinary meatus and promotes relaxation of external urinary sphincter, aiding in catheter insertion.
(2) Advance catheter total of 5 to 7.5 cm (2 to 3 inches) in an adult **or until urine flows out end of catheter.** Release labia but maintain secure hold on catheter.	Urine flow indicates that catheter tip is in bladder. Prevents accidental dislodgement of catheter.

CLINICAL DECISION: *If no urine appears, catheter may be in vagina. If misplaced, leave catheter in vagina as landmark indicating where not to insert and insert another sterile catheter.*

b. Male Patient	
(1) Gently apply upward traction to penis as it is held in 90-degree angle from body (see illustration).	Straightens urethra to ease catheter insertion.
(2) Ask patient to bear down as if to void and slowly insert catheter through urethral meatus.	Relaxation of external sphincter aids in insertion of catheter (Geng et al., 2012).
(3) Advance catheter 17 to 22.5 cm (7 to 9 inches) or until urine flows out end of catheter.	Length of male urethra varies. Flow of urine indicates that tip of catheter is in bladder but not necessarily the balloon part of an indwelling catheter.

CLINICAL DECISION: *If there is resistance or pain when advancing the catheter, DO NOT USE FORCE and stop catheter advancement. Ask the patient to take slow, deep breaths to promote relaxation. Hold catheter gently in place without forcing. After a few seconds the sphincter may relax, and catheter can be advanced. An inability to advance a catheter may mean an enlarged prostate or some other obstruction of the urethra.*

(4) Lower penis and hold catheter securely in nondominant hand.	Prevents accidental dislodgement of catheter.
16. Allow bladder to empty fully unless institution policy restricts maximum volume of urine drained (see agency policy).	There is no definitive evidence regarding whether there is benefit in limiting maximal volume drained.


STEP 15a(1) Inserting catheter into female urinary meatus.


STEP 15b(1) Position of penis perpendicular to body for catheter insertion.

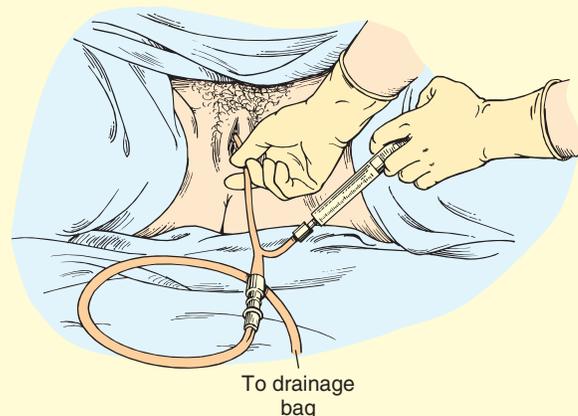
STEP	RATIONALE

CLINICAL DECISION: *In the case of acute urinary retention (rapid onset) when the volume of urine is known to be excessive (greater than 1 L), notify the health care provider for guidance related to gradual bladder decompression to avoid possible decompression-induced hematuria (Mendez-Probst et al., 2012).*

STEP	RATIONALE
17. Collect urine specimen as needed by holding end of catheter over cup. Fill to desired level. Label and bag specimen according to agency policy. Send specimen to laboratory as soon as possible.	A sterile specimen for culture analysis can be obtained. Fresh urine specimen ensures more accurate findings (Pagana and Pagana, 2013).
18. Straight/intermittent catheterization**:** when urine flow stops, withdraw catheter slowly and smoothly until removed.	
19. Indwelling catheterization: inflate catheter balloon.	
a. **Female patient**	
(1) As soon as urine appears, advance catheter another 2.5 to 5 cm (1 to 2 inches). Do not force catheter if resistance is met.	Ensures catheter tip is completely inside bladder.
(2) Release labia but maintain secure hold of catheter with nondominant hand.	Prevents accidental removal.
b. **Male patient**	
(1) After catheter is inserted through meatus and urine appears, advance catheter to bifurcation of drainage and balloon inflation port (see illustration).	There is natural resistance as the catheter passes through the U-shaped bulbar urethra. Further advancement of catheter to bifurcation of drainage and balloon inflation port ensures that balloon part of catheter is not still in prostatic urethra (Geng et al., 2012; Mendez-Probst et al., 2012).
(2) Lower penis and hold catheter securely in nondominant hand.	
c. With free dominant hand, connect prefilled syringe in injection port at end of catheter. Slowly inject amount of solution required to fill balloon as designated by manufacturer (see illustration).	Indwelling catheter balloons should not be overinflated or underinflated to prevent occlusion of catheter drainage holes, balloon distortion, and bladder irritation (Geng et al., 2012). Catheter balloons are only filled with sterile water. Other solutions might precipitate and occlude the fill tubing and catheter balloon fill valve (Mendez-Probst et al., 2012).

CLINICAL DECISION: *If the patient complains of sudden pain during inflation of a catheter balloon or resistance is felt when inflating the balloon, stop inflation, allow the fluid from the balloon to flow back into the syringe, advance catheter further, and reinflate balloon. The balloon may have been inflating in the urethra.*

STEP	RATIONALE
d. After inflating catheter balloon, release catheter from nondominant hand. Gently withdraw catheter until resistance is felt. Then advance catheter slightly.	Withdrawing catheter places catheter balloon at base of bladder; slight advancement reduces risk of excessive pressure (Geng et al., 2012).
e. **Male patient:** If retracted, replace foreskin over glans penis.	Leaving foreskin retracted can cause discomfort and dangerous edema.
f. Connect drainage tubing to catheter if it is not already preconnected.	Ensures proper drainage by gravity. Placement on side rails increases risk for tension applied to catheter, and bag can be raised above level of bladder.

STEP 19b(1) Male anatomy with correct catheter insertion to bifurcation of drainage and balloon inflation port.


STEP 19c Inflating balloon (indwelling catheter).

SKILL 46-2	INSERTING AND REMOVING A STRAIGHT (INTERMITTENT) OR INDWELLING CATHETER—cont'd

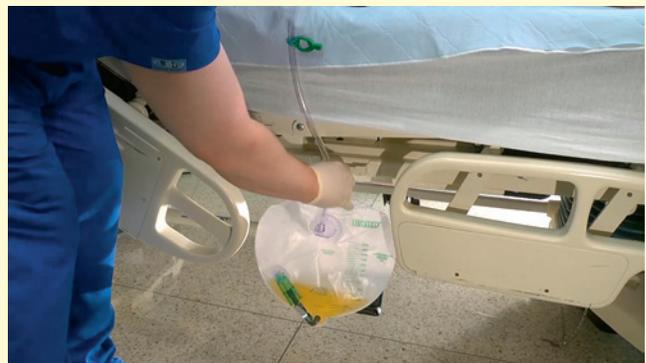
STEP	RATIONALE

20. Secure catheter with catheter securement device at catheter bifurcation (see manufacturer directions). Allow enough slack to allow leg movement and avoid any traction on catheter (see illustration).
  a. Female Patient: Secure catheter tubing to inner thigh.
  b. Male Patient: Secure catheter tubing to top of thigh or lower abdomen (with penis directed toward chest).
	Securing indwelling catheters reduces risk of urethral trauma, urethral erosion, CAUTI, or accidental removal (Callan et al., 2012; Cipa-Tatum and Kelly-Signs, 2011; Gould et al., 2009).

21. Clip drainage tubing to edge of mattress. Position drainage bag lower than bladder by attaching to bedframe. Do not attach to side rails of bed (see illustration).	Drainage bags that are below level of bladder ensure free flow of urine, thus decreasing risk for CAUTI (Gould et al., 2009). Bags attached to movable objects such as a side rail increase risk for urethral trauma because of pulling or accidental dislodgement (Gould et al., 2009).
22. Check to make sure that there is no obstruction to urine flow. Coil excess tubing on bed and fasten to bottom sheet with clip or other securement device.	Obstruction prevents free flow of urine and increases risk for CAUTI (Geng et al., 2012; Gould et al., 2009).
23. Provide hygiene as needed. Help patient to comfortable position.	
24. Dispose of used equipment in appropriate receptacles.	Reduces transmission of microorganisms.
25. Label specimen container correctly for culture with patient present, place in biohazard container, and send to laboratory with completed requisition.	Ensures prompt diagnostic analysis.
26. Measure urine and record.	
27. Remove gloves and perform hand hygiene.	
28. Removal of indwelling Foley catheter:	
a. Review medical order for removal of catheter. In cases of genitourinary surgery, it is especially important to obtain an order.	Premature removal of catheter inpatients who have undergone GU surgery could injure patient.
b. Perform hand hygiene, put on clean gloves, and provide privacy.	Procedure requires use of medical asepsis.

c. Prepare the patient:
    (1) Provide an explanation of procedure.
    (2) Position patient with waterproof pad under buttocks and cover with bath blanket, exposing only genital area and catheter. Position females in dorsal recumbent position and male patients in supine position.
    (3) Remove catheter securement device and free drainage tubing.
	Prepares patient to minimize anxiety.
	Shows respect for patient dignity by only exposing genital area and catheter.

d. If needed provide hygiene of genital area with soap and water.	Antiseptic cleaners have not been proven to decrease risk for CAUTI (Geng et al., 2012; Gould et al., 2009).
e. Move syringe plunger up and down to loosen and then withdraw plunger to 0.5 mL. Insert hub of syringe into inflation valve (balloon port). Allow balloon fluid to drain into syringe by gravity. Make sure that entire amount of fluid is removed by comparing removed amount to volume needed for inflation.	Partially inflated balloon can traumatize urethral wall during removal. Passive drainage of catheter balloon will prevent formation of ridges in balloon. These ridges can cause discomfort or trauma during removal.
f. Pull catheter out smoothly and slowly. Examine it to ensure that it is whole. Catheter should slide out easily. Do not use force. If you note any resistance, repeat Step 28e to remove remaining water. Notify health care provider if balloon does not deflate completely.	Promotes patient comfort and safety.
g. Wrap contaminated catheter in waterproof pad. Unhook collection bag and drainage tubing from bed.	Prevents transmission of microorganisms.

STEP 20 Catheter securement device. (Copyright © Mosby's Clinical Skills: Essentials Collection.)


STEP 21 Drainage bag below level of bladder, connected to bedframe. (Copyright © Mosby's Clinical Skills: Essentials Collection.)

STEP	RATIONALE
h. Reposition patient as necessary. Provide hygiene as needed. Lower level of bed and position side rails accordingly	
i. Empty, measure, and record urine present in drainage bag. Discard in appropriate receptacle. Remove and discard gloves. Perform hand hygiene.	Records urinary output. Reduces transmission of microorganisms.
j. Encourage patient to maintain or increase fluid intake (unless contraindicated).	Maintains normal urine output.
k. Initiate voiding record or bladder diary. Instruct patient to report when urge to void occurs and that all urine needs to be measured. Make sure that patient understands how to use collection container.	Evaluates bladder function.
l. Ensure easy access to toilet, commode, bedpan, or urinal. Place urine "hat" on toilet seat if patient is using toilet. Place call bell within easy reach.	

EVALUATION

1. **Intermittent catheter:**
   a. Palpate bladder for distention. — Determines if distention is relieved.
   b. Ask patient to describe level of comfort. — Determines if patient's sensation of discomfort or bladder fullness has been relieved.

2. **Indwelling catheter:**
   a. Observe character and amount of urine in drainage system. — Determines if urine is flowing adequately.
   b. Determine that no urine is leaking from catheter or tubing connections. — Prevents injury to patient's skin and ensures closed sterile system.
3. Observe time and measure amount of first voiding after catheter removal. — Indicates return of bladder function after catheter removal.
4. Evaluate patient for signs and symptoms of urinary tract infection. — Any patient with an indwelling catheter, who has recently had a catheter removed, or who has been catheterized recently is at risk for infection.

5. Use **Teach Back** to determine patient's and family's understanding about catheterization. State, "I want to be sure that I explained to you how you can help keep this catheter draining correctly. Can you explain to me the ways you can keep the catheter draining so urine can flow out the catheter?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly. — Evaluates what patient and family are able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Patient complains of bladder discomfort and/or catheter leaking.
   - Check catheter for kinking or bending causing occlusion of flow.
   - Check catheter to ensure that there is no traction/pulling on it.
   - Assess for signs of infection.
   - Notify health care provider. Patient may be experiencing bladder spasms or symptoms of a urinary tract infection.
2. Adult patient exhibits one or more of the following: fever, chills, burning sensation, flank pain, back pain, hematuria, painful urination, urgency, frequency, lower abdominal pain, change in mental status, lethargy (Gupta and Hooton, 2011; Hooton and Bradley, 2010).
   - Monitor vital signs and urine output.
   - Report findings to health care provider; signs and symptoms may indicate a urinary tract infection.
3. Older adults, particularly those with underlying cognitive impairments, may exhibit one or more of the following: cognitive changes, lethargy, anorexia, and more generalized symptoms (Matthews and Lancaster, 2011).
   - Monitor vital signs and urine output.
   - Report findings to health care provider; signs and symptoms may indicate a urinary tract infection.
4. Patient is unable to void after catheter removal, has a sensation of not emptying, strains to void, or experiences small voiding amounts with increasing frequency.
   - Assess for bladder distention.
   - Help to a normal position for voiding.
   - Provide privacy for voiding.
   - Perform bladder scan or ultrasound (if available) to assess for excessive urine volume in bladder.
   - If patient unable to void within 6 to 8 hours of catheter removal and/or experiences abdominal pain, notify health care provider.

RECORDING AND REPORTING

- Report and record type and size of catheter inserted, amount of fluid used to inflate the balloon, characteristics and amount of urine, and reasons for catheterization and specimen collection if appropriate.
- Document your evaluation of patient learning.
- Initiate intake and output (I&O) record.
- Report and record time of catheter removal and time, amount, and characteristics of first voiding.
- Report hematuria, dysuria, inability or difficulty voiding, or incontinence after catheter removal.

SKILL 46-2	INSERTING AND REMOVING A STRAIGHT (INTERMITTENT) OR INDWELLING CATHETER—cont'd

HOME CARE CONSIDERATIONS

- Patients who are at home may use a leg bag during the day and switch to a larger-volume bag at night. If a patient changes from a large-volume bag to a leg bag, instruct in the importance of handwashing and cleansing the connection ports with alcohol before changing bags.
- Teach patients and family caregivers how to properly position the drainage bag, empty a urinary drainage bag, and observe urine color, clarity, odor, and amount.
- Educate patients and/or caregivers about the signs of UTI and troubleshooting techniques for a leaking catheter.
- Arrange for home delivery of catheter supplies, always ensuring that there is at least one extra catheter, insertion kit, and drainage bag in the home.

SKILL 46-3	INDWELLING CATHETER CARE

DELEGATION CONSIDERATIONS

The skill of perineal care is often part of routine hygiene care that can be delegated to nursing assistive personnel (NAP). Proper assessment and care of the perineal area is the responsibility of the nurse. If patient has had trauma or surgical procedures that involve the perineal area, do not delegate this care.

The nurse instructs the NAP to:

- Report patient discomfort and perineal pain, discharge, perineal rash, and/or odor.
- Report condition of the catheter and drainage tubing (e.g., leaks, encrustations).
- Report any discolored or foul-smelling urine.

EQUIPMENT

- Clean gloves
- Clean washcloth and towel
- Warm water and soap
- Bath blanket
- Waterproof absorbent pad
- Antiseptic swab or cloth (e.g., chlorhexidine) (optional)

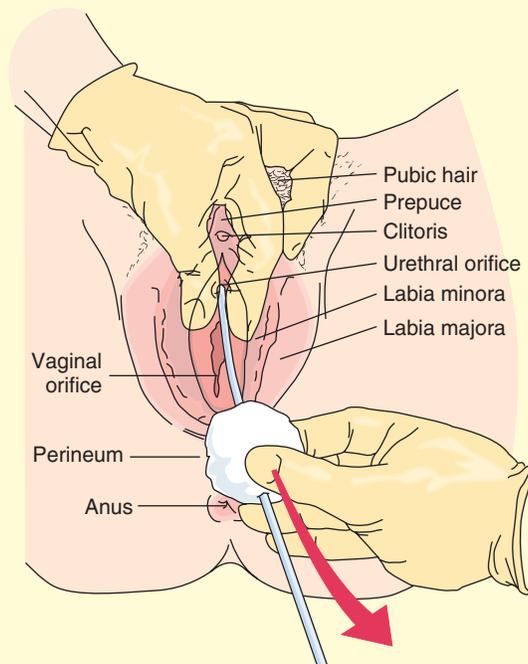
STEP	RATIONALE
ASSESSMENT	
1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
2. Perform hand hygiene and apply gloves (**NOTE:** This assessment can be completed just prior to cleansing). Assess urethral meatus and surrounding tissues for inflammation, swelling, secretions, and tissue trauma. Assess catheter for presence of debris or crusting. Remove gloves and perform hand hygiene.	Redness, swelling, and inflammation may indicate that there is urine leakage around catheter. Tissue trauma, especially near the meatus, indicates trauma from catheter pulling and rubbing. Debris or crusting on catheter indicates need for more frequent catheter hygiene.
3. Assess urine for color, clarity, and odor.	Cloudy and foul-smelling urine may indicate infection.
4. Assess for presence of fever, chills, burning, flank pain, back pain, blood in urine, lower abdominal pain, change in mental status and/or lethargy (Gupta et al., 2011; Hooton et al., 2010).	Signs and symptoms indicate catheter-associated urinary tract infection (CAUTI):
5. Assess patient's knowledge of and experience with catheter care.	Patients who perform their own catheter care may be uncomfortable or unsure of touching catheter. Assesses patient's ability and knowledge to provide instruction as needed.
PLANNING	
1. Explain procedure to patient. Offer patient opportunity to perform self-care.	Reduces anxiety and promotes cooperation.
2. Gather supplies.	Ensures organized procedure.
IMPLEMENTATION	
1. Perform hand hygiene and apply clean gloves.	Reduces transmission of microorganisms.
2. Provide privacy by closing curtains around bed and closing door.	Reduces embarrassment for patient.
3. Position patient:	Ensures easy access and visualization of perineal tissues.
a. **Female**	
(1) Dorsal recumbent position	
b. **Male**	
(1) Supine or Fowler's position	
4. Place waterproof pad under patient.	Protects bed linens from soiling.
5. Drape bath blanket on patient so only perineal area is exposed.	Prevents unnecessary exposure of body parts.
6. Provide perineal care (see Chapter 40). Dispose of gloves and perform hand hygiene.	Cleans area surrounding catheter of secretions, soiling.
7. Apply clean gloves.	Reduces transmission of microorganisms.
8. Remove catheter tubing from securing device.	Allows access of tubing for cleansing.

STEP	RATIONALE
9. With nondominant hand: **a. Female** **(1)** Gently retract labia to fully expose urethral meatus and catheter; maintain position of hand throughout procedure.	Provides full visualization of urethral meatus. Full retraction of labia prevents contamination of meatus during cleaning.
b. Male **(1)** Retract foreskin if not circumcised and hold penis at shaft just below glans; maintain position throughout procedure.	Retraction of foreskin provides full visualization of urethral meatus.
c. Grasp catheter with two fingers to stabilize it near meatus.	Secures catheter during cleaning.
10. Using clean washcloth, soap, and water, with your dominant hand wipe in a circular motion along length of catheter for about 10 cm (4 inches), starting at meatus and moving away (see illustration). Avoid placing tension on or pulling on exposed catheter tubing. Make sure to remove all traces of soap. If applicable, return the foreskin to down position.	Reduces presence of secretions, drainage, and bacteria on exterior of catheter surface. Formation of biofilms by urinary pathogens is common on the surfaces of catheters and collecting systems (CDC, 2015).

CLINICAL DECISION: *Some hospitals use antiseptic cloths or pads containing chlorhexidine to wipe off catheter tubing. Check agency policy.*

11. Reapply catheter securement device at area of catheter bifurcation (see manufacturer instructions). Catheter should not slide, and there should be some slack in it.	Catheter movement and traction (pulling) increases risk for local trauma to urethra, urinary meatus, and bladder (Cipa-Tatum and Kelly-Signs, 2011; Geng et al., 2012; Gould et al., 2009). In long-term catheter use, catheter traction can lead to formation of pressure ulcer in urinary meatus (Rassin and Markovski, 2013).
12. Place patient in safe, comfortable position.	Promotes comfort.
13. Dispose of contaminated supplies, remove gloves, and perform hand hygiene.	Prevents spread of infection.

EVALUATION

1. Check drainage tubing and bag to ensure that drainage bag is positioned below level of bladder and that there are no kinks in drainage tubing.	Prevents CAUTI (Cipa-Tatum and Kelly-Signs, 2011).
2. Use **Teach Back** to determine patient's understanding about peri-care. State, "We talked about the importance of preventing infection while you have a catheter. Can you tell me ways we try to prevent you from getting a urine infection?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly	Evaluates what the patient is able to explain or demonstrate.


STEP 10 Cleaning catheter during catheter care. (From Sorrentino S: *Mosby's textbook for nursing assistants*, St Louis, 2007, Mosby.)

SKILL 46-3	INDWELLING CATHETER CARE—cont'd

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Urethral discharge or perineal irritation is present.
- Observe for leaking from around catheter; catheter may need replacing.
- Increase frequency of indwelling catheter care.
- Notify health care provider.

2. Catheter is dislodged accidentally.
- Notify health care provider.
- Assess for urethral trauma.
- Monitor urine output.

RECORDING AND REPORTING

- Report and record presence and characteristics of drainage, condition of perineal tissue, and any discomfort reported by patient.
- If infection is suspected, report findings to health care provider.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- If patient is discharged with indwelling catheter, teach patient and family catheter care and signs and symptoms to report to nurse or health care provider.

SKILL 46-4	CLOSED CATHETER IRRIGATION

DELEGATION CONSIDERATIONS

The skill of catheter irrigation or instillation cannot be delegated to nursing assistive personnel (NAP). Direct the NAP to:
- Report patient complaints of abdominal pain or discomfort, fever, chills, and leakage of urine around catheter.
- Report presence of blood clots or change in color of urine.
- Monitor and record intake and output (I&O); immediately report any decrease or absence of urinary output.

EQUIPMENT

Closed Intermittent Irrigation
- Antiseptic swabs
- Sterile irrigation solution at room temperature as prescribed
- Sterile container
- Syringe to access system: Luer-Lok syringe without needle for needleless access port (per manufacturer directions)
- Screw clamp or rubber band (used to temporarily occlude catheter as irrigant is instilled)

Closed Continuous Irrigation
- Antiseptic swabs
- Sterile irrigation solution at room temperature (as prescribed)
- Irrigation tubing with clamp to regulate irrigation flow rate
- Y connector (optional) to connect irrigation tubing to double-lumen catheter
- Intravenous (IV) pole (closed continuous or intermittent)

STEP	RATIONALE

ASSESSMENT

1. Review patient's record to determine:

a. Purpose of bladder irrigation. Confer with health care provider as needed.	Allows you to anticipate observations to make (e.g., blood or mucus in urine).

> **CLINICAL DECISION:** *It is recommended to avoid catheter irrigation in these situations: Do not perform continuous irrigation of the bladder with antimicrobials as a routine infection prevention measure. If continuous irrigation is being used to prevent obstruction, maintain a closed system (Lo et al., 2014).*

b. Prescriber's order for method (continuous or intermittent), type and amount of irrigant (e.g., saline, medicated solutions).	Health care provider's order is required to initiate therapy. Frequency and volume of solution used for irrigation may be in the order or standardized as part of agency policy. Each type of irrigation requires different equipment. Procedure (frequency, dosage, and duration of time dwelling in bladder) for instilling medications into bladder are specific to medication.
c. Type of catheter used (see Figure 46-10).	Triple-lumen catheters are used for both intermittent and continuous closed irrigation. Double-lumen catheters can only be used for intermittent irrigation.
2. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).

STEP	RATIONALE
3. Assess patient:	
a. Perform hand hygiene and apply gloves.	Reduces transmission of microorganisms.
b. Inspect urine for color, amount, and clarity and presence of mucus, blood clots, or sediment.	Indicates if patient is bleeding or sloughing tissue, which would require increased irrigation rate or frequency of catheter irrigation.
c. Palpate bladder for distention and tenderness.	Bladder distention and tenderness may indicate that urine is not draining freely from bladder. Make sure there is free flow of urine through catheter drainage tubing (e.g., tubing kinked, occlusion with mucus or blood clots).
d. Observe patient for abdominal pain, spasms, sensation of bladder fullness or catheter bypassing (leaking).	May indicate overdistention of bladder caused by blockage of catheter. Offers baseline to determine if therapy is successful.
4. Review input and I&O record.	If continuous bladder irrigation (CBI) is being used, amount of fluid draining from bladder should exceed amount of fluid infused into bladder. If output does not exceed irrigant infused, catheter obstruction (i.e., blood clots, kinked tubing) should be suspected, irrigation stopped, and prescriber notified.
5. Remove gloves and perform hand hygiene.	Reduces transmission of microorganisms.
6. Assess patient's knowledge and experience regarding purpose of performing catheter irrigations.	Reveals extent of patient instruction needed.

PLANNING

1. Gather supplies needed for catheter irrigation.	Type of irrigation indicates supplies needed to take into patient's room.
2. Explain procedure to patient.	Reduces anxiety and promotes cooperation.

IMPLEMENTATION

1. Perform hand hygiene and apply clean gloves.	Reduces transmission of microorganisms.
2. Provide privacy by closing room door and bed curtains.	Protects patient confidentiality.
3. Raise bed to appropriate working height. If side rails are raised, lower side rail on working side.	Promotes use of good body mechanics and patient safety.
4. Position patient in dorsal recumbent or supine position and expose catheter junctions (catheter and drainage tubing).	Position provides access to catheter and promotes patient dignity as much as possible.
5. Remove catheter securement device.	Eases access to catheter irrigation ports.
6. Organize supplies according to type of irrigation prescribed.	Ensures easy access to supplies during procedure.
7. Closed intermittent irrigation or instillation with double-lumen catheter:	

> **CLINICAL DECISION:** *Closed intermittent irrigation should be done only in cases in which catheter is occluded and health care provider deems that removal of catheter can injure patient.*

a. Draw up in syringe prescribed amount of medication or sterile solution. Place sterile cap on tip of needleless syringe.	Ensures that irrigation or instillation fluid remains sterile.
b. Clamp indwelling retention catheter just below specimen port.	Occlusion of catheter ensures that irrigation solution goes into bladder not down into drainage tubing.

> **CLINICAL DECISION:** *Avoid irrigating with or instilling cold solution because it results in bladder spasm and discomfort.*

c. Using circular motion, thoroughly clean injection port with antiseptic swab (same port used for specimen collection). Allow to dry.	Reduces transmission of infection. Drying achieves full antimicrobial properties.
d. Insert tip of needleless syringe with twisting motion into irrigation port (see manufacturer instructions for possible variation).	Ensures that hub enters lumen of catheter and flow is directed into bladder.
e. Slowly and evenly inject fluid into catheter and bladder.	Slow injection minimizes potential trauma to bladder mucosa.

> **CLINICAL DECISION:** *If catheter does not irrigate easily, stop the irrigation. The catheter may be totally occluded, or the end of the catheter may have been displaced into the urethra. Contact the prescriber; the catheter may need to be removed and replaced.*

f. Withdraw syringe, cleanse port with antiseptic swab, remove clamp, and allow solution to drain into drainage bag. Some medicated irrigants may need to dwell in bladder for a prescribed period of time, requiring catheter to be clamped temporarily.	Allows drainage by gravity. Some irrigation solutions require time in catheter and bladder to exert therapeutic effect. Clamped catheters should not be left unattended.

SKILL 46-4	**CLOSED CATHETER IRRIGATION—cont'd**

STEP	RATIONALE

8. Closed continuous irrigation (see illustration).

   a. Close clamp on tubing and hang bag of solution on intravenous (IV) pole. Insert (spike) tip of sterile irrigation tubing into designated port of irrigation solution bag using aseptic technique.

   Closing clamp on tubing allows tubing drip chamber to fill after tip of tubing is inserted into port of irrigation solution bag.

   b. Fill drip chamber half full by squeezing chamber; then open clamp and allow solution to flow (prime) through tubing, keeping end of tubing sterile. Once fluid has completely filled tubing, close clamp and recap end of tubing.

   Priming tubing with fluid prevents introduction of air into bladder.

   c. Use aseptic technique to wipe off irrigation port of triple-lumen catheter and attach to irrigation tubing.

   Third lumen provides means for irrigation solution to enter bladder.

   d. Be sure that drainage bag and tubing are securely connected to drainage port of triple-lumen catheter.

   Ensures that urine and irrigation solution drain from bladder without leaking.

   e. Calculate drip rate and adjust rate at roller clamp. If urine is bright red or has clots, increase irrigation rate until drainage appears pink (according to ordered rate or agency protocol).

   Continuous drainage is expected. It helps with prevention of clotting in presence of active bleeding in bladder and flushes blood clots out of bladder.

   f. Observe for outflow of fluid into drainage bag. Empty catheter drainage bag as needed.

   Discomfort, bladder distention, and possibly injury can occur from overdistention of bladder when bladder irrigant cannot adequately flow from bladder. Bag will fill rapidly and may need to be emptied every 1 to 2 hours.

   g. Compare urine output with infusion of irrigation solution every hour.

   Determines urinary output and ensures that irrigant is draining freely.

9. When procedure is completed, dispose of contaminated supplies in appropriate receptacle, replace catheter securement device if removed, remove gloves, help patient to safe and comfortable position with bed in low position, and perform hand hygiene.

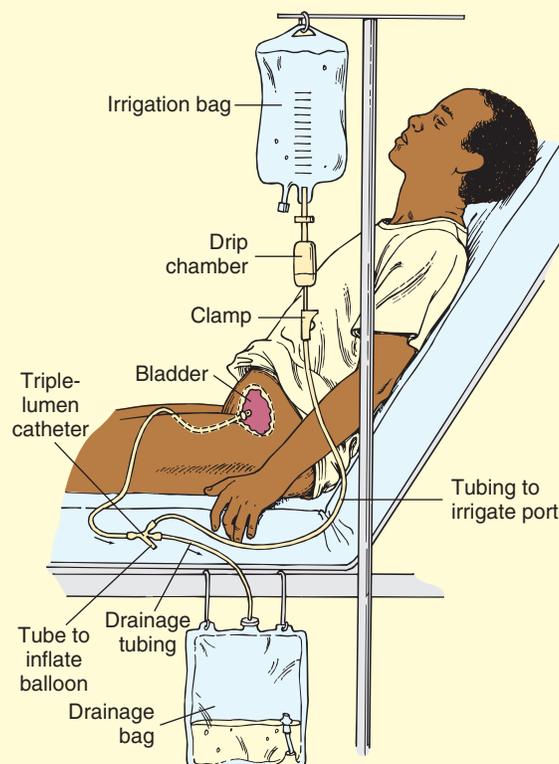
   Promotes patient comfort and safety and reduces transmission of microorganisms.

EVALUATION

1. Measure actual urine output by subtracting total amount of irrigation fluid infused from total volume drained.

   Determines accurate urinary output.

2. Review I&O flow sheet to verify that hourly output into drainage bag is in appropriate proportion to irrigating solution entering bladder. Expect more output than fluid instilled because of urine production.

   Determines urinary output in relation to irrigation.


STEP 8 Closed continuous bladder irrigation.

STEP	RATIONALE
3. Observe for catheter patency, inspect urine for blood clots and sediment, and ensure that tubing is not kinked or occluded.	Decrease in blood clots means that therapy is successful in maintaining catheter patency. Ensures that bladder is emptying freely.
4. Assess patient comfort.	An indicator of catheter patency by absence of symptoms of bladder distention.
5. Assess for signs and symptoms of infection.	Evaluates for presence of infection.
6. Use **Teach Back** to determine patient's understanding about irrigation. State, "I want to go over the reason we discussed about why we are irrigating your urinary catheter. Can you tell me the reason we need to irrigate it?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what the patient is able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Irrigating solution does not return (intermittent irrigation); drainage is less than amount of irrigation solution infused or is not flowing at prescribed rate (CBI).
   - Examine tubing for clots, sediment, and kinks.
   - Inspect urine for presence of or increase in blood clots and sediment.
   - Evaluate patient for pain and distended bladder.
   - Notify health care provider if irrigant does not flow freely from the bladder, patient complains of pain, or bladder distention occurs.
2. Bright-red bleeding with irrigation (CBI) drip is wide open.
   - Assess for hypovolemic shock (vital signs, skin color and moisture, anxiety level).
   - Leave irrigation drip wide open and notify health care provider.
3. Patient experiences pain with irrigation.
   - Examine drainage tubing for clots, sediment, or kinks.
   - Evaluate urine for presence of or increase in blood clots and sediment.
   - Evaluate for distended bladder.
   - Notify health care provider.

RECORDING AND REPORTING

- Record irrigation method, amount of and type of irrigation solution, amount returned as drainage, characteristics of output, and urine output.
- Report catheter occlusion, sudden bleeding, infection, or increased pain.
- Record I&O.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- Patients and/or family caregivers can be taught to perform catheter irrigations with adequate support, demonstration/return demonstration, and written instructions.
- Teach patients and/or family caregivers to observe urine color, clarity, odor, and amount.
- Arrange for home delivery and storage of catheter/irrigation supplies.
- Teach patients and/or family caregivers signs of catheter obstruction or urinary tract infection.

KEY POINTS

- Micturition involves complex interactions between the central nervous system, bladder, and urinary sphincter.
- Common urinary tract symptoms include urgency, dysuria, frequency, hesitancy, polyuria, oliguria, nocturia, dribbling, hematuria, and urinary retention.
- Nursing care for patients with urinary dysfunction needs to take into account multiple factors that affect urinary function such as fluid intake, medications, functional ability, environment, medical problems outside the urinary tract, and dysfunction within the urinary tract.
- The most common size for an indwelling catheter in adults is 14-16 Fr and a 10-mL balloon.
- The presence or recent history of an indwelling catheter increases risk for a UTI.
- Prevention of catheter associated urinary tract infection (CAUTI) requires use of an evidence based "bundle" to perform all elements of care at one time.
- To minimize the risk for infection when caring for a patient with a closed bladder drainage system, nursing care must include careful attention to aseptic technique.
- Planning care for an incontinent patient requires selecting interventions specific to the type of incontinence.
- A key intervention when caring for an incontinent patient is to ensure regular toilet access.

CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

Mrs. Grayson is a 75-year-old woman who has had problems with urge incontinence for the past 2 years. She has not spoken to anyone about her problems because she is embarrassed. She finally confides to her health care practitioner that the problem is causing her to avoid social situations and she would like help to regain urinary control. Mrs. Grayson has type 2 diabetes and is obese. She has been referred to a continence specialist. A plan of care was developed after a thorough assessment of her urinary pattern and symptoms.

1. She has recently begun pelvic muscle exercises (Kegel) and bladder retraining. She shares her concern that the exercises are not working and that she is still wet multiple times a day. Which additional teaching does Mrs. Grayson need?
2. Two months after your first encounter with Mrs. Grayson, she has been seen by her primary health care provider for burning on urination associated with increased incontinence, frequency, and urgency. She was treated with an antibiotic. Which health teaching does Mrs. Grayson need now?
3. Mrs. Grayson is seen in the emergency department for a fever, hematuria, and elevated postvoid residual (PVR). She is treated for a urinary tract infection (UTI). Which ongoing assessment is needed?

ⓔ *Answers to Clinical Application Questions can be found on the Evolve website.*

▉ REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. A patient is scheduled to have an intravenous pyelogram (IVP) the next morning. Which nursing measures should be implemented before the test? (Select all that apply.)
   1. Ask the patient about any allergies and reactions.
   2. Instruct the patient that a full bladder is required for the test.
   3. Instruct the patient to save all urine in a special container.
   4. Ensure that informed consent has been obtained.
   5. Explain that the test includes instrumentation of the urinary tract.
2. When assessing a patient's first voided urine of the day, which finding should be reported to the health care provider?
   1. Pale yellow urine
   2. Slightly cloudy urine
   3. Light pink urine
   4. Dark amber urine
3. What is a critical step when inserting an indwelling catheter into a male patient?
   1. Slowly inflate the catheter balloon with sterile saline.
   2. Secure the catheter drainage tubing to the bed sheets.
   3. Advance the catheter to the bifurcation of the drainage and balloon ports.
   4. Advance the catheter until urine flows, then insert ¼ inch more.
4. Which nursing intervention minimizes the risk for trauma and infection when applying an external/condom catheter?
   1. Leaving a gap of 3 to 5 inches between the tip of the penis and drainage tube
   2. Shaving the pubic area so hair does not adhere
   3. Washing with soap and water before applying the condom-type catheter
   4. Applying tape to the condom sheath to keep it securely in place
5. Which instructions should the nurse give the nursing assistive personnel (NAP) concerning a patient who has had an indwelling urinary catheter removed that day?
   1. Limit oral fluid intake to avoid possible urinary incontinence.
   2. Expect patient complaints of suprapubic fullness and discomfort.
   3. Report the time and amount of first voiding.
   4. Instruct patient to stay in bed and use a urinal or bedpan.
6. A postoperative patient with a three-way indwelling urinary catheter and continuous bladder irrigation (CBI) complains of lower abdominal pain and distention. What should be the nurse's *initial* intervention?
   1. Increase the rate of the CBI
   2. Assess the intake and output from system
   3. Decrease the rate of the CBI
   4. Assess vital signs
7. An ambulatory elderly woman with dementia is incontinent of urine. She has poor short-term memory and has not been seen toileting independently. What is the *best* nursing intervention for this patient?
   1. Recommend that she be evaluated for an overactive bladder (OAB) medication
   2. Start a scheduled toileting program
   3. Recommend that she be evaluated for an indwelling catheter
   4. Start a bladder-retraining program
8. What should the nurse teach a young woman with a history of urinary tract infections (UTIs) about UTI prevention? (Select all that apply.)
   1. Keep the bowels regular.
   2. Limit water intake to 1 to 2 glasses a day.
   3. Wear cotton underwear.
   4. Cleanse the perineum from front to back.
   5. Practice pelvic muscle exercise (Kegel) daily.
9. Which nursing assessment question would *best* indicate that an incontinent man with a history of prostate enlargement might not be emptying his bladder adequately?
   1. Do you leak urine when you cough or sneeze?
   2. Do you need help getting to the toilet?
   3. Do you dribble urine constantly?
   4. Does it burn when you pass your urine?
10. Place the following steps for insertion of an indwelling catheter in a female patient in appropriate order.
    1. Insert and advance catheter.
    2. Lubricate catheter.
    3. Inflate catheter balloon.
    4. Cleanse urethral meatus with antiseptic solution.
    5. Drape patient with the sterile square and fenestrated drapes.
    6. When urine appears, advance another 2.5 to 5 cm.
    7. Prepare sterile field and supplies.
    8. Gently pull catheter until resistance is felt.
    9. Attach drainage tubing.
11. The nursing assistive personnel (NAP) reports to the nurse that a patient's catheter drainage bag has been empty for 4 hours. What is a priority nursing intervention?
    1. Implement the "as-needed" order to irrigate the catheter
    2. Assess the catheter and drainage tubing for obvious occlusion
    3. Notify the health care provider immediately
    4. Assess the vital signs and intake and output record
12. Which nursing interventions should a nurse implement when removing an indwelling urinary catheter in an adult patient? (Select all that apply.)
    1. Attach a 3-mL syringe to the inflation port
    2. Allow the balloon to drain into the syringe by gravity
    3. Initiate a voiding record/bladder diary
    4. Pull the catheter quickly
    5. Clamp the catheter before removal
13. What best describes measurement of postvoid residual (PVR)?
    1. Bladder scan the patient immediately after voiding.
    2. Catheterize the patient 30 minutes after voiding.
    3. Bladder scan the patient when he or she reports a strong urge to void.
    4. Catheterize the patient with a 16 Fr/10 mL catheter.

14. Which nursing intervention decreases the risk for catheter-associated urinary tract infection (CAUTI)?
1. Cleansing the urinary meatus 3 to 4 times daily with antiseptic solution
2. Hanging the urinary drainage bag below the level of the bladder
3. Emptying the urinary drainage bag daily
4. Irrigating the urinary catheter with sterile water

15. There is no urine when a catheter is inserted 3 inches into a female's urethra. What should the nurse do next?

1. Remove the catheter and start all over with a new kit and catheter
2. Leave the catheter there and start over with a new catheter
3. Pull the catheter back and reinsert at a different angle
4. Ask the patient to bear down and insert the catheter further

Answers: 1. 1; 4; **2.** 3; 3; **3.** 4; 3; **5.** 5; **6.** 2; 7. 2; **8.** 1, 3, 4; **9.** 3; **10.** 5, 7, 2, 4, 1, 6, 3, 8, 9; **11.** 2; **12.** 2, 3; **13.** 1; **14.** 2; **15.** 2.

Bowel Elimination

Regular elimination of bowel waste products is essential for normal body functioning. Alterations in bowel elimination are often early signs or symptoms of problems within either the gastrointestinal (GI) tract or other body systems. Because bowel function depends on the balance of several factors, elimination patterns and habits vary among individuals.

Understanding normal bowel elimination and factors that promote, impede, or cause alterations in elimination help a nurse manage patients' elimination problems. Supportive nursing care respects a patient's privacy and emotional needs. Measures designed to promote normal elimination also need to minimize a patient's discomfort and embarrassment.

SCIENTIFIC KNOWLEDGE BASE

The GI tract is a series of hollow mucous membrane–lined muscular organs. These organs absorb fluid and nutrients, prepare food for absorption and use by body cells, and provide for temporary storage of feces (Figure 47-1). The GI tract absorbs high volumes of fluids, making fluid and electrolyte balance a key function of the GI system.

In addition to ingested fluids and foods, the GI tract also receives secretions from the gallbladder and pancreas.

Mouth

The mouth mechanically and chemically breaks down nutrients into usable size and form. The teeth chew food, breaking it down into a size suitable for swallowing. Saliva, produced by the salivary glands in the mouth, dilutes and softens the food in the mouth for easier swallowing.

Esophagus

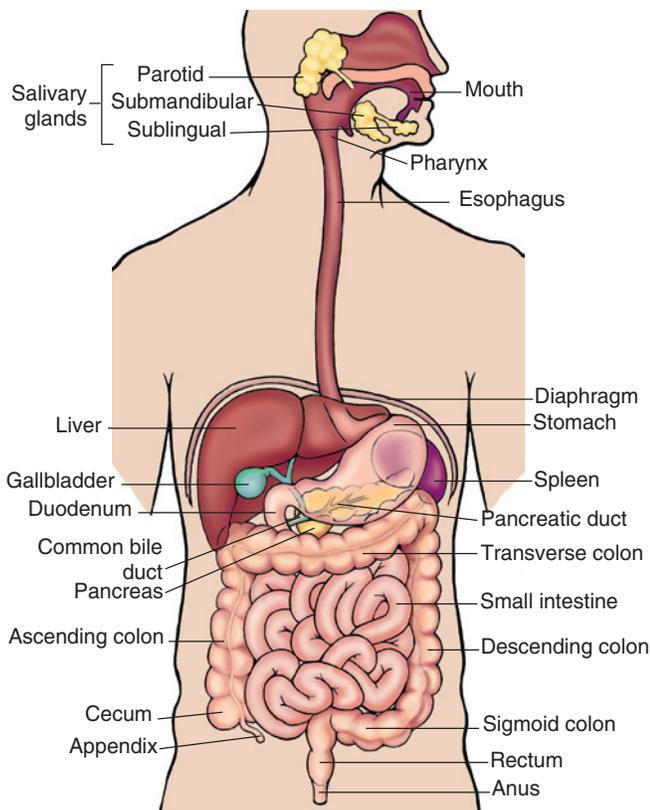
As food enters the upper esophagus, it passes through the upper esophageal sphincter, a circular muscle that prevents air from entering the esophagus and food from refluxing into the throat. The bolus of food travels down the esophagus with the aid of **peristalsis,** which is a contraction that propels food through the length of the GI tract. The food moves down the esophagus and reaches the cardiac sphincter, which lies between the esophagus and the upper end of the stomach. The sphincter prevents reflux of stomach contents back into the esophagus.


FIGURE 47-1 Organs of gastrointestinal tract. (From Monahan FD, Neighbors M: *Medical-surgical nursing,* ed 2, Philadelphia, 1998, Saunders.)

Stomach

The stomach performs three tasks: storage of swallowed food and liquid; mixing of food with digestive juices into a substance called chyme; and regulated emptying of its contents into the small intestine. The stomach produces and secretes hydrochloric acid (HCl), mucus, the enzyme pepsin, and intrinsic factor. Pepsin and HCl help to digest protein. Mucus protects the stomach mucosa from acidity and enzyme activity. Intrinsic factor is essential in the absorption of vitamin B_{12}.

Small Intestine

Movement within the small intestine, occurring by peristalsis, facilitates both digestion and absorption. Chyme comes into the small intestine as a liquid material and mixes with digestive enzymes. Resorption in the small intestine is so efficient that, by the time the fluid reaches the end of the small intestine, it is a thick liquid with semisolid particles in consistency. The small intestine is divided into three sections: the duodenum, the jejunum, and the ileum.

The duodenum is approximately 20 to 28 cm (8 to 11 inches) long and continues to process fluid from the stomach. The second section, the jejunum, is approximately 2.5 m (8 feet) long and absorbs carbohydrates and proteins. The ileum is approximately 3.7 m (12 feet) long and absorbs water, fats, and bile salts. The duodenum and jejunum absorb most nutrients and electrolytes in the small intestine. The ileum absorbs certain vitamins, iron, and bile salts. Digestive enzymes and bile enter into the small intestine from the pancreas and the liver to further break down nutrients into a form usable by the body.

The digestive process is greatly altered when small intestine function is impaired. Conditions such as inflammation, infection, surgical resection, or obstruction disrupt peristalsis, reduce absorption, or block the passage of fluid, resulting in electrolyte and nutrient deficiencies.

Large Intestine

The lower GI tract is called *the large intestine* or *colon* because it is larger in diameter than the small intestine. However, its length, 1.5 to 1.8 m (5 to 6 feet), is much shorter. The large intestine is divided into the cecum, ascending colon, transverse colon, descending colon, sigmoid colon, and rectum. The large intestine is the primary organ of bowel elimination.

Digestive fluid enters the large intestine by waves of peristalsis through the ileocecal valve (i.e., a circular muscle layer that prevents regurgitation back into the small intestine). The muscular tissue of the colon allows it to accommodate and eliminate large quantities of waste and gas (flatus). The colon has three functions: absorption, secretion, and elimination. The colon resorbs a large volume of water (up to 1.5 L) and significant amounts of sodium and chloride daily. The amount of water absorbed depends on the speed at which colonic contents move. Normally the fecal matter becomes a soft, formed solid or semisolid mass. If peristalsis is abnormally fast, there is less time for water to be absorbed, and the stool will be watery. If peristaltic contractions slow down, water continues to be absorbed, and a hard mass of stool forms, resulting in constipation.

Peristaltic contractions move contents through the colon. Intestinal content is the main stimulus for contraction. Mass peristalsis pushes undigested food toward the rectum. These mass movements occur only 3 or 4 times daily, with the strongest during the hour after mealtime.

The rectum is the final part of the large intestine. Normally the rectum is empty of fecal matter until just before defecation. It contains vertical and transverse folds of tissue that help to control expulsion of fecal contents during defecation. Each fold contains veins that can become distended from pressure during straining. This distention results in hemorrhoid formation.

Anus

The body expels feces and flatus from the rectum through the anus. Contraction and relaxation of the internal and external sphincters, which are innervated by sympathetic and parasympathetic nerves, aid in the control of defecation. The anal canal contains a rich supply of sensory nerves that allow people to tell when there is solid, liquid, or gas that needs to be expelled and aids in maintaining continence.

Defecation

The physiological factors essential to bowel function and defecation include normal GI tract function, sensory awareness of rectal distention and rectal contents, voluntary sphincter control, and adequate rectal capacity and compliance. Normal defecation begins with movement in the left colon, moving stool toward the anus. When stool reaches the rectum, the distention causes relaxation of the internal sphincter and an awareness of the need to defecate. At the time of defecation, the external sphincter relaxes, and abdominal muscles contract, increasing intrarectal pressure and forcing the stool out. Normally defecation is painless, resulting in passage of soft, formed stool. Straining while having a bowel movement indicates that the patient may need changes in diet or fluid intake or that there is an underlying disorder in GI function.

NURSING KNOWLEDGE BASE

Factors Influencing Bowel Elimination

Many factors influence the process of bowel elimination. Knowledge of these factors helps to anticipate measures required to maintain a normal elimination pattern.

Age. Infants have a smaller stomach capacity, less secretion of digestive enzymes, and more rapid intestinal peristalsis. The ability to control defecation does not occur until 2 to 3 years of age. Adolescents experience rapid growth and increased metabolic rate. There is also rapid growth of the large intestine and increased secretion of gastric acids to digest food fibers and act as a bactericide against swallowed organisms. Older adults may have decreased chewing ability. Partially chewed food is not digested as easily. Peristalsis declines, and esophageal emptying slows. This impairs absorption by the intestinal mucosa. Muscle tone in the perineal floor and anal sphincter weakens, which sometimes causes difficulty in controlling defecation (Constipation, n.d.).

Diet. Regular daily food intake helps maintain a regular pattern of peristalsis in the colon. Fiber in the diet provides the bulk in the fecal material. Bulk-forming foods such as whole grains, fresh fruits, and vegetables help remove the fats and waste products from the body with more efficiency. Some of these foods such as cabbage, broccoli, or beans may also produce gas, which distends the intestinal walls and increases colonic motility. The bowel walls stretch, creating peristalsis and initiating the defecation reflex.

Fluid Intake. Although individual fluid needs vary with the person, a fluid intake of 3L per day for men and 2.2 L per day for women is recommended (Mayo Clinic, 2014). Some fluid needs are met by drinking fluids, but there is also fluid in foods that are ingested such as fruits. An inadequate fluid intake or disturbances resulting in fluid loss (such as vomiting) affect the character of feces. Fluid liquefies intestinal contents by absorbing into the fiber from the diet and creating a larger, softer stool mass. This increases peristalsis and promotes movement of stool through the colon. Reduced fluid and fiber intake slows passage of food through the intestine and results in hardening of stool contents, causing constipation.

Physical Activity. Physical activity promotes peristalsis, whereas immobilization depresses it. Encourage early ambulation as illness begins to resolve or as soon as possible after surgery to promote maintenance of peristalsis and normal elimination. Maintaining tone of skeletal muscles used during defecation is important. Weakened abdominal and pelvic floor muscles impair the ability to increase intraabdominal pressure and control the external sphincter. Muscle tone is sometimes weakened or lost as a result of long-term illness, spinal cord injury, or neurological diseases that impair nerve transmission. As a result of these changes in the abdominal and pelvic floor muscles, there is an increased risk for constipation.

Psychological Factors. Prolonged emotional stress impairs the function of almost all body systems (see Chapter 38). During emotional stress the digestive process is accelerated, and peristalsis is increased. Side effects of increased peristalsis include diarrhea and gaseous distention. A number of diseases of the GI tract are exacerbated by stress, including ulcerative colitis, irritable bowel syndrome, certain gastric and duodenal ulcers, and Crohn's disease. If a person becomes depressed, the autonomic nervous system may slow impulses that decrease peristalsis, resulting in constipation.

Personal Habits. Personal elimination habits influence bowel function. Most people benefit from being able to use their own toilet facilities at a time that is most effective and convenient for them. A busy work schedule sometimes prevents the individual from responding appropriately to the urge to defecate, disrupting regular habits and

causing possible alterations such as constipation. Individuals need to recognize the best time for elimination.

Position During Defecation. Squatting is the normal position during defecation. Modern toilets facilitate this posture, allowing a person to lean forward, exert intraabdominal pressure, and contract the gluteal muscles. For a patient immobilized in bed, defecation is often difficult. In a supine position it is hard to effectively contract the muscles used during defecation. If a patient's condition permits, raise the head of the bed to help him or her to a more normal sitting position on a bedpan, enhancing the ability to defecate.

Pain. Normally the act of defecation is painless. However, a number of conditions such as hemorrhoids; rectal surgery; anal fissures, which are painful linear splits in the perianal area; and abdominal surgery result in discomfort. In these instances the patient often suppresses the urge to defecate to avoid pain, contributing to the development of constipation.

Pregnancy. As pregnancy advances, the size of the fetus increases, and pressure is exerted on the rectum. A temporary obstruction created by the fetus impairs passage of feces. Slowing of peristalsis during the third trimester often leads to constipation. A pregnant woman's frequent straining during defecation or delivery may result in formation of hemorrhoids.

Surgery and Anesthesia. General anesthetic agents used during surgery cause temporary cessation of peristalsis (see Chapter 50). Inhaled anesthetic agents block parasympathetic impulses to the intestinal musculature. The action of the anesthetic slows or stops peristaltic waves. A patient who receives a local or regional anesthetic is less at risk for elimination alterations because this type of anesthesia generally affects bowel activity minimally or not at all.

Any surgery that involves direct manipulation of the bowel temporarily stops peristalsis. This condition, called an **ileus,** usually lasts about 24 to 48 hours. If a patient remains inactive or is unable to eat after surgery, return of normal bowel elimination is further delayed.

Medications. Many medications prescribed for acute and chronic conditions have secondary effects on a patient's bowel elimination patterns. For example, opioid analgesics slow peristalsis and contractions, often resulting in constipation; and antibiotics decrease intestinal bacterial flora, often resulting in diarrhea (Burchum and Rosenthal, 2016). It is important for the nurse and patient to be aware of these possible side effects and use appropriate measures to promote healthy bowel elimination. Some medications are used primarily for their action on the bowel and will promote defecation such as **laxatives** or **cathartics** or control diarrhea. If laxatives are needed for regular evacuation of the rectum, a fiber laxative is the first type used. If this is not sufficient to relieve constipation, the next one tried should be an osmotic laxative. Patients need to avoid regular use of a stimulant laxative because the intestine often becomes dependent on it.

Diagnostic Tests. Diagnostic examinations involving visualization of GI structures often require a prescribed bowel preparation (e.g., laxatives and/or **enemas**) to ensure that the bowel is empty. Usually patients cannot eat or drink several hours before examinations such as an endoscopy, colonoscopy, or other testing that requires visualization of the GI tract. Following the diagnostic procedure, changes in elimination such as increased gas or loose stools often occur until the patient resumes a normal eating pattern.

Common Bowel Elimination Problems

You will frequently care for patients who have or are at risk for elimination problems because of physiological changes in the GI tract such as abdominal surgery, inflammatory diseases, medications, emotional stress, environmental factors, or disorders impairing defecation is common in the practice of nursing.

Constipation.   Constipation is a symptom, not a disease, and there are many possible causes (Box 47-1). Improper diet, reduced fluid intake, lack of exercise, and certain medications can cause constipation. For example, patients receiving opiates for pain after surgery often require a stool softener or laxative to prevent constipation. A recent integrative review of the literature revealed that female gender and older age were the highest risk factors for constipation (Schmidt and Santos, 2014). Signs of constipation include infrequent bowel movements (less than three per week) and hard, dry stools that are difficult to pass (Constipation, n.d.). When intestinal motility slows, the fecal mass becomes exposed to the intestinal walls over time, and most of the fecal water content is absorbed. Little water is left to soften and lubricate the stool. Passage of a dry, hard stool often causes rectal pain. Constipation is a significant source of discomfort. Assess the need for intervention before defecation becomes painful or the stool is impacted.

Impaction.   Fecal **impaction** results when a patient has unrelieved constipation and is unable to expel the hardened feces retained in the rectum. In cases of severe impaction the mass extends up into the sigmoid colon. If not resolved or removed, severe impaction results in intestinal obstruction. Patients who are debilitated, confused, or unconscious are most at risk for impaction. They are dehydrated or too weak or unaware of the need to defecate, and the stool becomes too hard and dry to pass.

An obvious sign of impaction is the inability to pass a stool for several days, despite the repeated urge to defecate. Suspect an impaction when a continuous oozing of liquid stool occurs. The liquid part of feces located higher in the colon seeps around the impacted mass. Loss of appetite (anorexia), nausea and/or vomiting, abdominal distention and cramping, and rectal pain may accompany the condition. If you suspect an impaction, gently perform a digital examination of the rectum and palpate for the impacted mass (Hussain et al., 2014).

Diarrhea.   **Diarrhea** is an increase in the number of stools and the passage of liquid, unformed feces. It is associated with disorders affecting digestion, absorption, and secretion in the GI tract. Intestinal contents pass through the small and large intestine too quickly to allow for the usual absorption of fluid and nutrients. Irritation within the colon results in increased mucus secretion. As a result, feces become watery, and the patient often has difficulty controlling the urge to defecate.

Excess loss of colonic fluid results in dehydration (Box 47-2) with fluid and electrolyte or acid-base imbalances if the fluid is not replaced. Infants and older adults are particularly susceptible to associated complications (see Chapter 42). Because repeated passage of diarrhea stools exposes the skin of the perineum and buttocks to irritating intestinal contents, meticulous skin care and containment of fecal drainage is necessary to prevent skin breakdown (see Chapter 48).

Incontinence.   Fecal **incontinence** is the inability to control passage of feces and gas from the anus. Incontinence harms a patient's body image (see Chapter 34). The embarrassment of soiling clothes often leads to social isolation. Physical conditions that impair anal sphincter function or large-volume liquid stools cause incontinence. Impaired cognitive function often leads to incontinence of both urine and stool.

Many conditions cause fecal incontinence or diarrhea. You need to identify precipitating conditions and refer patients to health care providers for medication management. Antibiotic use alters the normal flora in the GI tract. A common causative agent of diarrhea is *Clostridium difficile* (*C. difficile*), which produces symptoms ranging from mild diarrhea to severe colitis. Patients acquire *C. difficile* infection in one of two ways: by antibiotic therapy that causes an overgrowth of *C. difficile* and by contact with the *C. difficile* organism. A newly identified strain of *C. difficile* is more virulent with more toxic effects (Grossman and Mager, 2010). Patients are exposed to the organism from a health care worker's hands or direct contact with environmental surfaces contaminated with it. Only hand hygiene with soap and water is effective to physically remove *C. difficile* spores from the hands. The most common diagnostic test for the bacteria is the enzyme-linked immunosorbent assay (ELISA) test, which detects *C. difficile* A and B in the stool. Elderly patients are especially vulnerable to *C. difficile* infection when exposed to antibiotics, and higher mortality and morbidity are observed in this age-group (Daniel and Rapose, 2015).

Communicable foodborne pathogens also cause diarrhea. Hand hygiene following the use of the bathroom, before and after preparing foods, and when cleaning and storing fresh produce and meats greatly reduces the risk of foodborne illnesses. When diarrhea results from a foodborne pathogen, the goal usually is to rid the GI system of the pathogen rather than slow peristalsis.

Surgeries or diagnostic testing of the lower GI tract may also cause diarrhea. Patients receiving enteral nutrition are also at risk for diarrhea and need a dietary consult to find the right formula for the feeding (Chapter 45). Food intolerances can increase peristalsis and cause diarrhea. Food intolerance is not an allergy; rather, a particular food causes the body distress within a few hours of ingestion. The result is diarrhea, cramps, or **flatulence**. For example, people who drink cow's milk and have these symptoms are not allergic to milk but lack the enzyme needed to digest the milk sugar lactase and therefore are lactose intolerant. Another condition called *celiac disease* is a syndrome in which a patient has a hypersensitivity to protein in certain cereal grains and gluten. Food allergies are less common but do occur, and people with these allergies need to know how to read labels on foods carefully. True food allergies may be life threatening and lead to anaphylaxis (Food Allergies, 2015).

Flatulence. As gas accumulates in the lumen of the intestines, the bowel wall stretches and distends. **Flatulence** is a common cause of abdominal fullness, pain, and cramping. Normally intestinal gas escapes through the mouth (belching) or the anus (passing of flatus). However, flatulence causes abdominal distention and severe, sharp pain if intestinal motility is reduced because of opiates, general anesthetics, abdominal surgery, or immobilization.

Hemorrhoids. Hemorrhoids are dilated, engorged veins in the lining of the rectum. They are either external or internal. External hemorrhoids are clearly visible as protrusions of skin. There is usually a purplish discoloration (thrombosis) if the underlying vein is hardened. This causes increased pain and sometimes requires excision. Internal hemorrhoids occur in the anal canal and may be inflamed and distended. Increased venous pressure from straining at defecation, pregnancy, heart failure, and chronic liver disease causes hemorrhoids.

Bowel Diversions

Certain diseases or surgical alterations make the normal passage of intestinal contents throughout the small and large intestine difficult or inadvisable. When these conditions are present, a temporary or permanent opening (**stoma**) is created surgically by bringing part of the intestine out through the abdominal wall. These surgical openings are called an **ileostomy** or **colostomy**, depending on which part of the intestinal tract is used to create the stoma (Figures 47-2 and 47-3). Newer surgical techniques allow more patients to have parts of their small and large intestine removed and the remaining parts reconnected so they will continue to defecate through the anal canal.

Ostomies. The location of an ostomy determines stool consistency. A person with a sigmoid colostomy will have a more formed stool. The output from a transverse colostomy will be thick liquid to soft consistency. These ostomies are the easiest to perform surgically and are done as a temporary means to divert stool from an area of trauma or perianal wounds. They may also be a palliative diversion if obstruction from a tumor is present. With an ileostomy the fecal effluent leaves the body before it enters the colon, creating frequent, liquid stools.

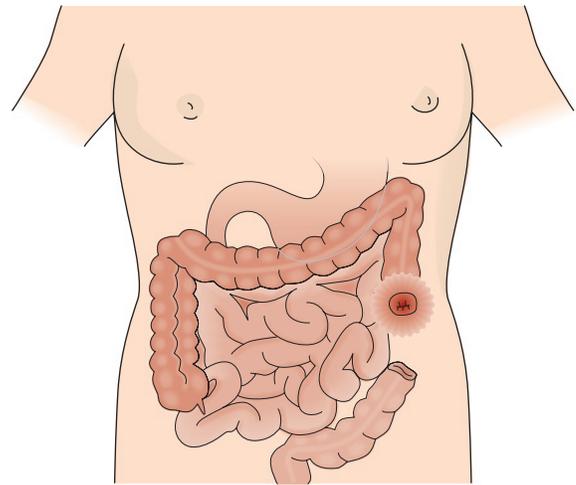
Loop colostomies are reversible stomas that a surgeon constructs in the ileum or the colon. The surgeon pulls a loop of intestine onto the abdomen and often places a plastic rod, bridge, or rubber catheter temporarily under the bowel loop to keep it from slipping back. The surgeon then opens the bowel and sutures it to the skin of the abdomen. The loop ostomy has two openings through the stoma. The proximal end drains fecal effluent, and the distal part drains mucus.


FIGURE 47-2 Sigmoid colostomy.
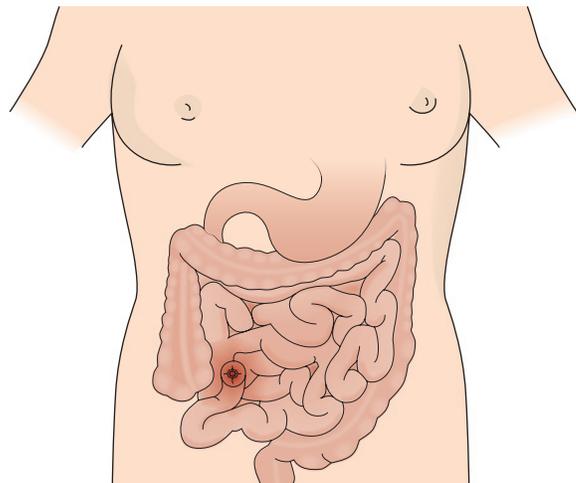

FIGURE 47-3 Ileostomy.

The end colostomy consists of a stoma formed by bringing a piece of intestine out through a surgically created opening in the abdominal wall, turning it down like a turtleneck and suturing it to the abdominal wall. The intestine distal to the stoma is either removed or sewn closed (called *Hartmann's pouch;* see Figure 47-2) and left in the abdominal cavity. End ostomies are permanent or reversible. The rectum is either left intact or removed.

Other Procedures

Ileoanal Pouch Anastomosis. The ileoanal pouch anastomosis is a surgical procedure for patients who need to have a colectomy for treatment of ulcerative colitis or familial adenopolyposis (FAP) (Goldberg et al., 2010). In this procedure the surgeon removes the colon, creates a pouch from the end of the small intestine, and attaches the pouch to the patient's anus (Figure 47-4). This pouch provides for the collection of fecal material, which simulates the function of the rectum. The patient is continent of stool because stool is evacuated via the anus. When the ileal pouch is created, the patient has a temporary ileostomy to divert the fecal stream or **effluent** and allow the suture lines in the pouch to heal.

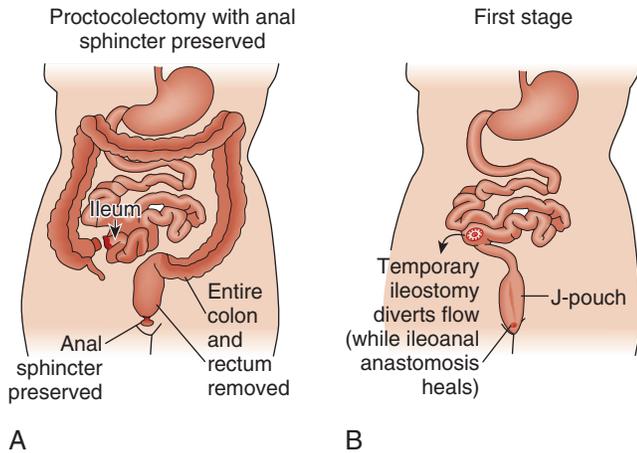
A continent ileostomy involves creating a pouch from the small intestine. The pouch has a continent stoma on the abdomen created with a valve that can be drained only when the patient places a large


FIGURE 47-4 Ileoanal pouch anastomosis.

catheter into the stoma. The patient empties the pouch several times a day. This procedure is rarely performed now.

Children with fecal soiling associated with neuropathic or structural abnormalities of the anal sphincter sometimes have an antegrade continence enema (ACE) procedure. The surgeon creates a continence valve with an opening on to the abdomen in the intestine so the patient or caregiver can insert a tube and give himself or herself an enema that comes out through the anus. Colonic evacuation begins about 10 to 20 minutes after a patient receives the enema fluid.

CRITICAL THINKING

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require you to anticipate the information necessary, analyze the data, and make decisions regarding patient care.

In the case of bowel elimination, integrate knowledge from nursing and other disciplines to understand a patient's response to bowel elimination alterations. Experience in caring for patients with elimination alterations helps you provide an appropriate plan of care. Use critical thinking attitudes such as fairness, confidence, and discipline when listening to and exploring a patient's nursing history. Apply relevant standards of practice when selecting nursing measures.

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care.

◆ Assessment

During the assessment process thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care. Consider all critical thinking elements that build toward making appropriate diagnoses (Figure 47-5).

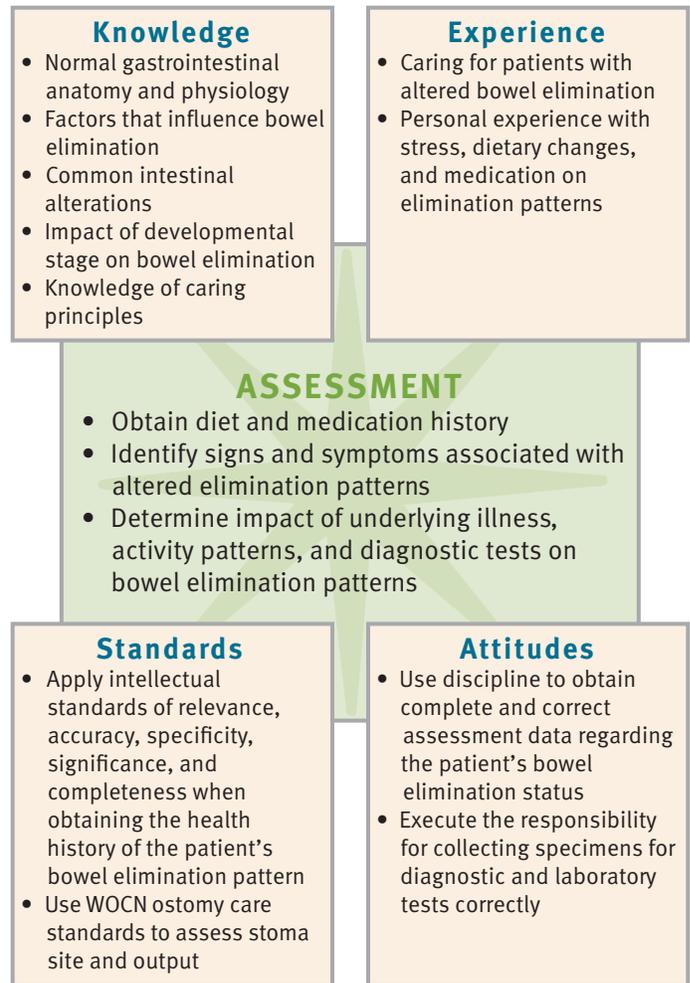
Assessment for bowel elimination patterns and abnormalities includes a nursing history, physical assessment of the abdomen, inspection of fecal characteristics, and review of relevant test results. In addition, determine the patient's medical history, pattern and types of fluid and food intake, mobility, chewing ability, medications, recent illnesses and/or stressors, and environmental situation.


FIGURE 47-5 Critical thinking model for elimination assessment. *WOCN,* Wound, Ostomy and Continence Nurses Society.

Through the Patient's Eyes. Patients expect nurses to answer all of their questions regarding diagnostic tests and the preparation for these tests. They are concerned about discomfort and exposure of their perineal area. Bowel problems are often a source of discomfort and embarrassment for the patient and their families. Fecal and urinary incontinence in older people is the second most common reason for admission to a long-term care facility (Long, 2010). Some older patients who fail to recognize their elimination needs need monitoring for elimination patterns so negative consequences do not occur. Remember that each patient has a unique situation and a perception of what is "right" for him or her. Patients expect a knowledgeable nurse with the ability to teach methods of promoting and maintaining normal bowel elimination patterns or means of managing altered elimination. Encourage the patient and/or caregiver to describe cultural practices and use this information when providing care to enhance the patient's comfort.

Nursing History. The nursing history provides information about a patient's usual bowel pattern and habits. What a patient describes as normal or abnormal is often different from factors and conditions that tend to promote normal elimination. Identifying normal and abnormal patterns, habits, and the patient's perception of normal and abnormal in regard to bowel elimination allows you to better determine a patient's problems. Organize the nursing history around factors that affect elimination.

- *Determination of the usual elimination pattern:* Include frequency and time of day. Having a patient or caregiver complete a bowel elimination diary provides an accurate assessment of a patient's current bowel elimination pattern.
- *Patient's description of usual stool characteristics:* Determine if the stool is normally watery or formed, soft or hard, and the typical color. Ask the patient to describe the shape of a normal stool and the number of stools per day. Use a scale such as the Bristol Stool Form Scale to get an objective measure of stool characteristics (Figure 47-6).
- *Identification of routines followed to promote bowel elimination:* Examples are drinking hot liquids, eating specific foods, or taking time to defecate during a certain part of the day or use of laxatives, enemas, or bulk-forming fiber additives.
- *Presence and status of bowel diversions:* If a patient has an ostomy, assess frequency of emptying the ostomy pouch, character of feces, appearance and condition of the stoma (color, height at or above skin level), condition of peristomal skin, type of pouching system device used, and methods used to maintain the function of the ostomy.
- *Changes in appetite:* Include changes in eating patterns and a change in weight (amount of loss or gain). If a loss of weight is present, ask if the patient intended to lose weight (e.g., a diet or exercise routine) or if it happened unexpectedly.
- *Diet history:* Determine the patient's dietary preferences. Determine the intake of fruits, vegetables, and whole grains and if mealtimes are regular or irregular.
- *Description of daily fluid intake:* This includes the type and amount of fluid. Patients often estimate the amount using common household measurements.
- *History of surgery or illnesses affecting the GI tract:* This information helps explain symptoms, the potential for maintaining or restoring normal bowel elimination pattern, and whether there is a family history of GI cancer.
- *Medication history:* Ask patients for a list of all the medications they take and assess whether they take medications such as laxatives, antacids, iron supplements, and analgesics that alter defecation or fecal characteristics.
- *Emotional state:* A patient's emotional status may alter frequency of defecation. Ask the patient if he or she has experienced unusual stress and if he or she thinks that this may have caused a change in bowel movements.
- *History of exercise:* Ask the patient to specifically describe the type and amount of daily exercise.
- *History of pain or discomfort:* Ask the patient whether there is a history of abdominal or anal pain. The type, frequency, and location of pain help identify the source of the problem. For instance, cramping pain, nausea, and the absence of bowel movements sometimes indicate there is an intestinal obstruction.
- *Social history:* Patients have many different living arrangements. Where patients live affects their toileting habits. If the patient lives with other people, ask how many bathrooms there are. Find out if the patient has to share a bathroom, creating a need to adjust the time that he or she uses the bathroom to accommodate others. If the patient lives alone, can he or she ambulate to the toilet safely? When patients are not independent in bowel management, determine who helps them and how.
- *Mobility and dexterity:* Evaluate patients' mobility and dexterity to determine if they need assistive devices or help from personnel.

See Box 47-3 for a summary of the types of assessment questions to use for gathering a detailed nursing history.

Physical Assessment. Conduct a physical assessment of body systems and functions likely to be influenced by the presence of elimination problems (see Chapter 31).

Mouth. Inspect the patient's teeth, tongue, and gums. Poor dentition or poorly fitting dentures influence the ability to chew. Sores in the mouth make eating not only difficult but also painful.

Abdomen. Inspect all four abdominal quadrants for contour, shape, symmetry, and skin color. Note masses, peristaltic waves, scars, venous patterns, stomas, and lesions. Normally you do not see peristaltic waves. Observable peristalsis is often a sign of intestinal obstruction.

Abdominal distention appears as an overall outward protuberance of the abdomen. Intestinal gas, large tumors, or fluid in the peritoneal cavity causes distention. A distended abdomen feels tight like a drum; the skin is taut and appears stretched.

Auscultate the abdomen with a stethoscope to assess bowel sounds in each quadrant (see Chapter 31). Normal bowel sounds occur every 5 to 15 seconds and last a second to several seconds. Absent (no auscultated bowel sounds) or hypoactive sounds occur with an ileus such as after abdominal surgery but may also mean that you did not capture the bowel sounds when you were assessing them. High-pitched and hyperactive bowel sounds occur with small intestine obstruction and inflammatory disorders. Although auscultating bowel sounds during assessment is standard nursing practice, some current research questions its validity. A recent study found that only 11.4% of nurses and 47.6% of doctors could make correct clinical judgments on the basis of their auscultatory findings (Li et al., 2014). Another study comparing surgical and internal medicine clinicians' interpretation of bowel sounds concluded that auscultation of bowel sounds is not a useful clinical practice when differentiating patients with normal versus pathological bowel sounds (Felder et al., 2014).

Percussion identifies underlying abdominal structures and detects lesions, fluid, or gas within the abdomen. Gas or flatulence creates a tympanic note. Masses, tumors, and fluid are dull to percussion.

Gently palpate the abdomen for masses or areas of tenderness. It is important for your patient to relax. Tensing abdominal muscles interferes with palpating underlying organs or masses.

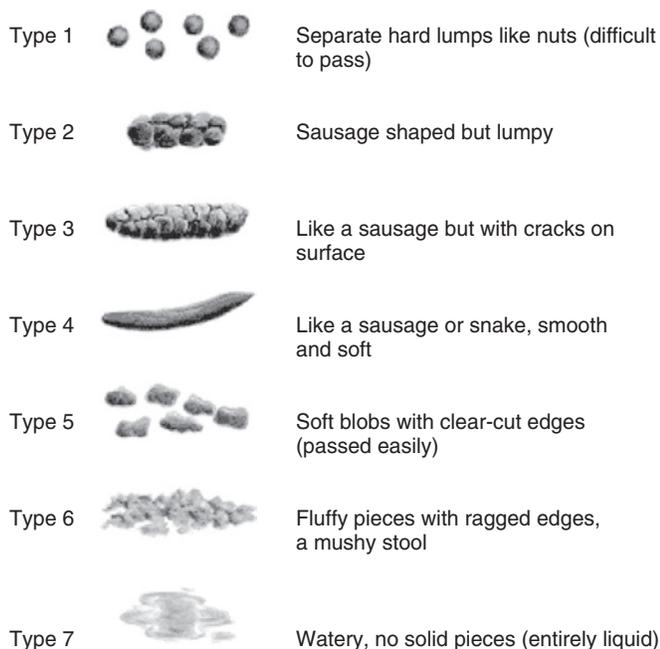
Type 1	Separate hard lumps like nuts (difficult to pass)
Type 2	Sausage shaped but lumpy
Type 3	Like a sausage but with cracks on surface
Type 4	Like a sausage or snake, smooth and soft
Type 5	Soft blobs with clear-cut edges (passed easily)
Type 6	Fluffy pieces with ragged edges, a mushy stool
Type 7	Watery, no solid pieces (entirely liquid)


FIGURE 47-6 Bristol stool form scale. (Used with permission. Bristol Stool Form Guideline, http://www.aboutconstipation.org/bristol.)

Signs and Symptoms
Nausea or Vomiting: Onset, Duration, Associated
Symptoms, Character, Exposures
- When did the nausea/vomiting start?
- Is it related to particular stimuli (odors, after eating specific food)?
- How does the emesis look (mucus, blood, coffee-ground appearance, undigested food) and what is the color?
- Do you have other symptoms such as fever, dizziness, headaches, abdominal pain, or weight loss?
- Do you have family members who are experiencing the same symptoms?

Indigestion: Onset, Character, Location, Associated
Symptoms, Alleviating Factors
- Is the indigestion related to meals, types or quantity of food, time of day or night?
- Does the discomfort from indigestion radiate to the shoulders or arms?
- Do you feel bloated after eating?
- Do you have any other symptoms (vomiting, headaches, diarrhea, belching, flatulence, heartburn, or pain)?
- Does the indigestion respond to antacids or other self-care measures?

Diarrhea: Onset, Duration, Character, Associated
Symptoms, Alleviating Factors, Exposure
- When did the diarrhea start? Was it gradual or sudden?
- How many stools do you have per day? Is it watery or explosive? What is the color and consistency?
- Have you had fever, chills, weight loss, or abdominal pain?
- Have you taken antibiotics recently?
- Have you been under stress?
- What have you used to try to alleviate the diarrhea? Was it successful?
- Have you been out of the country recently?

Constipation: Onset, Character, Symptoms,
Alleviating Factors
- When was your last bowel movement? How many bowel movements do you have in a typical week?
- Is this a recent occurrence or a long-standing problem?
- Describe your bowel movements.
- Do you have to strain to have a bowel movement?
- Do you have abdominal or rectal pain when you have a bowel movement?
- Do you feel as though your bowel movements are incomplete?
- Have you recently changed your diet or fluid intake?
- Do you use stool softeners, laxatives, or enemas?
- Has it ever been necessary to manually remove the bowel movements?

Medical History
- Do you have a previous history of gastrointestinal problems or disease? If yes, explain.
- Have you had abdominal surgery or trauma?
- Do you have a history of major illnesses such as cancer; arthritis; or respiratory, kidney, or cardiac disease?
- Which medications do you take?

Effect on the Patient
- How do these symptoms affect you?
- Have you missed work or social engagements because of these symptoms?

Rectum. Inspect the area around the anus for lesions, discoloration, inflammation, and hemorrhoids. Pain results when hemorrhoid tissues are irritated. The primary goal for a patient with hemorrhoids is to have soft-formed, painless bowel movements. Proper diet, fluids, and regular exercise improve the likelihood of stools being soft. If the patient becomes constipated, passage of hard stools causes bleeding and irritation. An ice pack or a warm sitz bath (see Chapter 48) provides temporary relief of swollen hemorrhoids. A health care provider sometimes prescribes topical medication to relieve the swelling and pain.

Laboratory Tests. There are no blood tests to specifically diagnose most GI disorders, but hemoglobin and hematocrit help determine if anemia from GI bleeding is present. Other laboratory tests often ordered by the health care provider include liver function tests, serum amylase, and serum lipase, which are used to assess for hepatobiliary diseases and pancreatitis.

Fecal Specimens. You need to ensure that specimens are obtained accurately, labeled properly in appropriate containers, and transported to the laboratory on time. Laboratories provide special containers for fecal specimens. Some tests require that specimens are placed in chemical preservatives, and some require that they are refrigerated or placed on ice after collection and before delivery to the laboratory. Use medical aseptic technique during collection of stool specimens (see Chapter 29).

Hand hygiene is necessary for anyone who comes in contact with the specimen. Often the patient is able to obtain the specimen if properly instructed. Teach the patient to avoid mixing feces with urine or water. He or she defecates into a clean, dry bedpan or a special container under the toilet seat. Observe the stool characteristics when collecting a specimen (Table 47-1).

Tests performed by the laboratory for occult (microscopic) blood in the stool and stool cultures require only a small sample. Collect about a 3-cm (1-inch) mass of formed stool or 15 to 30 mL of liquid stool. Tests for measuring the output of fecal fat require a 3- to 5-day collection of stool. You need to save all fecal material throughout the test period.

After obtaining a specimen, label and tightly seal the container and complete all laboratory requisition forms. Record specimen collections in the patient's medical record. It is important to avoid delays in sending specimens to the laboratory. Some tests such as measurement for ova and parasites require the stool to be warm. When stool specimens remain at room temperature, bacteriological changes that alter test results occur.

A common stool test is the **fecal occult blood test (FOBT),** which measures microscopic amounts of blood in the feces. It is a useful screening test for colon cancer as recommended by the American Cancer Society. There are two types of tests, the guaiac fecal occult blood test (gFOBT) and the fecal immunochemical test (FIT). The FIT test requires no preparation or dietary restrictions and is a more sensitive test, but it is more expensive; thus the gFOBT is more commonly used. The nurse or the patient needs to repeat the test at least 3 times on three separate bowel movements. The FOBT is done in a patient's home or health care provider's office (Box 47-4). All positive tests are followed up with flexible sigmoidoscopy or **colonoscopy** (ACS, 2015).

When your patients are going to have a gFOBT, it is important to instruct them to avoid eating red meat for 3 days before testing. If there are no contraindications and it is approved by the health care provider, instruct your patient to stop taking aspirin, ibuprofen, naproxen, or other nonsteroidal antiinflammatory drugs for 7 days because these could cause a false-positive test result. Patients also need to avoid vitamin C supplements and citrus fruits and juices for 3 days before the test because they can cause a false-negative result (ACS, 2015).

Diagnostic Examinations. For patients experiencing alterations in the GI system, various radiological and diagnostic examinations such as a colonoscopy require bowel preparation (bowel prep) for the test to be completed successfully. A bowel-cleansing program is sometimes difficult or unpleasant for patients. You provide education and support to ensure an optimal test result (Box 47-5).

◆ **Nursing Diagnosis**

Nursing assessment of a patient's bowel function sometimes reveals data that indicate an actual or potential elimination problem or a problem resulting from elimination alterations. In the examples discussed in the Nursing Care Plan, a patient has constipation as a result of pain medications and decreased fiber intake. Examples of diagnoses that apply to patients with elimination problems include the following:

- *Disturbed Body Image*
- *Bowel Incontinence*
- *Constipation*
- *Perceived Constipation*
- *Risk for Constipation*
- *Diarrhea*
- *Nausea*
- *Deficient Knowledge (Nutrition)*
- *Acute Pain*
- *Toileting Self-Care Deficit*

TABLE 47-1 Fecal Characteristics

Characteristic	Normal	Abnormal	Abnormal Cause
Color	Infant: yellow; adult: brown	White or clay Black or tarry (melena) Red Pale and oily	Absence of bile Iron ingestion or gastrointestinal (GI) bleeding GI bleeding, hemorrhoids, ingestion of beets Malabsorption of fat
Odor	Malodorous; may be affected by certain foods	Noxious change	Blood in feces or infection
Consistency	Soft, formed	Liquid Hard	Diarrhea, reduced absorption Constipation
Frequency	Varies: infant 4 to 6 times daily (breastfed) or 1 to 3 times daily (bottle-fed); adult twice daily to 3 times a week	Infant more than 6 times daily or less than once every 1 to 2 days; adult more than 3 times a day or less than once a week	Hypermotility or hypomotility
Shape	Resembles diameter of rectum	Narrow, pencil shaped	Obstruction, increased peristalsis
Constituents	Undigested food, dead bacteria, fat, bile pigment, cells lining intestinal mucosa, water	Blood, pus, foreign bodies, mucus, worms Oily stool Mucus	Internal bleeding, infection, swallowed objects, irritation, inflammation, infestation of parasites Malabsorption syndrome, enteritis, pancreatic disease, surgical resection of intestine Intestinal irritation, inflammation, infection, or injury

BOX 47-4 PROCEDURAL GUIDELINES

Performing a Guaiac Fecal Occult Blood Test

Delegation Considerations

The skill of fecal occult blood test (FOBT) can be delegated to nursing assistive personnel (NAP). However, the nurse is responsible for assessing the significance of the findings. You may need to send the specimen to the laboratory. Refer to your agency policies. The nurse instructs the NAP to:

Notify the nurse if frank bleeding occurs after obtaining the sample.

Equipment

Hemoccult test paper, Hemoccult developer, wooden applicator, and clean gloves (Check the expiration dates on the developer and the test paper before using.)

Steps

1. Identify patient using two identifiers (e.g., name and birthday or name and account number) according to agency policy.
2. Explain purpose of test and ways patient can help. Patient can collect own specimen if possible.
3. Perform hand hygiene and apply clean gloves.

4. Use tip of wooden applicator (see illustration) to obtain a small part of stool specimen. Be sure that specimen is free of toilet paper and not contaminated with urine.

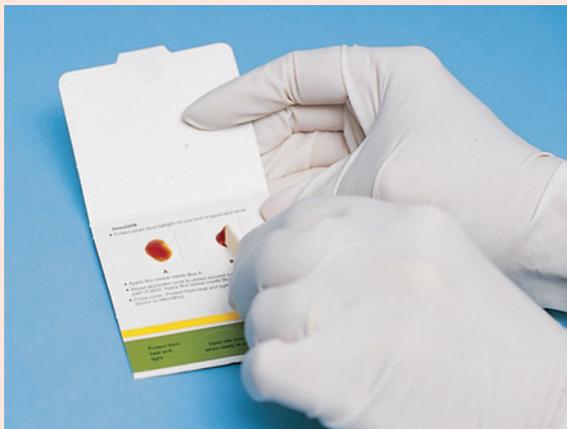
STEP 4 Equipment needed for fecal occult blood testing.

Continued

BOX 47-4   PROCEDURAL GUIDELINES

Performing a Guaiac Fecal Occult Blood Test—cont'd

5. Perform Hemoccult slide test:
   a. Open flap of slide and, using a wooden applicator, thinly smear stool in first box of the guaiac paper. Apply a second fecal specimen from a different part of the stool to second box of slide (see illustration).
   b. Close slide cover and turn the packet over to reverse side (see illustration). After waiting 3 to 5 minutes, open cardboard flap and apply 2 drops of developing solution on each box of guaiac paper. A blue color indicates a positive guaiac or presence of fecal occult blood.

   c. Interpret the color of the guaiac paper after 30 to 60 seconds.
   d. After determining if the patient's specimen is positive or negative, apply 1 drop of developer to the quality control section and interpret within 10 seconds.
   e. Dispose of test slide in proper receptacle.
6. Wrap wooden applicator in paper towel, remove gloves, and discard in proper receptacle.
7. Perform hand hygiene.
8. Record results of test; note any unusual fecal characteristics. (Submit only one sample per day.)


STEP 5a Application of fecal specimen on guaiac paper.

STEP 5b Application of Hemoccult developing solution on guaiac paper on reverse side of test kit.

BOX 47-5   Radiological and Diagnostic Tests

Direct Visualization
Endoscopy
- Examinations such as a gastroscopy or colonoscopy use a lighted fiberoptic tube to gain direct visualization of the upper gastrointestinal (GI) tract (upper **endoscopy**) or large intestine (colonoscopy). The fiberoptic tube contains a lens, forceps, and brushes for biopsy. If an endoscopy identifies a lesion such as a polyp, the polyp can be removed, and a biopsy will be done.
- These tests are done under sedation, usually in outpatient centers.
- Patients receive instruction about the preparation needed for the tests at the time they are scheduled for the procedure. Patients are usually on a clear liquid diet the day before the test. Bowel preparation is necessary before a colonoscopy can be performed successfully.

Indirect Visualization
Anorectal Manometry
- Measures the pressure activity of internal and external anal sphincters and reflexes during rectal distention, relaxation during straining, and rectal sensation.

Plain Film of Abdomen/Kidneys, Ureter, Bladder (KUB)
- A simple x-ray film of the abdomen requiring no preparation.

Barium Swallow/Enema
- An x-ray film examination using an opaque contrast medium (barium, which is swallowed) to examine the structure and motility of the upper GI tract, including pharynx, esophagus, and stomach. Barium instilled through the anal opening via an enema provides visualization of the structures of the lower GI tract.
- Preparation required varies by physician and agency doing the procedure but usually includes a clear liquid diet, laxatives the day before the procedure, and in some instances enemas to empty out any remaining stool particles.

Ultrasound Imaging
- A technique that uses high-frequency sound waves to echo off body organs, creating a picture of the GI tract.

Computed Tomography Scan (Virtual Colonoscopy)
- An x-ray examination of the body from many angles using a scanner analyzed by a computer. An oral contrast solution for the patient to drink may be ordered before the test. Intravenous contrast solution may be injected during the test to improve visualization. If contrast is used, patient should not have food or fluids for 4 to 6 hours before the examination.
- Virtual colonoscopy or computerized tomography (CT) colonography requires bowel preparation before the test. This does not replace the colonoscopy because it does not allow for removal of **polyps** and biopsies to be obtained.

Colonic Transit Study
- The patient swallows a capsule containing radiopaque markers.
- The patient maintains their normal diet and fluid intake for 5 days and refrains from medications that affect bowel function. On the fifth day x-ray film examination is performed.

Magnetic Resonance Imaging
- A noninvasive examination that uses magnet and radio waves to produce a picture of the inside of the body.
- Preparation is NPO 4 to 6 hours before examination.
- The patient needs to lie very still. If claustrophobia is a problem, light sedation may be ordered.
- No metallic objects, including metal objects on clothes, are allowed in the room. If the patient has a pacemaker or a metal implanted in his or her body, he or she may not be able to have magnetic resonance imaging (MRI).

Constipation

ASSESSMENT

Javier, a home care nurse, is visiting Mr. Johnson at his home. Mr. Johnson lives alone in a suburban community and has two grown children who reside in another state. They came to visit while he was hospitalized and helped him get settled back at home, but now they have returned to their homes and families. He is 76 years old and had surgery 10 days ago for a total knee replacement after suffering from osteoarthritis for many years. Mr. Johnson tells Javier that he is trying to follow the exercise program that the physical therapist has recommended but is having difficulty because of pain from the surgery. His past history includes hypertension, which has been controlled with medication for the last 10 years. He had some edema of both feet in the hospital and took a mild diuretic for 5 days for relief. Javier knows that immobility from the surgery, recent use of a diuretic, and opioid pain medication are factors that can cause constipation.

Assessment Activities	Findings/Defining Characteristics*
Ask Mr. Johnson about his bowel elimination patterns since his surgery.	Mr. Johnson tells Javier that **he had one small hard bowel movement in the hospital but has not had one in the 7 days since he has been home.**
Review patient's medication.	Mr. Johnson says he is taking his blood pressure medication, a daily multivitamin with **iron**, a stool softener once a day, and 1 or 2 **oxycodone** 4 times a day.
Review dietary and fluid intake over last day.	Diet included **whole grain cereal**, a banana, and toast for breakfast; a sandwich for lunch; and a frozen dinner in the evening, which has a small serving of meat, potatoes or rice, and corn or green beans. He says he is **trying to drink fluids but has started feeling a little nauseated when he drinks very much.** He also isn't sure if too much fluid would make his feet swell again. He has a cup of coffee and a small glass of orange juice in the morning. He drinks a small glass of iced tea with lunch and dinner.
Assess which foods and fluids Mr. Johnson likes, can obtain, and will prepare.	He reports that a friend will shop for him for groceries. Occasionally a friend brings him dinner, but he relies on frozen dinners because they are easy to get and to heat. **He hates prune juice but will drink apple or orange juice. He agrees that he can drink more water but prefers iced tea with sugar. He likes lettuce and tomato salads; most fruits; and frozen peas, corn or green beans. He'll try whole-grain bread but prefers white bread.**
Ask about any nausea or vomiting.	Complains of **mild nausea** when he eats and a constant **feeling of fullness** but no vomiting.
Palpate abdomen.	While Javier is palpating Mr. Johnson's abdomen, Mr. Johnson tells him, "It really feels full," and he winces with very little pressure applied. Abdomen feels taut and mildly distended.

***Defining characteristics** are shown in bold type.

NURSING DIAGNOSIS: Constipation related to opiate-containing pain medication, decreased mobility, and decreased food and fluid intake

PLANNING

Goals	Expected Outcomes (NOC)†
	Bowel Elimination
Mr. Johnson will establish normal defecation.	Mr. Johnson reports passage of soft, formed stool without straining in next 24 hours.
	Nutritional Status: Food and Fluid Intake
Mr. Johnson will make changes to his diet to prevent constipation.	Mr. Johnson drinks at least 1500 mL of fluid over the next 24 hours.
	Mr. Johnson increases the fiber content of his diet by eating an apple with his breakfast, lettuce and tomato on his sandwich, and some carrots with his dinner.

†Outcome classification labels from Moorhead S et al: *Nursing outcomes classification (NOC)*, ed 5, St Louis, 2013, Mosby.

INTERVENTIONS (NIC)‡	RATIONALE
Constipation/Impaction Management	
Encourage fluid intake of appropriate fluids, fruit juice, and water.	At least 1500 mL fluid intake daily will help to soften the stool.
Encourage activity within patient's mobility regimen.	Minimal activity (such as leg lifts) increases peristalsis.
Instruct Mr. Johnson to eat more fruits and vegetables and have a bran cereal for breakfast.	Added fiber in food relieves constipation.
Provide stimulant laxative and stool softeners as ordered.	Stimulant laxatives increase peristalsis and are an effective way to relieve constipation and promote normal bowel function when used on a short-term basis.
Encourage Mr. Johnson to try to have a bowel movement at the same time each day.	A regular time for bowel movements encourages normal bowel function.

‡Intervention classification labels from Bulechek GM et al: *Nursing interventions classification (NIC)*, ed 6, St Louis, 2013, Mosby.

EVALUATION

Nursing Actions	Patient Response/Finding	Achievement of Outcomes
Ask Mr. Johnson to identify foods high in fiber and fluid intake.	Able to state appropriate foods and fluids, but still has little appetite and feels full soon after eating.	Mr. Johnson verbalizes understanding of teaching.
Get medication history for last 2 days.	Patient has taken a stimulant laxative and stool softener twice a day for last 2 days.	Patient has not had a bowel movement.
Ask Mr. Johnson about physical activity.	Mr. Johnson states that he has not changed his activity pattern.	Mr. Johnson did not increase activity pattern and needs to continue to work on this intervention.
Inquire about bowel movements.	Mr. Johnson still has not had a bowel movement.	Mr. Johnson did not achieve passage of regular, formed stool.

BOX 47-6 Nursing Diagnostic Process

Constipation

Assessment Activities	Defining Characteristics
Ask patient about bowel elimination patterns.	Patient reports no bowel movement for 4 days.
Ask patient about other gastrointestinal symptoms.	Patient denies any feeling of nausea, abdominal cramping, or loss of appetite.
Ask patient to describe recent food and fluid intake.	Patient reports drinking two cups of coffee and one glass of iced tea each day; eating one serving of cooked vegetables and a banana every other day; having peanut butter and jelly sandwiches, meat, potatoes, and white bread every day.
Palpate abdomen.	Patient reports feeling of fullness. Left lower quadrant is firm.

Associated problems such as age, body-image changes, or skin breakdown require interventions unrelated to bowel function impairment. It is important to establish the correct "related to" factor for a diagnosis. This depends on the thoroughness of your assessment and your recognition of the defining characteristics and factors that impair elimination (Box 47-6). For example, with the diagnosis of *Constipation* you distinguish between related factors of *nutritional imbalance, exercise, medications,* and *emotional problems.* Selection of the correct related factors for each diagnosis ensures that you will implement the appropriate nursing interventions.

◆ **Planning**

When planning care, synthesize information from multiple resources (Figure 47-7). Critical thinking ensures that the plan of care integrates everything known about a patient and current clinical problems. Rely on professional standards when possible. For example, the Wound, Ostomy and Continence Nurse guidelines (WOCN, 2013) on fecal incontinence help to protect a patient's skin, promote continence, and reduce the embarrassment associated with incontinence.

Goals and Outcomes. Help patients establish goals and outcomes by incorporating their elimination habits or routines as much as possible and reinforcing the routines that promote health (see the Nursing Care Plan). In addition, consider preexisting health concerns. For example, if a patient's diet, activity, and irregular bowel habits caused the elimination problem, help him or her learn to make lifestyle changes to improve bowel function. The overall goal of returning a patient to a normal bowel elimination pattern includes the following outcomes:

- Patient establishes a regular defecation schedule.
- Patient lists proper fluid and food intake needed to soften stool and promote regular bowel elimination.
- Patient implements a regular exercise program.
- Patient reports daily passage of soft, formed brown stool.
- Patient does not report straining or discomfort associated with defecation.

Knowledge
- Role of other health care professionals in returning the patient's bowel elimination pattern to normal
- Impact of specific therapeutic diets and medication on bowel elimination patterns
- Expected results of cathartics, laxatives, and enemas on bowel elimination

Experience
- Previous patient response to planned nursing therapies for improving bowel elimination (what worked and what did not work)

PLANNING
- Select nursing interventions to promote normal bowel elimination
- Consult with dietitians and enteral stoma therapists
- Involve the patient/family in designing nursing interventions

Standards
- Individualize therapies to the patient's bowel elimination needs
- Select therapies within wound, ostomy, and continence professional practice standards.

Attitudes
- Be creative when planning interventions to achieve normal bowel elimination patterns
- Display independence when integrating interventions from other disciplines in the patient's plan of care
- Act responsibly by ensuring that interventions are consistent within standards

FIGURE 47-7 Critical thinking model for elimination planning. *AHRQ,* Agency for Healthcare Research and Quality; *WOCN,* Wound, Ostomy and Continence Nurses Society.

QSEN **QSEN: BUILDING COMPETENCY IN PATIENT-CENTERED CARE** Mr. Johnson started taking a stimulant laxative every day to avoid constipation after he had a fecal impaction removed. He drank more fluids, especially water, and began adding more fruits and vegetables to his diet. On the day after the impaction was removed, he had a formed, firm bowel movement with some straining required. Then he began having daily bowel movements with soft, formed stool. Now it is 1 month later, and he is still taking laxatives but not continuing with the fluid and dietary modifications that were recommended for him. The physical therapist is ready to discharge him from home care but asks the nurse to make another visit when Mr. Johnson states he is having trouble moving his bowels. Which assessment questions and teaching strategies, approaches, and tools does the nurse use to enhance Mr. Johnson's learning and ability to prevent constipation?

ⓔ*Answers to QSEN Activities can be found on the Evolve website.*

CONCEPT MAP

Nursing diagnosis: Constipation related to opioid medication
- Abdomen firm and describes "feeling full"
- Last bowel movement 7 days ago

Interventions
- Increase fluid and fiber in his diet
- Take stimulant laxative and stool softeners

Nursing diagnosis: Acute pain related to surgery
- Taking only opioid medication
- Health care provider recommended over-the-counter pain medication but he says he is "afraid to try it"

Interventions
- Encourage patient to try non-opioid pain medication
- Decrease use of opioid pain medication

Primary health problem: Constipation
Priority assessments: Bowel movements, diet and fluid intake, use of laxatives, use of opioid pain medication

Nursing diagnosis: Impaired physical mobility related to surgery
- Patient lives alone and is not exercising except when the physical therapist is present

Interventions
- Have physical therapist provide exercise/ambulation at home

Nursing diagnosis: Acute pain related to constipation
- Leakage of small amount of liquid stool
- Decreased appetite and nausea with feeling of fullness in abdomen
- Abdomen painful on palpation

Interventions
- Arrange for patient to go to emergency department of local hospital for possible fecal impaction

—— Link between medical diagnosis and nursing diagnosis   - - - - Link between nursing diagnoses

FIGURE 47-8 Concept map for Mr. Johnson.

Setting Priorities. Defecation patterns vary among individuals. For this reason a nurse and patient work together closely to plan effective interventions. Patients often have multiple diagnoses. The concept map (Figure 47-8) shows an example of how the nursing diagnosis of constipation is related to three other diagnoses and their respective interventions. A realistic time frame to establish a normal defecation pattern for one patient is sometimes very different for another. In the patient with recent abdominal surgery, the priorities of pain management and the avoidance of constipation through increasing fluids in the diet and encouraging early ambulation help in the recovery process.

Teamwork and Collaboration. When patients are disabled or debilitated by illness, you need to include the family in the plan of care. In some situations family members have the same ineffective elimination habits as the patient. Thus patient and family teaching is an important part of the care plan. Other health team members such as dietitians and WOCNs are often valuable resources. You coordinate activities of the multidisciplinary health care team.

A patient with alterations in bowel elimination sometimes requires intervention from several members of the health care team. Certain tasks such as assisting patients onto the bedpan or bedside commode

are appropriate to delegate to nursing assistive personnel (NAP). It is important to remind the NAP to report any abnormal findings or difficulties encountered during the elimination process. Many of the diagnostic tests for evaluation of the GI system are performed by nonnursing personnel. Maintaining ongoing communication with these caregivers will ensure that you provide safe and effective patient-centered care and address a patient's needs, wants, and concerns.

◆ **Implementation**

Successful nursing interventions improve patients' and family members' understanding of bowel elimination. Teach them about proper diet, adequate fluid intake, and factors that stimulate or slow peristalsis such as emotional stress. This is often best done during a patient's mealtime. Patients also need to learn the importance of establishing regular bowel routines, exercising regularly, and taking appropriate measures when elimination problems develop.

Health Promotion. One of the most important habits to teach regarding bowel habits is to take time for defecation. To establish regular bowel habits, a patient needs to know when the urge to defecate normally occurs. Advise the patient to begin establishing a routine

BOX 47-7   Screening for Colorectal Cancer

Risk Factors
- Age: Over 50
- Family history: Colorectal cancer, familial adenomatous polyposis, hereditary nonpolyposis colon cancer (Lynch syndrome)
- Personal history: Colorectal cancer or colorectal polyps, inflammatory bowel disease (IBD)
- Race: African-Americans have highest colon cancer rates
- Diet: High intake of animal fats or red meat and low intake of fruits and vegetables
- Obesity and physical inactivity
- Smoking and heavy alcohol consumption
- Type 2 diabetes

Warning Signs
- Change in bowel habits (e.g., diarrhea, constipation, narrowing of stool lasting more than few days)
- Rectal bleeding or blood in stool
- Sensation of incomplete evacuation
- Unexplained abdominal or back pain

American Cancer Society Screening Guidelines for the Early Detection of Colorectal Cancer in Average-Risk Asymptomatic People

Test	Frequency
Guaiac fecal occult blood test (gFOBT) done on multiple samples at home	Annual, starting at age 50
Fecal immunochemical test (FIT) done on multiple samples at home	Annual, starting at age 50
Flexible sigmoidoscopy	Every 5 years, starting at age 50
Double-contrast barium enema	Every 5 years, starting at age 50
Computed tomography, colonography	Every 5 years, starting at age 50
Colonoscopy	Every 10 years, starting at age 50

Data from American Cancer Society, 2015, www.cancer.gov. These procedures will be ordered by a health care provider, depending on availability of resources and patient needs. If positive findings result from the flexible sigmoidoscopy, barium enema, or colonography, follow-up with a colonoscopy should be done.

BOX 47-8   CULTURAL ASPECTS OF CARE

Variables Influencing Colorectal Cancer Screening in African-Americans

Biological, psychological, behavioral, and social variables influence colorectal cancer (CRC) screenings in African-Americans. African-Americans have a 20% higher rate of CRC and 40% higher incidence of disease-related death when compared with whites (ACS, 2015). Prevention resulting in early detection is key to finding CRC when it is often curable, but screening rates are lower in African-Americans than white people in the United States. A study looking at compliance rates with colorectal cancer screening in the United States showed that African-Americans and Asians were more compliant with a fecal occult blood test (FOBT) and whites and Asians were more compliant with having a colonoscopy. When barriers to care were removed, the rate of colonoscopy screening was higher in all groups (Inadomi et al., 2012).

Implications for Patient-Centered Care
- Lack of routine visits to a primary care provider is one of the strongest predictors for inadequate colorectal cancer (CRC) screening and advanced stage at presentation (Griffin, 2009).
- Patients who do not have health insurance frequently do not seek CRC screening (Griffin, 2009).
- Patients who participate in preventive health practices (e.g., regular physical activity) often seek regular screening for CRC because these patients are often interested in promoting their own health (Inadomi et al., 2012).
- Identification of additional social system predictors such as family support, church affiliation, and geographical access also help in receiving timely CRC screening (Griffin, 2009).
- Removing barriers of safety, quality, and cost-effectiveness improves the involvement of patients in CRC screening (ACS, 2015).

FIGURE 47-9 Types of bedpans. From left, Regular bedpan and fracture bedpan.

during a time when defecation is most likely to occur, usually an hour after a meal. When patients are restricted to bed or need help to ambulate, offer a bedpan or help them reach the bathroom in a timely manner.

Colorectal cancer is the third most common cancer to occur in the United States (ACS, 2015). When diagnosed early, it can be treated and eliminated. Following the guidelines for prevention, knowing the early symptoms, and seeking medical help if these symptoms occur are the most effective ways to prevent death from this disease (Box 47-7).

African-Americans have the highest rates of cancer and highest death rates from cancer of any cultural group. The death rates have dropped for lung and oropharyngeal cancers, but the rates for colorectal cancer continue to be 33% higher for African-American men and 16% higher for African-American women than for non-Hispanic white men and women. There still is a lower rate of colorectal cancer screening among African-Americans, but this disparity is decreasing (Box 47-8).

Promotion of Normal Defecation. A number of interventions stimulate the defecation reflex, affect the character of feces, or increase peristalsis to help patients evacuate bowel contents normally and without discomfort.

Sitting Position. Help patients who have difficulty sitting because of muscular weakness and mobility problems. Place an elevated seat on the toilet or a bedside commode when patients are unable to lower themselves to a sitting position because of pain or weakness. These seats require patients to use less effort to sit or stand.

Positioning on Bedpan. Patients restricted to bed use bedpans for defecation. Women use bedpans to pass both urine and feces, whereas men use bedpans only for defecation. Sitting on a bedpan is often uncomfortable. Help position patients comfortably. Two types of bedpans are available (Figure 47-9). The regular bedpan, made of plastic, has a curved smooth upper end and a sharper-edged lower end and is about 5 cm (2 inches) deep. The smaller fracture pan, designed for patients with lower-extremity fractures, has a shallow upper end

FIGURE 47-10 Improper positioning of patient on bedpan.

FIGURE 47-11 Proper position reduces patient's back strain.

about 2.5 cm (1 inch) deep. The shallow end of the pan fits under the buttocks toward the sacrum; the deeper end, which has a handle, goes just under the upper thighs. The pan needs to be high enough so feces enter it.

When positioning a patient, it is important to prevent muscle strain and discomfort. Never try to lift a patient onto a bedpan. Never place a patient on a bedpan and then leave with the bed flat unless activity restrictions demand it because it forces the patient to hyperextend the back to lift the hips on the pan. The proper position for the patient on a bedpan is with the head of the bed elevated 30 to 45 degrees (Figures 47-10 and 47-11). When patients are immobile or it is unsafe to allow them to raise their hips, it is safest for both caregivers and patients to roll them on to the bedpan (Box 47-9). Always wear gloves when handling a bedpan.

Acute Care. With some acute illnesses the GI system becomes affected. Changes in a patient's fluid status, mobility patterns, nutrition, and sleep cycle affect regular bowel habits. Surgical interventions on the GI tract obviously affect bowel elimination. However, surgery on other systems (e.g., the musculoskeletal and cardiovascular systems) also sometimes affects it.

Chronically ill and hospitalized patients are not always able to maintain privacy during defecation. In a hospital or extended care setting, patients sometimes share bathroom facilities with a roommate. In addition, chronic illness may limit a patient's mobility and activity tolerance and require the use of a bedpan or bedside commode. The sights, sounds, and odors associated with sharing toilet facilities or using bedpans are often embarrassing. This embarrassment often causes patients to ignore the urge to defecate, which leads to constipation and discomfort. Remain sensitive to patients' elimination needs and intervene to help them maintain as normal bowel elimination habits as possible.

Cathartics and Laxatives. Some medications initiate and facilitate stool passage. Laxatives and cathartics have the short-term action of emptying the bowel. These agents are also used to cleanse the bowel for patients undergoing GI tests and abdominal surgery. Although the terms *laxative* and *cathartic* are often used interchangeably, cathartics generally have a stronger and more rapid effect on the intestines. Teach patients about the potential harmful effects of overuse of laxatives such as impaired bowel motility and decreased response to sensory

stimulus. Make sure patients understand that laxatives are not to be used long term for maintenance of bowel function.

Although patients usually take medications orally, laxatives prepared as suppositories may act more quickly because of their stimulant effect on the rectal mucosa. Suppositories such as bisacodyl act within 30 minutes. Give the suppository shortly before a patient's usual time to defecate or immediately after a meal.

Laxatives are classified by the method by which the agent promotes defecation (Table 47-2). Some newer drugs are being used now for chronic constipation or motility disorders. It is too soon to tell if these medications will be effective and safe for long-term treatment, but they are not used for the relief of occasional constipation.

Antidiarrheal Agents. Antidiarrheal agents decrease intestinal muscle tone to slow the passage of feces. As a result, the body absorbs more water through the intestinal walls. However, the cause of diarrhea must be determined before effective treatment can be ordered by a health care provider. For example, if an infection is the causative factor, an antibiotic may be used for treatment; or if inflammation is the cause, steroids may be given. The most commonly used antidiarrheal agents are loperamide or diphenoxylate with atropine. Codeine or tincture of opium may be used for management of chronic severe diarrhea in patients with diseases such as Crohn's disease, ulcerative colitis, and acquired immunodeficiency syndrome (AIDS). Patients need to use antidiarrheal agents that contain opiates with caution because opiates are habit forming.

Enemas. An enema is the instillation of a solution into the rectum and sigmoid colon. The primary reason for an enema is to promote defecation by stimulating peristalsis. The volume of fluid instilled breaks up the fecal mass, stretches the rectal wall, and initiates the defecation reflex. Enemas are also a vehicle for medications that exert a local effect on rectal mucosa. They are used most commonly for the immediate relief of constipation, emptying the bowel before diagnostic tests or surgery, and beginning a program of bowel training.

Cleansing Enemas. Cleansing enemas promote the complete evacuation of feces from the colon. They act by stimulating peristalsis through the infusion of a large volume of solution or through local irritation of the mucosa of the colon. They include tap water, normal saline, soapsuds solution, and low-volume hypertonic saline. Each solution has a different osmotic effect, influencing the movement of fluids between the colon and interstitial spaces beyond the intestinal wall. Infants and children receive only normal saline because they are at greater risk for fluid imbalance.

Tap Water. Tap water is hypotonic and exerts an osmotic pressure lower than fluid in interstitial spaces. After infusion into the colon, tap water escapes from the bowel lumen into interstitial spaces. The net movement of water is low. The infused volume stimulates defecation before large amounts of water leave the bowel. Use caution if ordered to repeat tap-water enemas because water toxicity or circulatory overload develops if the body absorbs large amounts of water.

Normal Saline. Physiologically normal saline is the safest solution to use because it exerts the same osmotic pressure as fluids in interstitial spaces surrounding the bowel. The volume of infused saline stimulates peristalsis. Giving saline enemas lessens the danger of excess fluid absorption.

Hypertonic Solutions. Hypertonic solutions infused into the bowel exert osmotic pressure that pulls fluids out of interstitial spaces. The colon fills with fluid, and the resultant distention promotes defecation. Patients unable to tolerate large volumes of fluid benefit most from this type of enema, which is by design low volume. This type of enema is contraindicated for patients who are dehydrated and young infants. A hypertonic solution of 120 to 180 mL (4 to 6 ounces) is

---

BOX 47-9   PROCEDURAL GUIDELINES

Assisting Patient On and Off a Bedpan

Delegation Considerations

The skill of assisting a patient onto a bedpan can be delegated to nursing assistive personnel (NAP). The nurse guides and assists the NAP in the proper way to position patients who have mobility restrictions. The nurse also instructs the NAP in how to position patients who have therapeutic equipment present such as drains, intravenous catheters, or traction.

Equipment

Appropriate type of clean bedpan; toilet tissue; specimen container (if necessary); washbasin; washcloths; towels; soap; waterproof, absorbent pads; clean drawsheet *(optional);* clean gloves

Steps

1. Assess the patient's level of mobility, strength, ability to help, and presence of any condition (e.g., orthopedic) that interferes with the use of a bedpan.
2. Explain the technique you will use in turning and positioning to the patient.
3. Offer the bedpan after meals because the patient may have an urge to defecate at that time.
4. Perform hand hygiene and apply clean gloves.
5. Close the room curtain for privacy.
6. Raise bed to a comfortable working height. Position patient high in bed with head elevated 30 degrees (unless contraindicated).
7. Fold back top linen to patient's knees.
8. Help with positioning an independent patient: Raise side rails. Instruct patient to bend knees, place weight on feet, grasp side rails, and lift hips while you slip bedpan into place.

9. Dependent patient: Raise side rail on side of bed opposite from nurse. Lower head of bed flat and roll patient onto side facing away from nurse. Apply powder lightly to lower back and buttocks *(optional).* Place bedpan firmly against buttocks (see illustration *A*). Push bedpan down into mattress with open rim toward patient's feet (see illustration *B*). Keeping one hand against bedpan, place other hand on patient's hip (see illustration *C*). Ask patient to roll onto pan, flat on bed. With patient positioned comfortably, raise head of bed 30 degrees.
10. Place rolled towel under lumbar curve of patient's back if needed for support.
11. Place call light and toilet tissue within patient's reach and keep side rails up as needed. Give patient time to defecate.
12. Remove bedpan as patient lifts hips up or carefully rolls off pan and to side. Hold pan firmly as patient moves.
13. Help to cleanse anal area. Wipe from pubic area toward anus. Replace top covers.
14. If you are collecting a specimen or recording urine output, do not dispose of tissue in bedpan.
15. Have patient wash and dry hands.
16. Empty contents of pan and rinse pan, dispose of gloves, and perform hand hygiene.
17. Inspect stool for color, amount, consistency, odor, or presence of abnormal substances. Document findings.

A   B   C

---

usually effective. The commercially prepared Fleet enema is the most common.

Soapsuds. You add soapsuds to tap water or saline to create the effect of intestinal irritation to stimulate peristalsis. Use only pure castile soap that comes in a liquid form included in most soapsuds enema kits. Use soapsuds enemas with caution in pregnant women and older adults because they could cause electrolyte imbalance or damage to the intestinal mucosa.

A health care provider sometimes orders a high- or low-cleansing enema. The terms *high* and *low* refer to the height from which, and hence the pressure with which, the fluid is delivered. High enemas

cleanse more of the colon. After the enema is infused, ask the patient to turn from the left lateral to the dorsal recumbent, over to the right lateral position. The position change ensures that fluid reaches the large intestine. A low enema cleanses only the rectum and sigmoid colon.

Oil Retention. Oil-retention enemas lubricate the feces in the rectum and colon. The feces absorb the oil and become softer and easier to pass. To enhance action of the oil, the patient retains the enema for several hours if possible.

Other Types of Enemas. Carminative enemas provide relief from gaseous distention. They improve the ability to pass flatus. An example

TABLE 47-2   Common Types of Laxatives and Cathartics

Agent/Brand Name	Action	Indications	Risks
Bulk Forming Methylcellulose (Citrucel) Psyllium (Metamucil, Naturacil) Polycarbophil (Fibercon)	High-fiber content absorbs water and increases solid intestinal bulk, which will stretch intestinal wall to stimulate peristalsis. Passage of stool will occur in 12 to 24 hours. These agents must be taken with water and should be used with patients who have an adequate food and fluid intake. Patients may note increased gas formation and flatus when they first start taking these laxatives, but this will abate after 4-5 days.	Agents are least irritating, most natural, and safest type of laxatives. Agents are drugs of choice for chronic constipation (e.g., pregnancy, low-residue diet). They also relieve mild diarrhea. If treating diarrhea, administer less water.	Agents that are in powder form could cause constipation if not mixed with at least 240 mL of water or juice and swallowed quickly. Caution is necessary with bulk-forming laxatives that also contain stimulants. Agents are not for patients for whom large fluid intake is contraindicated.
Emollient or Wetting Docusate sodium (Colace) Docusate calcium (Surfak) Docusate potassium (Dialose)	Stool softeners are detergents that lower surface tension of feces, allowing water and fat to penetrate. They increase secretion of water by intestine.	Agents are for short-term therapy to relieve straining on defecation (e.g., hemorrhoids, perianal surgery, pregnancy, recovery from myocardial infarction).	Agents are of little value for treatment of chronic constipation.
Osmotic Saline-based Magnesium citrate or citrate of magnesia Magnesium hydroxide (Milk of Magnesia) Sodium phosphate (Fleet Phospho-Soda) Polyethylene glycol, lactulose, sorbitol based, Lactulose, Miralax	Osmotic effect increases pressure in bowel to act as stimulant for peristalsis. Osmotic laxatives are any agents that pull fluid into the bowel to soften the stool and distend the bowel to stimulate peristalsis.	Saline-based agents are only for acute emptying of bowel (e.g., endoscopic examination, suspected poisoning, acute constipation). Agents may be used to treat chronic constipation.	Saline-based agents are not for long-term management of constipation or for patients with kidney dysfunction. They may cause toxic buildup of magnesium. Phosphate salts are not recommended for patients on fluid restriction.
Stimulant Cathartics Bisacodyl (Dulcolax) Castor oil Casanthranol (Peri-Colace) Correctol Senna (Ex-Lax, Senokot)	Agents cause local irritation to the intestinal mucosa, increase intestinal motility, and inhibit resorption of water in the large intestine. The rapid movement of feces causes retention of water in the stool. The drugs cause formation of a soft-to-liquid stool in 6 to 8 hours and usually contain bisacodyl or senna. These laxatives should be used occasionally because regular use of a stimulant laxative can lead to dependence on the stimulus for defecation.	Agents prepare bowel for diagnostic procedures or may be needed for those with constipation from frequent opioid use	Agents cause severe cramping. Agents are not for long-term use. Chronic use could cause fluid and electrolyte imbalances.

of a carminative enema is MGW solution, which contains 30 mL of magnesium, 60 mL of glycerin, and 90 mL of water.

Medicated enemas contain drugs. An example is sodium polystyrene sulfonate (Kayexalate), used to treat patients with dangerously high serum potassium levels. This drug contains a resin that exchanges sodium ions for potassium ions in the large intestine. Another medicated enema is neomycin solution, an antibiotic used to reduce bacteria in the colon before bowel surgery. An enema containing steroid medication may be used for acute inflammation in the lower colon.

Enema Administration. Enemas are available in commercially packaged, disposable units or with reusable equipment prepared before use. Sterile technique is unnecessary because the colon normally contains bacteria. However, wear gloves to prevent the transmission of fecal microorganisms.

Explain the procedure, including the position to assume, precautions to take to avoid discomfort, and length of time necessary to retain the solution before defecation. If a patient needs to take the enema at home, explain the procedure to a family member.

Giving an enema to a patient who is unable to contract the external sphincter poses difficulties. Give the enema with the patient positioned on the bedpan. Giving the enema with a patient sitting on the toilet is unsafe because the position of the rectal tubing could injure the rectal wall. Skill 47-1 on pp. 1170–1173 outlines the steps for an enema administration.

Digital Removal of Stool. For a patient with an impaction, the fecal mass is sometimes too large to pass voluntarily. If a digital rectal examination reveals a hard stool mass in the rectum, it may be necessary to manually remove it by breaking it up and bringing out a section at a time. Digital removal is the last resort in the management of severe constipation, but it may be necessary if the fecal mass is too large to pass through the anal canal. The procedure (Box 47-10) is very uncomfortable for the patient. Excess rectal manipulation causes irritation to the mucosa, bleeding, and stimulation of the vagus nerve, which sometimes results in a reflex slowing of the heart rate (Hussain et al., 2014).

Inserting and Maintaining a Nasogastric Tube. A patient's condition or situation sometimes requires special interventions to decompress the GI tract. Such conditions include surgery (see Chapter 50), obstruction of the GI tract often caused by tumors, trauma to the GI tract, and conditions in which peristalsis is absent.

A nasogastric (NG) tube is a pliable hollow tube that is inserted through the patient's nasopharynx into the stomach. NG intubation has several purposes (Table 47-3). There are two main categories of NG tubes: fine- or small-bore tubes and large-bore tubes. Small-bore tubes are frequently used for medication administration and enteral feedings (see Chapter 45 for enteral feedings). Large-bore tubes, 12-Fr and above, are usually used for gastric decompression or removal of gastric secretions. The Levin and Salem sump tubes are the most common for stomach decompression. The Levin tube is a single-lumen tube with holes near the tip. It is connected to a drainage bag or an intermittent suction device to drain stomach secretions.

The Salem sump tube is preferable for stomach decompression. The tube has two lumina: one for removal of gastric contents and one to provide an air vent. A blue "pigtail" is the air vent that connects with the second lumen. When the main lumen of the sump tube is connected to suction, the air vent permits free, continuous drainage of secretions. Do not clamp off the air vent if the tube is connected to suction.

NG tube insertion does not require sterile technique. Instead you use clean technique. The procedure is uncomfortable. Patients experience a burning sensation as the tube passes through the sensitive nasal mucosa. When it reaches the back of the pharynx, patients sometimes begin to gag. Help them relax to make tube insertion easier. Some institutions allow the use of Xylocaine jelly or atomized lidocaine when inserting the tube because it decreases patient discomfort during the procedure. The procedure for inserting an NG tube is described in Skill 47-2 on pp. 1174–1179.

One of the greatest problems in caring for a patient with a NG tube is maintaining comfort. Because the tube irritates the nasal and pharyngeal mucosa, you assess the condition of the patient's nares and throat for inflammation. The tape or fixation device used to anchor the tube often becomes soiled or loosened. Change it as needed to prevent migration of the tube. Frequent lubrication of the nares may minimize discomfort. With one nostril occluded, the patient breathes through the mouth. Frequent mouth care helps minimize discomfort from a dry mouth. Water-moistened swabs or lozenges for the patient to suck may provide some relief of mouth and throat dryness. Often patients complain of a sore throat. A health care provider may order gargles with topical Xylocaine jelly to minimize the irritation.

After you insert the tube, you need to maintain its patency. Sometimes the tip of the tubing rests against the stomach wall, or the tube becomes blocked with thick secretions. Flushing the tube

---

BOX 47-10   PROCEDURAL GUIDELINES

Digital Removal of Stool

Delegation Considerations

The skill of digitally removing stool cannot be delegated to nursing assistive personnel (NAP). In some institutions only health care providers perform this procedure. The nurse instructs the NAP:

- To provide perineal care and other necessary hygiene following each bowel movement.
- To observe any evacuated stool for color and consistency.

Equipment

Bedpan, waterproof pad, water-soluble lubricant, washcloths, towels, soap, and clean gloves

Steps

1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.
2. Perform hand hygiene, pull curtains around bed, obtain patient's baseline vital signs and assess level of comfort, and palpate for abdominal distention before the procedure.
3. Explain the procedure and help patient lie on left side in Sims' position with knees flexed and back toward you.
4. Drape trunk and lower extremities with a bath blanket and place a waterproof pad under buttocks. Keep a bedpan next to patient.
5. Perform hand hygiene and apply clean gloves; lubricate index finger of dominant hand with water-soluble lubricant.
6. Instruct patient to take slow, deep breaths. Gradually and gently insert index finger into the rectum, and advance the finger slowly along the rectal wall.
7. Gently loosen the fecal mass by massaging around it. Work the finger into the hardened mass.
8. Work the feces downward toward the end of the rectum. Remove small pieces one at a time and discard into bedpan.
9. Periodically reassess patient's pulse and look for signs of fatigue. Stop the procedure if pulse rate drops significantly (check agency policy) or rhythm changes.
10. Continue to clear rectum of feces and allow patient to rest at intervals.
11. After completion, wash and dry buttocks and anal area.
12. Remove bedpan; inspect feces for color and consistency. Dispose of feces. Remove gloves by turning them inside out and then discard.
13. Help patient to toilet or on a bedpan if urge to defecate develops.
14. Perform hand hygiene. Record results of procedure by describing fecal characteristics and amount.
15. Follow procedure with enemas or cathartics as ordered by health care provider.
16. Reassess patient's vital signs and level of comfort and observe status of abdominal distention.

---

regularly with a catheter-tipped syringe filled with normal saline or warm water helps to prevent blockage of the tube. If a NG tube does not drain properly after flushing, reposition it by advancing or withdrawing it slightly. Any change in tube position requires you to verify its placement in the patient's GI tract.

Continuing and Restorative Care. Regular elimination patterns should begin before a patient goes home or to an extended care facility. With a new ostomy, a patient and/or a caregiver need to learn to manage the care that is required (Box 47-11). Other patients require bowel retraining. It is important to remember that you initiate ostomy

TABLE 47-3 Purposes of Nasogastric Intubation

Purpose	Description	Type of Tube
Decompression	Removal of secretions and gaseous substances from gastrointestinal (GI) tract; prevention or relief of abdominal distention (Lewis et al., 2014)	Salem sump, Levin, Miller-Abbott
Enteral feeding (see Chapter 45)	Instillation of liquid nutritional supplements or feedings into stomach or small intestine for patients with impaired swallowing (Lewis et al., 2014)	Duo, Dobhoff, Levin
Compression	Internal application of pressure by means of inflated balloon to prevent internal esophageal or GI hemorrhage (Lewis et al., 2014)	Sengstaken-Blakemore
Lavage	Irrigation of stomach in cases of active bleeding, poisoning, or gastric dilation (Lewis et al., 2014)	Levin, Ewald, Salem sump

BOX 47-11 PATIENT TEACHING

Teaching Patients How to Provide Ostomy Care

Objective
- Patient/caregiver will demonstrate how to empty and change an ostomy pouch.

Teaching Strategies
- Provide a comprehensive list of the products needed to care for the ostomy (Prinz et al., 2015)
- Provide patient/caregiver with supplies to last 1 to 2 weeks and the contact number information for a medical supply company (Prinz et al., 2015)
- Show patient/caregiver the step-by-step approach for changing an ostomy pouch.
- Provide at least one opportunity for patient/caregiver to empty and change the ostomy pouch while patient is in the hospital (Prinz et al., 2015)
- Provide detailed instructions for diet, fluids, peristomal skin care, restrictions on lifting, resuming exercise, intimacy, and when to contact the health care provider (Prinz et al., 2015).
- Arrange follow-up with an ostomy nurse if possible.

Evaluation
- Observe patient/caregiver change ostomy pouch.
- Ask patient/caregiver to teach back instructions given.

BOX 47-12 EVIDENCE-BASED PRACTICE

Recognition of Peristomal Skin Problems

PICO Question: In patients with ostomies, what is the effect of patient education and knowledge on the prevention of peristomal skin breakdown?

Evidence Summary
Patients with an ostomy are at risk for development of peristomal skin problems. In a study looking at patients with an ostomy in the first 3 months after surgery, 63% developed peristomal skin breakdown (Salvadena, 2013). Maintenance of healthy peristomal skin, with the skin around the stoma being clean, dry, and intact, is a priority following ostomy surgery (Goldberg et al., 2010). The most common cause of peristomal skin disorders is effluent, which causes skin irritation, ulceration, or erosion. Reasons for effluent leakage include poor-fitting stoma pouches, poor adhesive adherence, peristomal hernia, and surgical complications (Williams et al., 2010). With shorter postoperative hospital stays, it is challenging for nurses to provide the extensive patient education on pouching systems, ostomy care, and problem-solving techniques needed to prevent peristomal skin problems (Pittman et al., 2014). Patients often failed to recognize early signs of skin irritation and did not report a skin problem (Erwin-Toth et al., 2012). This lack of knowledge resulted in patients delaying to seek health care to treat the skin problem. Patient education is an important factor in preventing complications following ostomy surgery. Nurses need to provide education to patients before discharge and follow up with them after discharge to prevent peristomal skin problems (Prinz et al., 2015).

Application to Nursing Practice
- Evaluate patients' knowledge and ability to assess their peristomal skin changes for early recognition and treatment of skin disorders.
- Provide patient education about signs and symptoms of skin disorders to ensure early identification of skin problems.
- Refer patients to an ostomy nurse if assistance is needed to manage the ostomy (Erwin-Toth et al., 2012)

important because the effluent has digestive enzymes that cause irritant dermatitis if there is leakage on the peristomal skin. Other peristomal skin problems are fungal rashes, folliculitis, or ulcerations. Refer patients with these problems to an ostomy care nurse (Goldberg et al., 2010) (Box 47-12).

Irrigating a Colostomy. Although this practice is not as common because of improved odor-proof pouches, some patients irrigate their sigmoid colostomies to regulate colon emptying. This process takes about an hour a day to complete but usually means that a patient wears only a mini-pouch afterward to absorb mucus from the stoma and contain gas. Specific equipment designed for ostomies is used. The equipment has a silicone cone attached by plastic tubing to a bag that will hold the irrigation fluid, which is usually warm water. Follow the routine that the patient has established for this care. Occasionally a patient with a colostomy who has constipation will have an irrigation or enema ordered. Use equipment that is designed specifically for the irrigation rather than an enema administration set used by patients without a stoma.

Pouching Ostomies. An ostomy requires a pouch to collect fecal material. An effective pouching system protects the skin, contains fecal material, remains odor free, and is comfortable and inconspicuous. A person wearing a pouch needs to feel secure enough to participate in any activity (Goldberg et al., 2010).

Many pouching systems are available. To ensure that a pouch fits well and meets a patient's needs, consider the location of the ostomy, type and size of the stoma, type and amount of ostomy drainage, size

care and bowel retraining in acute care settings. However, because these are long-term care needs, teaching usually continues in restorative care or home settings.

Care of Ostomies. Patients with temporary or permanent bowel diversions have unique elimination needs. An individual with an ostomy wears a pouch to collect effluent or output from the stoma. The pouches are odor proof and have a protective skin barrier surrounding the stoma. Empty the pouch when it is $\frac{1}{3}$ to $\frac{1}{2}$ full. Change the pouching system approximately every 3 to 7 days, depending on a patient's individual needs (Goldberg et al., 2010). Assess the stoma color. It should be pink or red. You observe the skin at each pouch change for signs of irritation or skin breakdown. Skin protection is

FIGURE 47-12 Ostomy pouches and skin barriers. **A,** SenSura® one-piece pouch with Velcro closure. **B,** SenSura® two-piece pouching system with separate skin barrier and attachable pouch. Note: Skin barriers need to be custom cut according to stoma size. (Courtesy Coloplast, Minneapolis, Minn.)

BOX 47-13   FOCUS ON OLDER ADULTS

Bowel Retraining

- Older age is a risk factor for having constipation.
- Increase fiber in diet with whole grains, legumes, fruits, and vegetables.
- A minimum of 1500 mL of fluid per day reduces the risk of constipation, with increased fluid needs during summer months and for those on diuretics with stable cardiovascular status.
- If holding a drinking cup is a problem, consider using a lighter plastic cup and filling half full, refilling frequently.
- Encourage regular exercise within the limitations imposed by other conditions.
- Patients need to feel at ease during elimination. Lack of privacy leads a patient to ignore the urge to defecate.
- Review all medications with a patient's health care provider to substitute medications that are less likely to cause constipation whenever possible.
- Behavioral interventions such as timed toileting helps establish a scheduled time for bowel elimination. Try to maintain the same schedule each day for toileting.

---

and contour of the abdomen, condition of the skin around the stoma, physical activities of the patient, patient's personal preference, age and dexterity, and cost of equipment. A **wound, ostomy and continence nurse (WOCN)** is a nurse specially educated to care for ostomy patients. A WOCN collaborates with staff nurses and patients to be sure that the patients have the best pouching system for their individual needs. A pouching system consists of a pouch and skin barrier (Figure 47-12). Pouches come in one- and two-piece systems and are flat or convex. Some pouches have the opening precut by the manufacturer; others require the stoma opening to be custom cut to a patient's specific stoma size. Newer pouches have an integrated closure; older ones use a clip to close the pouch. One of the first skills to teach a patient with a new ostomy is how to open and close the pouch. Skill 47-3 on pp. 1179–1181 describes steps for applying an ostomy pouch.

Nutritional Considerations. After surgery it usually takes a few days for patients with new ostomies to feel that their appetite has returned to normal. Small servings of soft foods are typically more appetizing as they would be for any patient who has had an abdominal surgery.

Patients with colostomies have no diet restrictions other than the diet discussed for normal healthy bowel function, with adequate fiber and fluid to keep the stool softly formed. Patients with ileostomies digest their food completely but lose both fluid and salt through their stoma and need to be sure to replace this to avoid dehydration. A good reminder for patients is to encourage drinking an 8-ounce glass of fluid when they empty their pouch. This helps them remember that they have greater fluid needs than they did before having an ileostomy. A condition that occurs infrequently with people with ileostomies is called a *food blockage*. Foods with indigestible fiber such as sweet corn, popcorn, raw mushrooms, fresh pineapple, and Chinese cabbage can cause this problem. However, if patients eat these foods in small quantities, drink fluids with the food and chew it well, they are unlikely to experience any difficulty.

Psychological Considerations. After ostomy surgery patients face a variety of anxieties and concerns, from learning how to manage their stoma to coping with conflicts of self-esteem, body image, and sexuality. Provide emotional support before and after surgery (Goldberg et al., 2010). Adjustment to a stoma takes time and is a very individual matter. A study of patients with colorectal cancer and a colostomy showed that the lowest quality of life after ostomy surgery occurred at 2 months, with improvement at 6 months and return to almost

preoperative levels at 12 months (Li, 2014). Important factors affecting adjustment to the stoma include the ability to successfully assume care of the ostomy, including emptying the pouch and changing the pouching system so unexpected odor and leakage of stool does not occur. Inability to resume self-care sometimes causes a loss of self-esteem. The aging process often affects the ability to manage stomas, even in people who have had them for years. You need to recognize and intervene when problems resulting from advanced age such as skin changes, weight loss or gain, visual impairments, or changes in diet occur. If possible, consult with an ostomy nurse. The Wound, Ostomy and Continence Nurses Society (http://www.wocn.org) provides information and helps patients locate a WOCN. Consider referral to local ostomy groups such as those affiliated with the United Ostomy Associations of America at http://www.uoaa.org.

Bowel Training. A patient with chronic constipation or fecal incontinence secondary to cognitive impairment may benefit from **bowel training**, also called *habit training*. The training program involves setting up a daily routine. By attempting to defecate at the same time each day and using measures that promote defecation, a patient may establish a normal defecation pattern. The program requires time, patience, and consistency. A patient with cognitive impairment needs to have a caregiver able to devote the time to the training program. A successful program includes the following:

- Assessing the normal elimination pattern and recording times when a patient is incontinent
- Incorporating principles of gerontological nursing when providing bowel retraining programs for an older adult (Box 47-13)
- Choosing a time based on the patient's pattern to initiate defecation-control measures
- Offering a hot drink (hot tea) or fruit juice (prune juice) (or whatever fluids normally stimulate peristalsis for the patient) before the defecation time
- Helping the patient to the toilet at the designated time
- Providing privacy
- Instructing the patient to lean forward at the hips while sitting on the toilet, apply manual pressure with the hands over the abdomen, and bear down but not strain to stimulate colon emptying
- An unhurried environment and a nonjudgmental caregiver
- Maintaining normal exercise within the patient's physical ability

Maintenance of Proper Fluid and Food Intake. In choosing a diet for promoting normal elimination, consider the frequency of defecation, characteristics of feces, and types of foods that impair or promote defecation. A well-balanced diet with whole grains, legumes, fresh fruits, and vegetables eaten regularly promotes normal elimination. Fiber adds bulk to the stool, eliminates excess fluids, and promotes more frequent and regular movements. With increasing fiber it is important to drink enough fluids. If fluid intake is inadequate, the stool becomes hard because less water is retained in the large intestine to soften it. The amount of fiber and fluids necessary for optimal bowel function varies among individuals. Consulting a dietitian may be helpful if a patient has chronic problems with constipation.

When a patient has diarrhea, low-residue foods such as white rice, potatoes, bread, bananas, and cooked cereals are recommended until the diarrhea is controlled. Discourage foods that typically cause gastric upset or abdominal cramping. Diarrhea caused by illness is sometimes debilitating. If the patient cannot tolerate foods or liquids orally, intravenous therapy with electrolyte replacement is necessary. The patient returns to a normal diet slowly, often beginning with fluids.

Promotion of Regular Exercise. A daily exercise program helps prevent elimination problems. Walking, riding a stationary bicycle, or swimming stimulates peristalsis. It is recommended by the American Heart Association and the Centers for Disease Control and Prevention that adults get at least 150 minutes of exercise each week.

For a patient temporarily immobilized, attempt ambulation as soon as possible. If the condition permits, help the patient walk to a chair on the evening of the day of surgery and encourage him or her to walk a little more each day.

Management of the Patient with Fecal Incontinence or Diarrhea. You may apply a fecal collector around the anal opening if the skin is intact. These can be difficult to apply when there is a deep fold between the buttocks and there is hair in the area; but it may be considered if a patient is having very frequent liquid stools. There are also fecal-management systems available for short-term use with high-volume diarrhea. They are intended for use primarily in acute care settings. The devices have an intra-anal soft silicone catheter with a retention balloon much like a Foley catheter for insertion into the rectal vault to divert liquid stool away from the skin in immobilized patients. The catheter is connected to a drainage bag for collection of the liquid fecal effluent (Bliss and Norton, 2010). Refer to package insertion instructions and agency policies for appropriate use.

Maintenance of Skin Integrity. A patient with diarrhea, fecal incontinence, or an ileostomy is at risk for skin breakdown when fecal contents remain on the skin. Liquid stool usually contains digestive enzymes, which causes rapid skin breakdown. Irritation from repeated wiping with toilet tissue or frequent ostomy pouch changes further irritate the skin. Meticulous perianal skin care and frequent removal of fecal drainage is necessary to prevent skin breakdown (see Chapter 48). Clean the skin with a no-rinse cleanser and apply a barrier ointment after each episode of diarrhea. If a patient is incontinent, check on the patient frequently and change absorbent products immediately after providing thorough but gentle skin cleansing. Patients with ostomies are often unaware of the skin irritation under their ostomy wafer or think that this is a normal part of having an ostomy. Education about skin breakdown and its management are important roles for the ostomy nurse (see Box 47-12).

◆ **Evaluation**

Through the Patient's Eyes. The effectiveness of care depends on success in meeting the expected outcomes of self-care. Optimally a patient will be able to have regular, pain-free defecation of soft-formed

Knowledge
- Characteristics of normal bowel elimination pattern
- Expected results of cathartics, laxatives, or enemas

Experience
- Previous patient responses to planned nursing therapies for improving bowel elimination (what worked and what did not work)

EVALUATION
- Observe characteristics of stool and evaluate defecation pattern
- Observe for signs and symptoms of altered elimination
- Ask patient to report perception of bowel elimination patterns following interventions
- Ask if the patient's expectations are being met

Standards
- Use established expected outcomes to evaluate the patient's response to care (e.g., bowel movement within 24 hours)
- Apply intellectual standards of relevance, accuracy, specificity, significance, and completeness when evaluating outcomes of care

Attitudes
- Be creative when developing new interventions
- Display integrity when identifying those interventions that were not successful

FIGURE 47-13 Critical thinking model for elimination evaluation.

stools. The patient or caregiver is the only one who is able to determine if the bowel elimination problems have been relieved and which therapies were the most effective (Figure 47-13).

Patient Outcomes. When you establish a therapeutic relationship with a patient, the patient feels comfortable to discuss the intimate details often associated with bowel elimination. Patients are less embarrassed as you help them with elimination needs. Patients relate feelings of comfort and freedom from pain as elimination needs are met within the limits of their condition and treatment. Evaluate a patient's level of knowledge regarding establishing a normal elimination pattern, caring for an ostomy, and promoting skin integrity. Also determine the extent to which the patient accomplishes normal defecation. Ask the patient to describe changes in diet, fluid intake, and activity to promote bowel health. Ask the following questions when the patient's expected outcome has not been achieved:

- Do you use medications such as laxatives or enemas to help you defecate? How often?
- Which barriers prevent you from eating a diet high in fiber and participating in regular exercise?
- How much fluid do you drink in a typical day? Which types of fluids do you normally drink?
- What challenges do you encounter when you change your ostomy pouch?

SAFETY GUIDELINES FOR NURSING SKILLS

Ensuring patient safety is an essential role of the professional nurse. To ensure patient safety, communicate clearly with members of the health care team, assess and incorporate the patient's priorities of care and preferences, and use the best evidence when making decisions about your patient's care. When performing the skills in this chapter, remember the following points to ensure safe, individualized, patient care:

- Instruct patients who self-administer enemas to use the side-lying position. Tell them not to self-administer an enema while sitting on the toilet because

this position results in the rectal tubing causing friction that could injure the rectal wall.

- If a patient has cardiac disease or is taking cardiac or hypertensive medication, obtain a pulse rate, because manipulation of rectal tissue stimulates the vagus nerve and sometimes causes a sudden decline in pulse rate, which increases the patient's risk of fainting while on the bedpan, bedside commode, or toilet.

SKILL 47-1   ADMINISTERING A CLEANSING ENEMA

DELEGATION CONSIDERATIONS

The skill of administering an enema can be delegated to nursing assistive personnel (NAP). It is the nurse's responsibility to assess the patient for specific considerations such as need for alternative positioning, comfort, and stable vital signs before the procedure. Instruct NAP about:

- Proper ways to position patients who have mobility restrictions.
- Positioning of patients with therapeutic equipment present such as drains, intravenous (IV) catheters, or traction.
- Signs and symptoms of patient not tolerating the procedure and when to stop it, including abdominal pain more than a pressure sensation, abdominal cramping, abdominal distention, or rectal bleeding.
- The expected outcome of the enema and to immediately inform the nurse about the presence of blood in the stool or around the rectal area, any change in patient vital signs, or new symptoms so the nurse is able to assess the patient further.

EQUIPMENT

- Clean gloves
- Water-soluble lubricant
- Waterproof, absorbent pads
- Bath blanket
- Toilet tissue
- Bedpan, bedside commode, or access to toilet
- Basin, washcloths, towel, and soap
- IV pole

ENEMA BAG ADMINISTRATION

- Clean gloves
- Enema container with tubing and clamp attachment
- Appropriate-size rectal tube:
  - Adult: 22 to 30 Fr
  - Child: 12 to 18 Fr
- Correct volume of warmed solution:
  - Adult: 750 to 1000 mL
  - Child:
    - 150 to 250 mL, infant
    - 250 to 350 mL, toddler
    - 300 to 500 mL, school-age child
    - 500 to 700 mL, adolescent

ENEMA ADMINISTRATION

An enema container with rectal tip (Figure 47-14).

FIGURE 47-14 Prepackaged enema container with rectal tip.

STEP	RATIONALE
ASSESSMENT	
1. Assess status of patient: last bowel movement, normal versus most recent bowel pattern, presence of hemorrhoids, mobility, and presence of abdominal pain.	Determines factors indicating need for enema and influencing type of enema used. Also establishes a baseline for bowel function.
2. Review medical record for presence of increased intracranial pressure, glaucoma, or recent abdominal, rectal, or prostate surgery.	These conditions contraindicate use of enemas.
3. Inspect abdomen for presence of distention.	Provides a baseline for determining effectiveness of the enema.
4. Determine patient's level of understanding of purpose of enema.	Allows you to plan for appropriate teaching measures.
5. Review the health care provider's order for type of enema and number to administer.	Enemas require a health care provider's order. Determines number and type of enema you will give.

CLINICAL DECISION: *"Enemas until clear" order means that you repeat enemas until patient passes fluid that is clear of fecal matter. Check agency policy, but usually patients receive no more than three consecutive enemas to avoid disruption of fluid and electrolyte balance. It is essential to observe contents of solution passed. Consider the results "clear" when no solid fecal material exists but the solution is sometimes colored.*

STEP	RATIONALE
PLANNING	
1. Collect appropriate equipment.	
2. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
3. Assemble enema bag with appropriate solution and rectal tube if enema administration set does not have tube integrated into kit.	The proper equipment promotes the best outcome from the procedure.
IMPLEMENTATION	
1. Perform hand hygiene and apply clean gloves.	Reduces transmission of microorganisms.
2. Provide privacy by closing curtains around bed or closing door.	Reduces embarrassment for patient.
3. Raise bed to appropriate working height for nurse: Stand on right side of bed and raise side rail on opposite side.	Promotes good body mechanics and patient safety.
4. Help patient into left side-lying (Sims') position with right knee flexed. Children may also be placed in dorsal recumbent position.	Positioning allows enema solution to flow downward by gravity along natural curve of sigmoid colon and rectum, thus improving retention of solution.

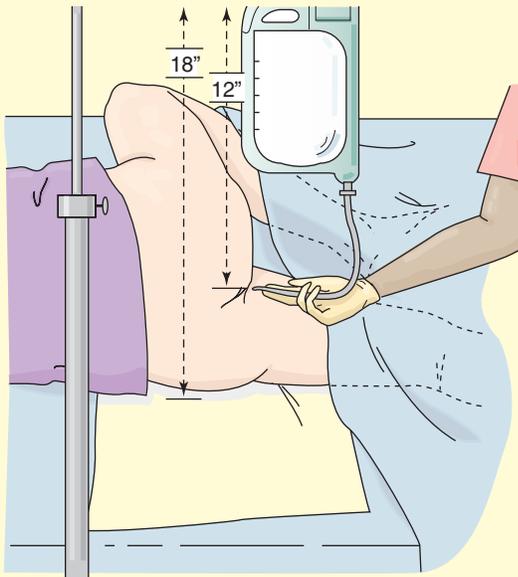
CLINICAL DECISION: *If you suspect the patient has poor sphincter control, position on bedpan in a comfortable dorsal recumbent position. Patients with poor sphincter control are unable to retain all of the enema solution. Administering an enema with the patient sitting on the toilet is unsafe because it is impossible to safely guide the tubing into the rectum, and it will be difficult for the patient to retain the fluid as he or she is in the position used for emptying the bowel.*

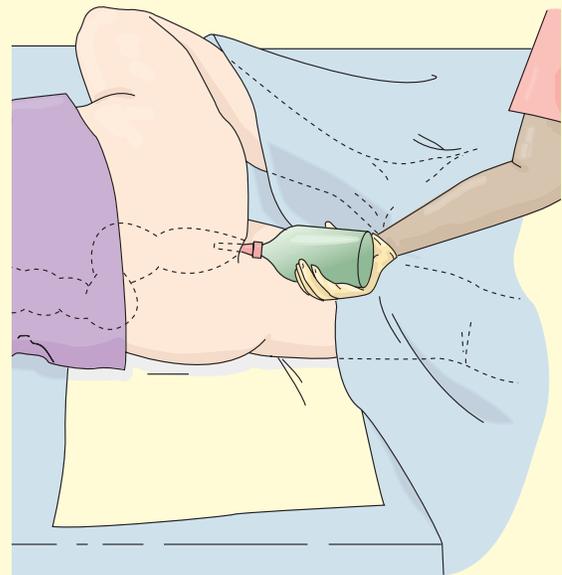
STEP	RATIONALE
5. Place waterproof pad under hips and buttocks.	Prevents soiling of linen.
6. Cover patient with bath blanket, exposing only rectal area, clearly visualizing anus. Separate buttocks and examine perianal region for abnormalities, including hemorrhoids, anal fissure, and rectal prolapse (protrusion of the colon through the anal opening).	Provides warmth, reduces exposure of body parts, and allows patient to feel more relaxed and comfortable. Findings will influence approach to insert enema tip. An enema is contraindicated if there is a prolapse.
7. Place bedpan or commode in easily accessible position. If patient will be expelling contents in toilet, ensure that toilet is free. (If patient will be getting up to go to bathroom to expel enema, place his or her slippers and bathrobe in easily accessible position.)	Try to avoid incontinence of the stool and enema fluid to avoid discomfort and psychological stress.
8. Administer enema:	
a. Enema bag	
(1) Add warmed solution to enema bag: warm tap water as it flows from faucet, place saline container in basin of hot water before adding saline to enema bag, and check temperature of solution by pouring small amount of solution over inner wrist. If soapsuds enema is ordered, add castile soap.	Hot water will burn intestinal mucosa. Cold water causes abdominal cramping and is difficult to retain.
(2) Raise container, release clamp, and allow solution to flow long enough to fill tubing.	Removes air from tubing.
(3) Reclamp tubing.	Prevents further loss of solution.
(4) Lubricate 6 to 8 cm (2½ to 3 inches) of tip of rectal tube with water-soluble lubricating jelly.	Allows smooth insertion of rectal tube without risk for irritation or trauma to mucosa.
(5) Gently separate buttocks and locate anus. Instruct patient to relax by breathing out slowly through mouth.	Breathing out promotes relaxation of external anal sphincter.

SKILL 47-1	**ADMINISTERING A CLEANSING ENEMA—cont'd**

STEP	**RATIONALE**
(6) Insert tip of enema tube slowly by pointing tip in direction of patient's umbilicus. Length of insertion varies: adult and adolescent: 7.5 to 10 cm (3 to 4 inches); child: 5 to 7.5 cm (2 to 3 inches); infant: 2.5 to 3.75 cm (1 to 1½ inch).	Careful insertion prevents trauma to rectal mucosa from accidental lodging of tube against rectal wall. Insertion beyond proper limit causes bowel damage.

CLINICAL DECISION: *If pain occurs or resistance is felt during the procedure, stop the instillation of the fluid and confer with health care provider. Do not force tube into rectum.*

STEP	**RATIONALE**
(7) Hold tubing in rectum constantly until end of fluid instillation.	Bowel contraction causes expulsion of rectal tube.
(8) Open regulating clamp and allow solution to enter slowly while holding container at patient's hip level.	Rapid instillation stimulates evacuation of rectal tube.
(9) Raise height of enema container slowly to appropriate level above anus: 30 to 45 cm (12 to 18 inches) for high enema, 30 cm (12 inches) for regular enema, 7.5 cm (3 inches) for low enema. Instillation time varies, depending on volume of solution you administer (e.g., 1 L/10 min) (see illustration).	Allows for continuous, slow instillation of solution; raising container too high causes rapid instillation and possible painful distention of colon.
(10) Lower container or clamp tubing if patient complains of cramping or if fluid escapes around rectal tube.	Temporarily stopping instillation prevents cramping, which prevents patient from retaining all fluid, altering the effectiveness of enema.
(11) Clamp tubing after you instill all solution.	Prevents air from entering rectum.
b. Prepackaged disposable container	
(1) Remove plastic cap from rectal tip. Apply more jelly as needed to the prelubricated tip.	Lubrication provides for smooth insertion of rectal tube without causing rectal irritation or trauma.
(2) Gently separate buttocks and locate rectum. Instruct patient to relax by breathing out slowly through mouth.	Breathing out promotes relaxation of external rectal sphincter.
(3) Expel air from the enema container.	Introducing air into colon causes further distention and discomfort.
(4) Insert tip of bottle gently into rectum toward the umbilicus (see illustration). *Adult/adolescent:* 7.5 to 10 cm (3 to 4 inches) *Child:* 5 to 7.5 cm (2 to 3 inches) *Infant:* 2.5 to 3.75 cm (1 to 1½ inches)	Gentle insertion prevents trauma to rectal mucosa.
(5) Squeeze bottle until all solution has entered rectum and colon. Instruct patient to retain solution until urge to defecate occurs, usually 2 to 5 minutes.	Hypertonic solutions require only small volumes to stimulate defecation.


STEP 8a(9) An enema is given in the Sims' position. The IV pole is positioned so the enema bag is 12 inches above the anus and approximately 18 inches above the mattress (depending on patient's size). (From Sorrentino SA: *Mosby's textbook for nursing assistants*, ed 8, St Louis, 2012, Mosby.)


STEP 8b(4) Insertion of enema tube into rectum. (From Sorrentino SA: *Mosby's textbook for nursing assistants*, ed 8, St Louis, 2012, Mosby.)

STEP	RATIONALE
9. Place layers of toilet tissue around tube at anus and gently withdraw rectal tube.	Provides for patient's comfort and cleanliness.
10. Explain to patient that a feeling of distention and some abdominal cramping are normal. Ask patient to retain solution as long as possible while lying quietly in bed. (For infant or young child, gently hold buttocks together for few minutes.)	Solution distends bowel. Length of retention varies with type of enema and patient's ability to contract rectal sphincter. Longer retention promotes more effective stimulation of peristalsis and defecation.
11. Discard enema container and tubing in proper receptacle or rinse bag out thoroughly with warm soap and water if container is reusable.	Reduces transmission and growth of microorganisms.
12. Help patient to bathroom or help to position patient on bedpan.	Normal sitting position promotes defecation.
13. Help patient as needed to wash anal area with warm water, premoistened perineal wipe, or no-rinse perineal cleanser. (If you administer perineal care, use clean gloves.)	Fecal contents irritate skin. Hygiene promotes patient's comfort.
14. Remove and discard gloves and perform hand hygiene.	Reduces transmission of microorganisms.

EVALUATION

1. Observe character of feces and solution evacuated. (Caution patient against flushing toilet before inspection.) Inspect color, consistency, amount of stool, odor, and fluid passed.	Determines if stool is evacuated or fluid is retained. Note abnormalities such as presence of blood or mucus.
2. Assess condition of abdomen; cramping, rigidity, or distention indicates a serious problem.	Determines if distention is relieved. Excess volume distends or damages the bowel.
3. Use **_Teach Back_** to determine patient's and family's understanding about the reason for the enema. State, "I want to be sure I explained how the enema works to clean your bowel. Can you explain to me why the enema is being given to you?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient is able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Abdomen becomes rigid and distended, and patient complains of severe pain.
- Stop enema.
- Notify health care provider.
- Obtain vital signs.

2. Abdominal pain or cramping develops.
- Slow rate of instillation; have patient take slow, deep breaths.

3. Bleeding develops.
- Stop enema.
- Notify health care provider.
- Remain with patient and obtain vital signs.

RECORDING AND REPORTING

- Record type and volume of enema given, time administered, characteristics of results, and patient's tolerance to the procedure in nurses' notes.
- Report failure of patient to defecate and any adverse effects to health care provider.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- For patients who require enemas at home, instruct family not to exceed recommended fluid volume levels or number of enemas. Instruct family about need for slow administration of warmed fluid.
- Place waterproof padding on the bed.
- Instruct family members not to give the enema on the toilet.

SKILL 47-2   INSERTING AND MAINTAINING A NASOGASTRIC TUBE FOR GASTRIC DECOMPRESSION

DELEGATION CONSIDERATIONS

The skill of inserting and maintaining a nasogastric (NG) tube cannot be delegated to nursing assistive personnel (NAP). Instruct the NAP to:

- Measure and record the drainage.
- Provide oral and nasal hygiene.
- Perform selected comfort measures such as positioning and offering ice chips if allowed.
- Correctly anchor NG tube to patient's gown after changing gown or repositioning patient.

EQUIPMENT

- Inserting large-bore tube
  - 14- or 16-Fr NG tube (smaller lumens are not used for decompression in adults because the tube must be able to remove thick secretions)
  - Water-soluble lubricating jelly
  - Clean gloves
  - pH test strips (measure gastric aspirate acidity)
  - Tongue blade
  - Flashlight
  - Emesis basin
  - Asepto bulb or catheter-tipped syringe
  - Normal saline
  - 2.5 cm (1 inch)–wide hypoallergenic tape or commercial fixation device
  - Tincture of benzoin (optional)
  - Safety pin and rubber band
  - Clamp of suction machine and pressure gauge if wall suction is used
  - Towel, facial tissues
  - Glass of water with straw
- Irrigating NG tube
  - Asepto bulb or catheter-tipped syringe
  - Normal saline and basin
  - Clean gloves
- Discontinuing NG tube
  - Towel, facial tissue
  - Clean gloves
  - Soap and water

STEP	RATIONALE
ASSESSMENT	
1. Perform hand hygiene.	Good hygiene reduces transmission of organisms.
2. Inspect condition of patient's nasal and oral cavity.	Baseline condition of nasal and oral cavity determines need for special nursing measures for oral hygiene after tube placement.
3. Ask if patient has had history of nasal surgery and note if deviated nasal septum is present.	Insert tube into uninvolved nasal passage. Procedure is often contraindicated if surgery is recent.
4. Auscultate for bowel sounds. Palpate patient's abdomen for distention, pain, and rigidity.	Baseline determination of level of abdominal distention later serves as comparison once tube is inserted. In presence of diminished or absent bowel sounds, auscultate each quadrant for 5 minutes.
5. Assess patient's level of consciousness and ability to follow instructions.	Assessment determines patient's ability to help in procedure.

CLINICAL DECISION: *If patient is confused, disoriented, or unable to follow commands, obtain assistance from another staff member to insert the tube.*

PLANNING	
1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
2. Explain procedure.	Explanation gains patient's cooperation and lessens possibility that patient will remove tube.
3. Determine if patient had an NG tube insertion in the past and, if so, which naris was used.	Previous experience complements explanations and helps you determine which naris to use.
4. Check medical record for health care provider's order; type of NG tube to be placed; and whether tube is to be attached to suction, gravity, or feeding solution.	Procedure requires health care provider's order. Adequate decompression depends on NG suction.
5. Prepare equipment at bedside. Cut a piece of tape about 10 cm (4 inches) long and split one end in half to form a V or have NG tube fixator device available.	Ensures well-organized procedure. Tape or fixator device is used to hold tube in place after insertion.

IMPLEMENTATION	
1. Position patient in high-Fowler's position with pillows behind head and shoulders. Raise bed to horizontal level comfortable for nurse.	Promotes patient's ability to swallow during procedure. Positioning of bed prevents strain on nurse.

STEP	RATIONALE
2. Have patient blow nose. Place bath towel over his or her chest; give him or her facial tissues. Place emesis basin within reach.	Removes existing nasal secretions. Prevents soiling of patient's gown. Tube insertion through nasal passages sometimes causes tearing and coughing with increased salivation.
3. Pull curtain around bed or close room door.	Provides privacy.
4. Stand on patient's right side if right-handed, left side if left-handed.	Allows easiest manipulation of tubing.
5. Perform hand hygiene and apply clean gloves.	Reduces transmission of microorganisms.
6. Instruct patient to relax and breathe normally while occluding one naris. Repeat this action for other naris. Select nostril with greater airflow.	Tube passes more easily through naris that is more patent. Ensures that tube insertion does not obstruct nasal airflow.
7. Measure distance to insert tube:	Approximates distance from naris to stomach. Distance varies with each patient.
a. Traditional method: Measure distance from tip of nose to earlobe to xiphoid process (see illustration).	
b. Hanson method: Mark 50-cm (20-inch) point on tube and measure traditionally. Tube insertion is at midway point between 50 cm (20 inches) and traditional mark.	
8. Mark length of tube to be inserted by placing small piece of tape so it can be removed easily.	Marks amount of tube to be inserted from nares to stomach (Miller et al., 2014).
9. Curve 10 to 15 cm (4 to 6 inches) of end of tube tightly around index finger and release.	Curving tube tip aids insertion and decreases tube stiffness.
10. Lubricate 7.5 to 10 cm (3 to 4 inches) of end of tube with water-soluble lubricating jelly.	Minimizes friction against nasal mucosa and aids insertion of tube. Water-soluble lubricant is less toxic than oil-based if aspirated.
11. Initially instruct patient to extend neck back against pillow (see illustration); insert tube gently and slowly through naris, aiming end of tube downward.	Facilitates initial passage of tube through naris and maintains clear airway for open naris.
12. Continue to pass tube along floor of nasal passage, aiming downward toward patient's ear. If resistance is met, apply gentle downward pressure to advance tube. (Do not force past resistance.)	Minimizes discomfort of tube rubbing against upper nasal turbinates. Resistance is caused by posterior nasopharynx. Downward pressure helps tube curl around corner of nasopharynx.
13. If you meet resistance, try to rotate tube and see if it advances. If still resistant, withdraw tube, allow patient to rest, re-lubricate tube, and insert into other naris.	Forcing against resistance causes trauma to mucosa. Helps relieve patient's anxiety.

CLINICAL DECISION: *If unable to insert tube in either naris, stop procedure and notify health care provider.*

STEP	RATIONALE
14. Continue inserting tube until just past nasopharynx by gently rotating it toward opposite nostril and passing it just above oropharynx.	Helps prevent coiling of tube in oropharynx.
a. Stop tube advancement, allow patient to relax, and provide tissues.	Relieves patient's anxiety; tearing is natural response to mucosal irritation, and excessive salivation often occurs because of oral stimulation.
b. Explain to patient that next step requires that he or she swallow. Give patient glass of water unless contraindicated.	Sipping water aids passage of NG tube into esophagus.

STEP 7a Technique for measuring distance to insert NG tube.

STEP 11 Insert nasogastric tube with curved end pointing downward.

SKILL 47-2	INSERTING AND MAINTAINING A NASOGASTRIC TUBE FOR GASTRIC DECOMPRESSION—cont'd

STEP	RATIONALE
15. With tube just above oropharynx, instruct patient to flex head forward, take a small sip of water, and swallow. Advance tube 2.5 to 5 cm (1 to 2 inches) with each swallow of water. If patient is not allowed fluids, instruct to dry swallow or suck air through straw.	Flexed position closes off upper airway to trachea and opens esophagus. Swallowing closes epiglottis over trachea and helps move tube into esophagus. Swallowing water reduces gagging or choking. Suction removes water from stomach once it is connected.
16. If patient begins to cough, gag, or choke, withdraw tube slightly (do not remove it) and stop tube advancement. Instruct patient to breathe easily and take sips of water.	Sometimes tube accidentally enters larynx and produces coughing; withdrawal of tube reduces risk of laryngeal entry. Swallowing water eases gagging. Give water cautiously to reduce risk of aspiration.

CLINICAL DECISION: *If vomiting occurs, help patient clear airway; use oral suctioning if needed. Do not proceed until airway is cleared.*

STEP	RATIONALE
17. If patient continues to gag and cough or complains that tube feels as though it is coiling in back of throat, check back of oropharynx with tongue blade. If tube has coiled, withdraw it until tip is back in oropharynx. Reinsert with patient swallowing.	When tube coils around itself in back of throat, it stimulates gag reflex.
18. After patient relaxes, continue to advance tube with swallowing until tape or mark is reached. Temporarily anchor tube to patient's cheek with piece of tape until tube placement is verified.	Tip of tube needs to be well within stomach for adequate decompression. Anchor tube before verifying placement.
19. Verify tube placement. Check agency policy for preferred methods for checking NG tube placement.	
a. Inspect posterior pharynx for presence of coiled tube.	Tube is pliable and can coil up in back of pharynx instead of advancing into esophagus.
b. Attach Asepto or catheter-tipped syringe to end of tube and aspirate gently back on syringe to obtain gastric contents, observing color (see illustration).	Gastric contents are usually cloudy and green but may be off-white, tan, bloody, or brown in color. Aspiration of contents provides means to measure fluid pH and thus determine tube tip placement in gastrointestinal tract. Other common aspirate colors include the following: duodenal placement (yellow or bile stained), esophagus (may or may not have saliva-appearing aspirate).
c. Measure pH of aspirate with color-coded pH paper with range of whole numbers from 1.0 to 11.0 or greater (see illustration).	Gastric aspirates have decidedly acidic pH values, preferably 5.5 or less, compared with intestinal aspirates, which are usually 6.0 or greater, or respiratory secretions, which are usually alkaline at 7.0 or greater. Use only gastric (Gastroccult) pH test and not Hemoccult test.
d. Have ordered x-ray film examination performed of chest/abdomen.	X-ray film is best verification of initial placement of tube (Miller et al., 2014).
e. If tube is not in stomach, advance another 2.5-5 cm (1-2 inches) and repeat Steps 19a-e to check tube position.	Tube must be in stomach to provide decompression.
20. Anchoring tube:	
a. After tube is properly inserted and positioned, either clamp end or connect it to drainage bag or suction source.	Drainage bag is used for gravity drainage. Intermittent low suction is most effective for decompression. Patient going to operating room or for diagnostic test often has tube clamped.

STEP 19b Aspiration of gastric contents.

STEP 19c Checking pH of gastric aspirate.

STEP	RATIONALE
b. Tape tube to nose; avoid putting pressure on nares.	Prevents tissue necrosis. Tape anchors tube securely.
(1) Apply small amount of tincture of benzoin to lower end of nose and allow to dry (optional).	Benzoin prevents loosening of tape if patient perspires.
(2) Apply tape to nose, leaving split ends free. Be sure that top end of tape over nose is secure.	
(3) Carefully wrap two split ends of tape around tube (see illustration).	
(4) Alternative: Apply tube fixation device using shaped adhesive patch (see illustration).	
c. Fasten end of NG tube to patient's gown by looping rubber band around tube in slipknot. Pin rubber band to gown (provides slack for movement).	Reduces pressure on nares if tube moves.
21. Unless health care provider orders otherwise, elevate head of bed 30 degrees.	Helps prevent esophageal reflux and minimizes irritation of tube against posterior pharynx.
22. Once placement is confirmed:	The mark or tube length is to be used as a guide to indicate whether displacement may have occurred.
a. Place red mark on tube to indicate where it exits nose.	
b. Measure tube length from nares to connector as an alternate method.	
c. Document tube length in patient record.	
23. Remove gloves and perform hand hygiene.	Reduces transmission of microorganisms.
24. Tube irrigation:	
a. Perform hand hygiene and apply gloves.	Reduces transmission of microorganisms.
b. Check for tube placement in stomach (see Step 19). Reconnect NG tube to connecting tube.	Prevents accidental entrance of irrigating solution into lungs.
c. Draw up 30 mL of normal saline into Asepto or catheter-tipped syringe.	Use of saline minimizes loss of electrolytes from stomach fluids.
d. Clamp NG tube. Disconnect from connection tubing and lay end of connection tubing on towel.	Reduces soiling of patient's gown and bed linen.
e. Insert tip of irrigating syringe into end of NG tube. Remove clamp. Hold syringe with tip pointed at floor and inject saline slowly and evenly. Do not force solution.	Position of syringe prevents introduction of air into vent tubing, which could cause gastric distention. Solution introduced under pressure causes gastric trauma. Do not introduce saline through blue "pigtail" air vent of Salem sump tube.
f. If resistance occurs, check for kinks in tubing. Turn patient onto left side. Report repeated resistance to health care provider.	Tip of tube may be against stomach lining. Repositioning on left side helps to dislodge tube away from stomach lining. Buildup of secretions causes distention.
g. After instilling saline, immediately aspirate or pull back slowly on syringe to withdraw fluid. If amount aspirated is greater than amount instilled, record difference as output. If amount aspirated is less than amount instilled, record difference as intake.	Irrigation clears tubing; thus stomach remains empty. Fluid remaining in stomach is measured as intake.
h. Reconnect NG tube to drainage or suction. (If solution does not return, repeat irrigation.)	Reestablishes drainage collection; repeat irrigation or repositioning of tube until NG tube drains properly.
i. Remove gloves and perform hand hygiene.	Reduces transmission of microorganisms.

EVALUATION

1. Determine amount and character of contents draining from NG tube. Ask if patient feels nauseated.	Determines if tube is decompressing stomach of contents.
2. After palpating patient's abdomen, note any distention, pain, and rigidity and auscultate for presence of bowel sounds. Turn off suction while auscultating.	Determines success of abdominal decompression and return of peristalsis. The sound of suction apparatus is transmitted to abdomen and misinterpreted as bowel sounds.
3. Evaluate condition of nares and nose.	Evaluates onset of skin and tissue irritation.
4. Observe position of tubing.	Determines if tension is being applied to nasal structures.
5. Ask if patient feels sore throat or irritation in pharynx.	Evaluates level of patient's discomfort.

STEP 20b(3) Tape is crossed over and around NG tube.

STEP 20b(4) Patient with tube fixation device.

SKILL 47-2	**INSERTING AND MAINTAINING A NASOGASTRIC TUBE FOR GASTRIC DECOMPRESSION—cont'd**

STEP	RATIONALE
6. Use **Teach Back** to determine patient's and family's understanding about the nasogastric tube. State, "I want to be sure I explained the reason for the nasogastric tube and the care of the tube. Can you explain to me why you need the nasogastric tube after surgery?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what the patient is able to explain or demonstrate.

DISCONTINUATION OF NASOGASTRIC TUBE

ASSESSMENT

1. Auscultate for presence of bowel sounds.	Serves as baseline for when tube is removed.

PLANNING

1. Verify order to discontinue NG tube.	Health care provider's order required for procedure.
2. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
3. Explain procedure to patient and reassure that removal is less distressing than insertion.	Minimizes anxiety and increases patient cooperation.

IMPLEMENTATION

1. Perform hand hygiene and apply clean gloves.	Reduces transmission of microorganisms.
2. Turn off suction and disconnect NG tube from drainage bag or suction. Remove tape or fixation device from bridge of nose and unpin tube from gown.	Have tube free of all connections before removal.
3. Stand on patient's right side if right-handed, left side if left-handed.	Allows easiest manipulation of tube.
4. Hand patient facial tissue; place clean towel across chest. Instruct patient to take and hold deep breath.	Patient sometimes needs to blow nose after removal of tube. Towel prevents gown from getting soiled. Airway is temporarily obstructed during tube removal.
5. Clamp or kink tubing securely and pull tube out steadily and smoothly into towel held in other hand while patient holds breath.	Clamping prevents tube contents from draining into oropharynx. Reduces trauma to mucosa and minimizes patient's discomfort. Towel covers tube, which is usually an unpleasant sight. Holding breath prevents aspiration.
6. Clean nares and provide mouth care.	Promotes comfort.
7. Dispose of tube and drainage equipment into proper container.	Reduces transmission of microorganisms.
8. Remove gloves and perform hand hygiene.	Reduces transmission of microorganisms.

EVALUATION

1. After tube removal, auscultate patient's bowel sounds and periodically check for abdominal distention.	Confirms that peristalsis has returned.
2. Measure amount of drainage in container and note character of content.	Provides accurate measure of fluid output.
3. Explain procedure for drinking fluids if not contraindicated.	Requires health care provider's order. Once fluids are allowed, the order usually begins with small amount of ice chips; amount increases as patient is able to tolerate more.
4. Use **Teach Back** to determine patient's and family's understanding about the procedure for removing the nasogastric tube. State, "I want to be sure I explained to you what to expect as the nasogastric tube is removed. Can you explain to me how the nasogastric tube will be removed?" Revise your instructions now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient is able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Patient's abdomen becomes distended and/or painful.
- Assess patency of tube and irrigate as needed.
- Verify that suction is on as ordered.

2. Patient complains of sore throat from dry, irritated mucous membranes.
- Increase frequency of oral hygiene.
- Ask health care provider if patient can suck on ice chips or throat lozenges.

3. Patient develops irritation of skin around nares.
- Provide skin care to nares and retape so tube does not press against nares.
- Consider switching tube to other naris.

4. Patient develops signs of pulmonary aspiration: fever, shortness of breath, pulmonary congestion.
- Perform respiratory assessment.
- Notify health care provider; expect order for chest x-ray film.

RECORDING AND REPORTING

- Record in nurses' notes time, type, and size of NG tube inserted; patient's tolerance of procedure; confirmation of placement; character of gastric contents; pH value; whether tube is clamped or connected to drainage device; and amount of suction applied.
- Record in nurses' notes and/or flow sheet placement checks and amount and character of contents draining from NG tube every shift, unless ordered more often by health care provider.
- Record in nurse's notes time and date that NG tube was removed, patient's tolerance of procedure, and his or her status following procedure.
- Document your evaluation of patient learning.

SKILL 47-3	POUCHING AN OSTOMY

DELEGATION CONSIDERATIONS

The skill of pouching an ostomy can be delegated to nursing assistive personnel (NAP) who have been trained to do this procedure. Whether this skill can be delegated depends on agency policy. The nurse should do the first postoperative pouch change. The nurse informs the NAP about:

- Expected amount, color, and consistency of drainage from ostomy.
- Expected appearance of the stoma.
- Special equipment needed to complete procedure.
- When to report changes in patient's stoma and surrounding skin integrity.

EQUIPMENT

- Clear drainable one-piece or two-piece, cut-to-fit or precut ostomy wafer/pouch
- Pouch closure device such as a clip if needed
- Ostomy measuring guide
- Adhesive remover *(optional)*
- Clean gloves
- Washcloth
- Towel or disposable waterproof barrier
- Basin with warm tap water
- Scissors

STEP	RATIONALE

ASSESSMENT

1. Perform hand hygiene and apply gloves (e.g., if there is drainage). Observe existing skin barrier and pouch for leakage and length of time in place. Pouch should be changed every 3 to 7 days, not daily (Goldberg et al., 2010). Depending on type of pouching system used (such as opaque pouch), you may have to remove pouch to fully observe stoma. Clear pouches permit viewing of stoma without their removal.

Assesses effectiveness of pouching system and allows for early detection of potential problems. To minimize skin irritation, avoid unnecessary changing of entire pouching system; but, if effluent is leaking under wafer, change it because skin damage from effluent will cause more skin trauma than early removal of wafer. Repeated leaking sometimes indicates the need for a different type of pouch.

CLINICAL DECISION: *If the ostomy pouch is leaking, change it. Taping or patching it to contain effluent leaves the skin exposed to chemical or enzymatic irritation.*

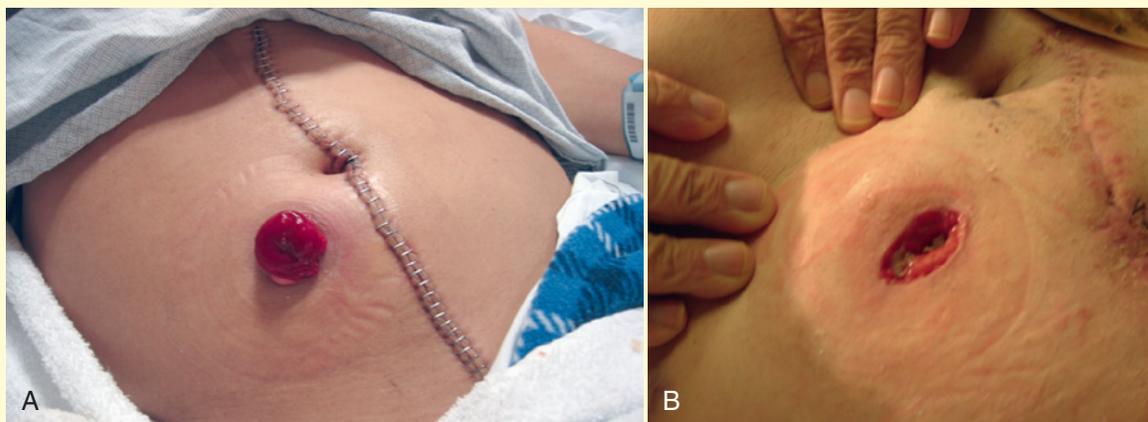
2. Observe amount of effluent in pouch and empty pouch if it is more than one-third to one-half full by opening clip and draining it into a container for measurement of the output. Note consistency of effluent and record intake and output.

Empty pouches when they are one-third to one-half full because weight of pouch disrupts seal of adhesive on skin.
Monitors fluid balance, return of bowel function after surgery.

3. Observe stoma for location, color, swelling, trauma, and healing or irritation of peristomal skin. Assess type of stoma. Determine if it is budded, flush with the skin level, or retracted below skin level (see illustrations). Remove gloves.

Stoma characteristics are a factor to consider in selecting an appropriate pouching system. Convexity in skin barrier is often necessary with a flush or retracted stoma.

4. Observe abdomen for best type of pouching system. Consider:
   a. Abdominal contour.
   b. Presence of scars or incisions.

Determines pouching system selection. Abdominal contours, scars, or incisions affect type of system and adhesion to skin surface.


STEP 3 **A,** Budded stoma. **B,** Retracted stoma. (Courtesy Jane Fellows.)

SKILL 47-3	POUCHING AN OSTOMY—cont'd

STEP	RATIONALE
5. Explore patient's attitude toward learning self-care and identify others who will be helping patient after leaving hospital.	Facilitates teaching plan and timing of care to coincide with availability of caregivers.

PLANNING

1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
2. Explain procedure to patient; encourage patient's interaction and questions.	Lessens patient's anxiety and promotes his or her participation.
3. Assemble equipment and close room curtains or door.	Optimizes use of time; provides privacy.

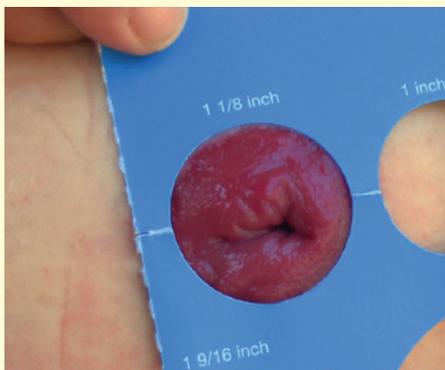
IMPLEMENTATION

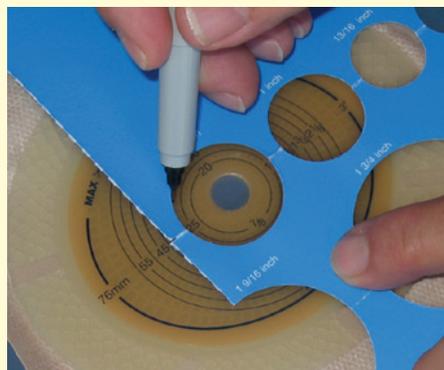
1. Position patient in semireclining position. If possible, provide patient a mirror for observation.	When patient is semireclining, there are fewer skin wrinkles, which allows for ease of application of pouching system.
2. Perform hand hygiene and apply clean gloves.	Reduces transmission of microorganisms.
3. Place towel or disposable waterproof barrier across patient's lower abdomen.	Protects bed linen; maintains patient's dignity.
4. If not done during assessment, remove used pouch and skin barrier gently by pushing skin away from barrier. An adhesive remover may be used to facilitate removal of skin barrier.	Reduces skin trauma. Improper removal of pouch and barrier can cause peristomal skin irritation or breakdown.
5. Cleanse peristomal skin gently with warm tap water using washcloth; do not scrub skin. Pat the skin dry.	Avoid soap. It leaves residue on skin, which may irritate skin (Wound, Ostomy, and Continence Nurses Society et al., 2016). Pouch does not adhere to wet skin.
6. Measure stoma (see illustration). Size of stoma may change in the 2-4 weeks after surgery; thus measurement may change during this time.	Allows for proper fit of pouch that will protect peristomal skin. Pouch opening should fit around stoma and cover peristomal skin to prevent contact with effluent.
7. Trace pattern on pouch/skin barrier (see illustration).	Prepares for cutting opening in the pouch.
8. Cut opening on skin barrier wafer (see illustration).	Customizes pouch to provide appropriate fit over stoma.
9. Remove protective backing from adhesive (see illustration).	Prepares skin barrier for placement.
10. Apply pouch over stoma (see illustration). Press firmly into place around stoma and outside edges. Have patient hold hand over pouch to apply heat to secure seal.	Pouch adhesives are heat and pressure sensitive and will hold more securely at body temperature.
11. Close end of pouch with clip or integrated closure.	Contains effluent.
12. Properly dispose of used pouch and remove drape from patient.	Avoids odor in room.
13. Remove gloves. Perform hand hygiene.	Reduces transmission of microorganisms.

EVALUATION

1. Observe condition of skin barrier and adherence to abdominal surface.	Determines presence of leaks.
2. Observe appearance of stoma, peristomal skin, abdominal contours, and suture line during pouch change.	Provides information if another type of pouching system or additional skin care products are needed.

> **CLINICAL DECISION:** *If peristomal skin is raw, blistered, or weeping, the skin surface will be moist, and the pouch will not adhere, making the patient vulnerable to more severe skin breakdown. Consult the ostomy care nurse before proceeding with placing a pouch over moist, damaged skin.*

3. Observe patient's, family caregiver's or significant other's willingness to view stoma and ask questions about procedure.	Determines level of adjustment and understanding of stoma care and pouch application. Allows planning for future education needs and progress toward acceptance of altered body image.


STEP 6 Measure stoma. (Courtesy Coloplast, Minneapolis, MN.)


STEP 7 Trace measurement on skin barrier. (Courtesy Coloplast, Minneapolis, MN.)

STEP 8 Cut opening in wafer. (Courtesy Coloplast, Minneapolis, MN.)

STEP	RATIONALE
4. Use **Teach Back** to determine patient's and family's understanding about caring for the ostomy. State, "I want to be sure I explained how to pouch the ostomy to protect your skin. Can demonstrate to me how to change the pouch on your ostomy?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient and family are able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Skin around stoma is irritated, blistered, or bleeding; or a rash is noted. May be caused by undermining of pouch seal by fecal contents, allergic reaction, or fungal skin eruption.
- Remove pouch more carefully.
- Change pouch more frequently or use a different type of pouching system.
- Consult ostomy care nurse.

2. Necrotic stoma is manifested by purple or black color, dry instead of moist texture, or failure to bleed when washed gently or tissue sloughing.
- Report to health care provider.
- Document appearance.

3. Patient refuses to view stoma or participate in care.
- Obtain referral for ostomy care nurse.
- Allow patient to express feelings.
- Encourage family support.

RECORDING AND REPORTING

- Record type of pouch and skin barrier used, amount and appearance of effluent in pouch, size and appearance of stoma, and condition of peristomal skin.
- Record patient/family level of participation, teaching performed, and response to teaching.
- Report abnormal appearance of stoma, suture line, peristomal skin, or character of output to health care provider.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- Evaluate patient's home toileting facilities and help patient develop an ostomy care routine that is compatible with available facilities. Ostomy pouches are not flushable.
- Encourage patient to stand in front of a mirror when changing pouch to increase visibility and avoid abdominal creases that might be present in the sitting position.

STEP 9 Remove protective backing. (Courtesy Coloplast, Minneapolis, MN.)

STEP 10 Apply pouch over stoma. (Courtesy Coloplast, Minneapolis, MN.)

▮ KEY POINTS

- Mechanical breakdown of food elements, GI motility, and selective absorption and secretion of substances by the large intestine influence the character of feces.
- Food high in fiber content and an increased fluid intake normalize stool consistency.
- Use of cathartics, laxative, and enemas are short-term solutions to constipation; long-term management includes lifestyle changes in diet, activity, and defecation schedule.
- Fecal incontinence is a source of physical and psychological distress and frequently leads to the need for agency-based care in the elderly.
- The greatest risk from diarrhea is development of fluid and electrolyte imbalance.
- The location of an ostomy influences consistency of the stool.
- Focus assessment of elimination patterns on bowel habits, factors that normally influence defecation, recent changes in elimination, and a physical examination.
- Endoscopic procedures for diagnostic testing of the GI tract may require cleansing of the bowel before the procedure.

- Consider frequency of defecation and fecal characteristics when instructing a patient on establishing a bowel-elimination routine.
- NG intubation decompresses the stomach by removing gastric contents until GI motility returns and decreases the risk of vomiting and aspiration.
- Proper selection and use of an ostomy-pouching system are necessary to prevent damage to the skin around the stoma.
- Digital removal of stool relieves the obstruction and discomfort of a fecal impaction but causes trauma to the rectal mucosa and vagal nerve stimulation.
- Skin breakdown occurs after repeated exposure to liquid stool.

■ CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

On his next visit to Mr. Johnson 2 days later, Javier, the home care nurse, found that Mr. Johnson still had not had a normal bowel movement and his blood pressure is 160/92. He had tried to increase his intake of fruits and vegetables but had very little appetite and felt mildly nauseous after eating even a small meal. Mr. Johnson took a laxative with a stool softener each evening, but reported only small, liquid bowel movements 2 to 3 times a day. He feels pressure in his rectum that is not relieved when he takes his pain medication. Because of his elevated blood pressure, increasing discomfort, and his lack of bowel movement for at least 9 days, Javier thinks that Mr. Johnson should go to the emergency department of his local hospital.

1. Mr. Johnson arrives in the emergency department of the hospital with rectal pressure and a lack of appetite. Which nursing assessment questions do you ask?
2. The emergency medicine health care provider does a digital rectal examination and feels a hard stool mass. You receive an order to remove a fecal impaction. Describe what you need to do to prepare the patient for this procedure.
3. After successfully removing the impaction, what do you need to teach Mr. Johnson before he is discharged from the emergency department?

ⓔ *Answers to Clinical Application Questions can be found on the Evolve website.*

■ REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. Which of the following nursing actions do you take after placing a bedpan under an immobilized patient?
   1. Lift the patient's hips off the bed and slide the bedpan under the patient
   2. After positioning the patient on the bedpan, elevate the head of the bed to a 45-degree angle
   3. Adjust the head of the bed so it is lower than the feet and use gentle but firm pressure to push the bedpan under the patient
   4. Have the patient stand beside the bed and then have him or her sit on the bedpan on the edge of the bed
2. A patient has not had a bowel movement for 4 days. Now she has nausea and severe cramping throughout her abdomen. On the basis of these findings, what do you suspect is wrong with the patient?
   1. An intestinal obstruction
   2. Irritation of the intestinal mucosa
   3. Gastroenteritis
   4. A fecal impaction

3. During the administration of a warm tap-water enema, a patient complains of cramping abdominal pain that he rates 6 out of 10. What is your priority nursing intervention?
   1. Stop the instillation
   2. Ask the patient to take deep breaths to decrease the pain
   3. Add soapsuds to the enema
   4. Tell the patient to bear down as he would when having a bowel movement
4. Which instructions do you include when educating a person with chronic constipation? (Select all that apply.)
   1. Increase fiber and fluids in the diet
   2. Use a low-volume enema daily
   3. Avoid gluten in the diet
   4. Take laxatives twice a day
   5. Exercise for 30 minutes every day
   6. Schedule time to use the toilet at the same time every day
   7. Take probiotics 5 times a week
5. Which skills do you teach a patient with a new colostomy before discharge from the hospital? (Select all that apply.)
   1. How to change the pouch
   2. How to empty the pouch
   3. How to open and close the pouch
   4. How to irrigate the colostomy
   5. How to determine if the ostomy is healing appropriately
6. Which of the following cause *Clostridium difficile* infection? (Select all that apply.)
   1. Chronic laxative use
   2. Contact with *C. difficile* bacteria
   3. Overuse of antibiotics
   4. Frequent episodes of diarrhea caused by food intolerance
   5. Inflammation of the bowel
7. Place the steps for an ostomy pouch change in the correct order.
   1. Close the end of the pouch.
   2. Measure the stoma.
   3. Cut the hole in the wafer.
   4. Press the pouch in place over the stoma.
   5. Remove the old pouch.
   6. Trace the correct measurement onto the back of the wafer.
   7. Assess the stoma and the skin around it.
   8. Cleanse and dry the peristomal skin.
8. Which of the following symptoms are warning signs of possible colorectal cancer according to the American Cancer Society guidelines? (Select all that apply.)
   1. Change in bowel habits
   2. Blood in the stool
   3. A larger-than-normal bowel movement
   4. Fecal impaction
   5. Muscle aches
   6. Incomplete emptying of the colon
   7. Food particles in the stool
   8. Unexplained abdominal or back pain
9. A nurse is teaching a patient to obtain a specimen for fecal occult blood testing using fecal immunochemical (FIT) testing at home. How does the nurse instruct the patient to collect the specimen?
   1. Get three fecal smears from one bowel movement.
   2. Obtain one fecal smear from an early-morning bowel movement.
   3. Collect one fecal smear from three separate bowel movements.
   4. Get three fecal smears when you see blood in your bowel movement.
10. What do you need to teach family caregivers when a patient has fecal incontinence as a result of cognitive impairment?

1. Cleanse the skin with antibacterial soap and apply talcum powder to the buttocks
2. Use diapers and heavy padding on the bed
3. Initiate bowel or habit training program to promote continence
4. Help the patient to toilet once every hour

11. Your patient states, "I have diarrhea and cramping every time I have ice cream. I am sure this is because the food is cold." Based on this assessment data, which health problem do you suspect the patient has?
    1. A food allergy
    2. Irritable bowel syndrome
    3. Increased peristalsis
    4. Lactose intolerance

12. Place the steps to administering a prepackaged enema the correct order.
    1. Insert enema tip gently in the rectum.
    2. Help patient to bathroom when he or she feels urge to defecate.
    3. Position patient on side.
    4. Perform hand hygiene and apply clean gloves.
    5. Squeeze contents of container into rectum.
    6. Explain procedure to the patient.

13. Which nursing intervention is most important when caring for a patient with an ileostomy?

1. Cleansing the stoma with hot water
2. Inserting a deodorant tablet in the stoma bag
3. Selecting or cutting a pouch with an appropriate-size stoma opening
4. Wearing sterile gloves while caring for the stoma

14. A nurse is taking a health history of a newly admitted patient with a diagnosis of possible fecal impaction. Which of the following is the priority question to ask the patient or caregiver?
    1. Have you eaten more high-fiber foods lately?
    2. Are your bowel movements soft and formed?
    3. Have you experienced frequent, small liquid stools recently?
    4. Have you taken antibiotics recently?

15. An elderly patient comes to the hospital with a complaint of severe weakness and diarrhea for several days. Of the following problems, which is the most important to assess initially?
    1. Malnutrition
    2. Dehydration
    3. Skin breakdown
    4. Incontinence

Answers: 1. 2; **2.** 1; **3.** 1; **4.** 1, 5; **5.** 1, 2, 3; **6.** 2, 3; **7.** 5, 8, 7, 2, 6, 3, 4, 1; **8.** 1, 2, 6, 8; **9.** 3; **10.** 3; **11.** 4; **12.** 6, 4, 3, 1, 5, 2; **13.** 3; **14.** 3; **15.** 2.

Skin Integrity and Wound Care

OBJECTIVES

- Discuss the risk factors that contribute to pressure ulcer formation.
- Describe the pressure ulcer staging system.
- Discuss the normal process of wound healing.
- Describe the differences in wound healing by primary and secondary intention.
- Describe complications of wound healing.
- Explain the factors that impede or promote wound healing.
- Describe the differences between nursing care of acute and chronic wounds.

- Complete an assessment for a patient with impaired skin integrity.
- List nursing diagnoses associated with impaired skin integrity.
- Develop a nursing care plan for a patient with impaired skin integrity.
- List appropriate nursing interventions for a patient with impaired skin integrity.
- State evaluation criteria for a patient with impaired skin integrity.

Skin, the largest organ in the body, constitutes 15% of the total adult body weight (Wysocki, 2016). It is a protective barrier against disease-causing organisms and a sensory organ for pain, temperature, and touch; and it synthesizes vitamin D. Injury to the skin poses risks to safety and triggers a complex healing response. Your most important responsibilities include assessing and monitoring skin integrity, identifying patient risks for skin problems, identifying actual problems, and planning, implementing, and evaluating interventions to maintain skin integrity. Once a wound occurs, it is critical to know the process of normal wound healing to identify the appropriate nursing interventions.

SCIENTIFIC KNOWLEDGE BASE

Skin

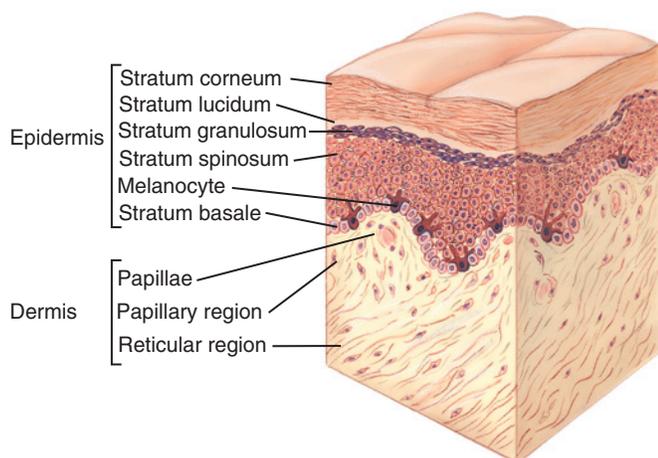
The skin has two layers: the epidermis and the dermis (Figure 48-1). They are separated by a membrane, often referred to as the *dermal-epidermal junction*. The epidermis, or the top layer, has several layers. The stratum corneum is the thin, outermost layer of the epidermis. It consists of flattened, dead, keratinized cells. The cells originate from the innermost epidermal layer, commonly called the *basal layer*. Cells in the basal layer divide, proliferate, and migrate toward the epidermal surface. After they reach the stratum corneum, they flatten and die.


FIGURE 48-1 Layers of skin. (From Applegate E: *The anatomy and physiology learning system*, ed 3, St Louis, 2006, Saunders.)

FIGURE 48-2 Pressure ulcer with tissue necrosis.

This constant movement ensures replacement of surface cells sloughed during normal desquamation or shedding. The thin stratum corneum protects underlying cells and tissues from dehydration and prevents entrance of certain chemical agents. The stratum corneum allows evaporation of water from the skin and permits absorption of certain topical medications.

The dermis, the inner layer of the skin, provides tensile strength; mechanical support; and protection for the underlying muscles, bones, and organs. It differs from the epidermis in that it contains mostly connective tissue and few skin cells. **Collagen** (a tough, fibrous protein), blood vessels, and nerves are found in the dermal layer. Fibroblasts, which are responsible for collagen formation, are the only distinctive cell type within the dermis.

Understanding skin structure helps you maintain skin integrity and promote wound healing. Intact skin protects the patient from chemical and mechanical injury. When the skin is injured, the epidermis functions to resurface the wound and restore the barrier against invading organisms, and the dermis responds to restore the structural integrity (collagen) and the physical properties of the skin. The normal aging process alters skin characteristics and makes skin more vulnerable to damage. Box 48-1 provides a summary of the changes in aging skin.

Pressure Ulcers

Pressure ulcer, pressure sore, decubitus ulcer, and *bedsore* are terms used to describe impaired skin integrity related to unrelieved, prolonged pressure. The most current terminology is **pressure ulcer** (Figure 48-2), which is consistent with the recommendations of the pressure ulcer guidelines written by the Wound, Ostomy and Continence Nurses Society (WOCN, 2010). A pressure ulcer is localized injury to the skin and other underlying tissue, usually over a bony prominence (e.g., sacrum, greater trochanter), as a result of pressure or pressure in combination with shear and/or friction. A number of contributing factors are also associated with pressure ulcers; the significance of these factors is not yet clear (NPUAP, EPUAP, PPPIA, 2014). Any patient experiencing decreased mobility, decreased sensory perception, fecal or urinary incontinence, and/or poor nutrition is at risk for pressure ulcer development. Examples of patients who are at risk for development of pressure ulcers include the following:

- Older adults, those who have experienced trauma
- Those with spinal-cord injuries (SCI)
- Those who have sustained a fractured hip
- Those in long-term homes or community care, the acutely ill

BOX 48-1 FOCUS ON OLDER ADULTS

Skin-Associated Issues

The older adult has several skin-related issues that should be considered when assessing skin and skin breakdown. Age-related changes such as reduced skin elasticity, decreased collagen, and thinning of underlying muscle and tissues can cause the older adult's skin to be easily torn in response to mechanical trauma, especially shearing forces (Wysocki, 2016). The attachment between the epidermis and dermis becomes flattened in older adults, allowing the skin to be easily torn in response to mechanical trauma (e.g., tape removal). Concomitant medical conditions and polypharmacy, which are common in the older adult, are factors that interfere with wound healing. Aging causes a diminished inflammatory response, resulting in slow epithelialization and wound healing (Doughty and Sparks-Defriese, 2016). The hypodermis decreases in size with age. Older patients have little subcutaneous padding over bony prominences; thus they are more prone to skin breakdown (Wysocki, 2016).

Implications for Practice

1. When removing any adhesive dressings or tapes, gently release the skin from the tape; do not pull the tape away from the skin. Release the skin from the adhesive by pushing the skin from the adhesive.
2. To help an elder patient reposition in bed consider the use of a repositioning device and teach the patient or family caregiver how to reposition without sliding on the sheets.
3. Be diligent about assessing bony prominences where impaired skin integrity and injury to other tissues are most likely to occur.
4. Assess the medications that a patient may be taking for effect on delayed wound healing and revise outcomes in the plan of care to reflect that possibility.

- Individuals with diabetes
- Patients in critical care settings (NPUAP, EPUAP, PPPIA, 2014)

Many factors contribute to the formation of a pressure ulcer. Pressure is the major cause. Tissue receives oxygen and nutrients and eliminates metabolic wastes via the blood. Any factor that interferes with blood flow in turn interferes with cellular metabolism and the function or life of the cells. Prolonged, intense pressure affects cellular metabolism by decreasing or obliterating blood flow, resulting in tissue ischemia and ultimately tissue death.

Pathogenesis of Pressure Ulcers. Pressure is the major element in the cause of pressure ulcers. Three pressure-related factors

contribute to pressure ulcer development: (1) pressure intensity, (2) pressure duration, and (3) tissue tolerance.

Pressure Intensity. A classic research study identified capillary closing pressure as the minimal amount of pressure required to collapse a capillary (e.g., when the pressure exceeds the normal capillary pressure range of 15 to 32 mm Hg) (Burton and Yamada, 1951). Therefore, if the pressure applied over a capillary exceeds the normal capillary pressure and the vessel is occluded for a prolonged period of time, **tissue ischemia** can occur. If the patient has reduced sensation and cannot respond to the discomfort of the ischemia, tissue ischemia and tissue death result.

The clinical presentation of obstructed blood flow occurs when evaluating areas of pressure. After a period of tissue ischemia, if the pressure is relieved and the blood flow returns, the skin turns red. The effect of this redness is vasodilation (blood vessel expansion), called *hyperemia* (redness). You assess an area of hyperemia by pressing a finger over the affected area. If it blanches (turns lighter in color) and the erythema returns when you remove your finger, the hyperemia is transient and is an attempt to overcome the ischemic episode, thus called **blanchable hyperemia**. However, if the erythematous area does not blanch (**nonblanchable erythema**) when you apply pressure, deep tissue damage is probable.

Blanching occurs when the normal red tones of the light-skinned patient are absent. When checking for pressure ulcers in dark-skinned patients, dark skin may not show the blanch response. Instead, after applying light pressure, look for an area darker than the surrounding skin or one that is taut, shiny, or indurated (hardened). The light from a camera flash can be used to enhance visualization of dark skin. Check for localized changes in skin texture and temperature. Early signs of skin damage include **induration**, bogginess (less-than-normal stiffness), and increased warmth at the injury site compared to nearby areas. Over time, as tissues become more damaged, the area becomes cooler to the touch (Sommers, 2011). There are characteristics of intact dark skin that alert nurses to the potential for pressure ulcers Box 48-2.

Pressure Duration. Low pressure over a prolonged period and high-intensity pressure over a short period are two concerns related to duration of pressure. Both types of pressure cause tissue damage. Extended pressure occludes blood flow and nutrients and contributes to cell death (Pieper, 2016). Clinical implications of pressure duration include evaluating the amount of pressure (checking skin for nonblanching hyperemia) and determining the amount of time that a patient tolerates pressure (checking to be sure after relieving pressure that the affected area blanches).

Tissue Tolerance. The ability of tissue to endure pressure depends on the integrity of the tissue and the supporting structures. The extrinsic factors of shear, friction, and moisture affect the ability of the skin to tolerate pressure: the greater the degree to which the factors of shear, friction, and moisture are present, the more susceptible the skin will be to damage from pressure. The second factor related to tissue tolerance is the ability of the underlying skin structures (blood vessels, collagen) to help redistribute pressure. Systemic factors such as poor nutrition, increased aging, hydration status, and low blood pressure affect the tolerance of the tissue to externally applied pressure.

Risk Factors for Pressure Ulcer Development. A variety of factors predispose a patient to pressure ulcer formation. These factors are often directly related to disease such as decreased level of consciousness, the presence of a cast, or secondary to an illness (e.g., decreased sensation following a cerebrovascular accident).

Impaired Sensory Perception. Patients with altered sensory perception for pain and pressure are more at risk for impaired skin integrity than those with normal sensation. Patients with impaired sensory

---

BOX 48-2 Characteristics of Dark Skin with Impaired Integrity

Dark skin tones may not demonstrate change in color, especially darkly pigmented skin. To assess a dark-skinned patient for the presence of a category/stage I pressure ulcer, the following should be considered: assess the skin in a well-illuminated setting (i.e., a well-lit environment). Use natural light or halogen light. Avoid florescent light. Assess the following (assess noninjured skin areas first):

Color
- Color remains unchanged and does not blanch when pressure is applied.
- If patient previously had a pressure ulcer, that area of skin might be lighter than original color.
- Localized areas of inflammation may take on an eggplant (purplish-blue or violet) color rather than appearing reddened.

Temperature
- Circumscribed area of intact skin may be warm to touch. As tissue changes color, intact skin feels cool to touch.
- Inflammation is detected by making comparisons to surrounding skin.

Appearance
- Edema may occur with induration and appear taut and shiny.
- Injured skin with a stage I pressure ulcer might show low resilience. Document tissue resilience: tissue on palpation is boggy or mushy when compared to surrounding skin.

Palpation
- Surrounding area may be sensitive or tender to touch or may be hard or lumpy on palpation.

Adapted from Nix DP: Skin and wound inspection and assessment. In Bryant RA, Nix DP, editors: *Acute and chronic wounds: current management concepts*, ed 5, St Louis, 2016, Elsevier.

---

perception of pain and pressure are unable to feel when a part of their body undergoes increased, prolonged pressure or pain. Thus a patient who can't feel or sense that there is pain or pressure is at risk for the development of pressure ulcers.

Impaired Mobility. Patients unable to independently change positions are at risk for pressure ulcer development. For example, a morbidly obese patient who is seriously ill will be weakened and less likely to turn independently. Patients with spinal cord injuries have decreased or absent motor and sensory impairment and are unable to reposition off bony prominences.

Alteration in Level of Consciousness. Patients who are confused or disoriented, those who have expressive aphasia or the inability to verbalize, or those with changing levels of consciousness are unable to protect themselves from pressure ulcer development. Patients who are confused or disoriented are sometimes able to feel pressure but are not always able to understand how to relieve it or communicate their discomfort. A patient in a coma cannot perceive pressure and is unable to move voluntarily to relieve pressure.

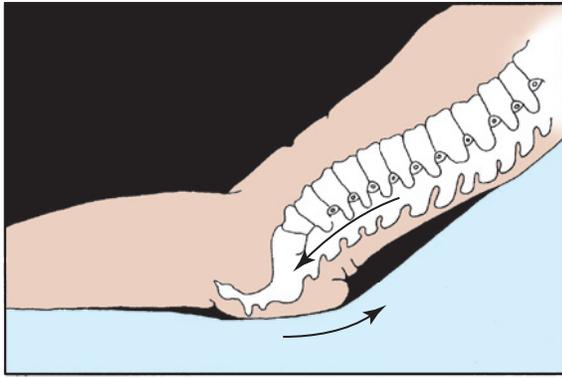
Shear. Shear force is the sliding movement of skin and subcutaneous tissue while the underlying muscle and bone are stationary (Bryant, 2016). For example, shear force occurs when the head of the bed is elevated and the sliding of the skeleton starts but the skin is fixed because of friction with the bed (Figure 48-3). It also occurs when transferring a patient from bed to stretcher and the patient's skin is pulled across the bed. When shear is present, the skin and subcutaneous layers adhere to the surface of the bed, and the layers


FIGURE 48-3 Shear exerted in sacral area.

of muscle and the bones slide in the direction of body movement. The underlying tissue capillaries are stretched and angulated by the shear force. As a result, necrosis occurs deep within the tissue layers. The tissue damage is deep in the tissues and causes undermining of the dermis.

Friction. The force of two surfaces moving across one another such as the mechanical force exerted when skin is dragged across a coarse surface such as bed linens is called **friction** (WOCN, 2010). Unlike shear injuries, friction injuries affect the epidermis or top layer of the skin. The denuded skin appears red and painful and is sometimes referred to as a *sheet burn.* A friction injury occurs in patients who are restless, in those who have uncontrollable movements such as spastic conditions, and in those whose skin is dragged rather than lifted from the bed surface during position changes or transfer to a stretcher.

Moisture. The presence and duration of moisture on the skin increases the risk of ulcer formation. Moisture reduces the resistance of the skin to other physical factors such as pressure and/or shear force. Prolonged moisture softens skin, making it more susceptible to damage. Immobilized patients who are unable to perform their own hygiene needs depend on nurses to keep the skin dry and intact. Skin moisture originates from wound drainage, excessive perspiration, and fecal or urinary incontinence.

Classification of Pressure Ulcers

As a nurse, you need to perform an initial assessment of a pressure ulcer using systematic parameters. Then you will evaluate at regular intervals to determine the status and progress toward wound healing and to plan appropriate interventions.. Assessment includes wound location, depth of tissue involvement (staging), type and approximate percentage of tissue in wound bed, wound dimensions (if present, include sinus tracts and tunneling), exudate description (if present, odor), and condition of surrounding skin.

One method for assessment of a pressure ulcer is the use of a staging system. Staging systems for pressure ulcers are based on describing the depth of tissue loss. Accurate staging requires knowledge of the skin layers. A major drawback of a staging system is that you cannot stage an ulcer covered with necrotic tissue because the necrotic tissue is covering the depth of the ulcer. The necrotic tissue must be debrided or removed to expose the wound base to allow for assessment.

Pressure ulcer staging describes the pressure ulcer depth at the point of assessment. Thus, once you have staged the pressure ulcer, this stage endures even as it heals. Pressure ulcers do not progress from a stage III to a stage I; rather, a stage III ulcer demonstrating signs of healing is described as a healing stage III pressure ulcer (Pieper, 2016). The NPUAP, EPUAP, and PPPIA (2014) have developed clinical

practice guidelines for pressure ulcers and have advanced the following classification/staging system. The NPUAP uses the term *staging* and the European group uses the term *category,* both describing the same assessment parameter.

Category/Stage I: Nonblanchable Redness. Intact skin presents with nonblanchable redness of a localized area, usually over a bony prominence. Discoloration of the skin, warmth, edema, hardness, or pain may also be present. Darkly pigmented skin may not have visible blanching but its coloring may differ from the surrounding area. The area may be painful, firm, soft, warmer, or cooler compared to adjacent tissue. Category I may be difficult to detect in individuals with dark skin tones. It may indicate "at risk" people (Figure 48-4, A).

Category/Stage II: Partial-Thickness. Partial thickness loss of dermis presents as a shallow, open ulcer with a red-pink wound bed without slough. It may also present as an intact or open/ruptured serum-filled or serosanguineous-filled blister. It presents as a shiny or dry shallow ulcer without slough or bruising (see Figure 48-4, B). The presence of bruising indicates deep tissue injury. This category should not be used to describe skin tears, tape burns, incontinence-associated dermatitis, maceration, or excoriation.

Category/Stage III: Full-Thickness Skin Loss. In full-thickness tissue loss subcutaneous fat may be visible; but bone, tendon, and muscle are *not* exposed. Slough may be present but does not obscure the depth of tissue loss. It *may* include undermining and tunneling. The depth of a category/stage III pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput, and malleolus do not have (adipose) subcutaneous tissue; and category/stage III ulcers can be shallow. In contrast, areas of significant adiposity can develop extremely deep category/stage III pressure ulcers. Bone/tendon is not visible or directly palpable (see Figure 48-4, C).

Category/Stage IV: Full-Thickness Tissue Loss. In full-thickness tissue loss with exposed bone, tendon, or muscle, subcutaneous fat may be visible; but bone, tendon, and muscle are *not* exposed. Slough or eschar may be present. It often includes undermining and tunneling. The depth of a category/stage IV pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput, and malleolus do not have (adipose) subcutaneous tissue; and these ulcers can be shallow. Category/stage IV ulcers can extend into muscle and/or supporting structures (e.g., fascia, tendon, or joint capsule), making osteomyelitis or osteitis likely to occur. Exposed bone/muscle is visible or directly palpable (see Figure 48-4, D).

Unstageable/Unclassified: Full-Thickness Skin or Tissue Loss—Depth Unknown. Full-thickness tissue loss in which actual depth of an ulcer is completely obscured by slough (yellow, tan, gray, green or brown) and/or eschar (tan, brown or black) in the wound bed is unstageable. Until enough slough and/or eschar are removed to expose the base of a wound, the true depth cannot be determined; but it will be either a category/stage III or IV. Stable (dry, adherent, intact without erythema or **fluctuance**) eschar on the heels serves as "the natural (biological) cover of the body" and should not be removed (see Figure 48-4, E).

Suspected Deep-Tissue Injury—Depth Unknown. Suspected deep-tissue injury is a purple or maroon localized area of discolored intact skin or a blood-filled blister caused by damage of underlying soft tissue from pressure and/or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer, or cooler compared

to adjacent tissue. Deep-tissue injury may be difficult to detect in individuals with dark skin tones. It may begin as a thin blister over a dark wound bed. The wound may further evolve and become covered by thin eschar. Evolution may be rapid, exposing additional layers of tissue even with optimal treatment (see Figure 48-4, *F*).

The NPUAP, EPUAP, PPPIA (2014) guidelines suggest that, when conducting a skin assessment on an individual with darkly pigmented skin, prioritize assessment of skin temperature, edema, and change in tissue consistency in relation to surrounding tissue. Additional aspects of assessing dark skin are in Box 48-3.

You need to assess the type of tissue in a wound base; then use this information to plan appropriate interventions. The assessment includes the amount (percentage) and appearance (color) of viable and nonviable tissue. **Granulation tissue** is red, moist tissue composed of new blood vessels, the presence of which indicates progression toward healing. Soft yellow or white tissue is characteristic of **slough** (stringy substance attached to wound bed), and it must be removed by a skilled clinician or with the use of an appropriate wound dressing before the wound is able to heal. Black, brown, tan, or necrotic tissue is **eschar,** which needs to be removed before healing can proceed.

BOX 48-3 CULTURAL ASPECTS OF CARE

Impact of Skin Color

Detecting cyanosis and other changes in skin color in patients is an important clinical skill. However, this detection becomes a challenge in dark-skinned patients (Nix, 2016). There are concerns about the inability of practitioners to describe early pressure ulcer or pressure injury in people with darkly pigmented skin accurately (Henderson et al., 1997). Cyanosis is "a slightly bluish-grayish slatelike or dark purple discoloration of the skin caused by the presence of at least 5 g of reduced hemoglobin in arterial blood." Color differentiation of cyanosis varies according to skin pigmentation. In dark-skinned patients you need to know the individual's baseline skin tone. You should not confuse the normal hyperpigmentation of Mongolian spots that are seen on the sacrum of African, Native American, and Asian patients with cyanosis. Observe the patient's skin in nonglare daylight. The Gaskin Nursing Assessment of Skin Color (GNASC) is a useful tool for assessment for identifying changes in skin color that increase the patient's risk for pressure ulcers (Gaskin, 1986).

Implications for Patient-Centered Care
- It is difficult but possible to detect cyanosis in the dark-skinned patient.
- Be aware of situations that produce changes in skin tone such as inadequate lighting.
- Examine body sites with the least melanin such as under the arm for underlying color identification (Nix, 2016).
- When conducting a skin assessment in an individual with darkly pigmented skin, prioritize assessment of skin temperature, edema, and change in tissue consistency in relation to surrounding tissues (NPUAP, EPUAP, PPPIA, 2014).

The measurement of the wound size provides overall changes in dimensions, which is an indicator for wound healing progress (Nix, 2016). This includes measuring the length and width of a wound as well as determining its depth.

Wound **exudate** should describe the amount, color, consistency, and odor of wound drainage and is part of the wound assessment. Excessive exudate indicates the presence of infection. The skin around the wound (periwound) should be assessed. Examine the periwound area for redness, warmth, and signs of maceration and palpate the area for signs of pain or induration. The presence of any of these factors on the periwound skin indicates wound deterioration.

Wound Classifications

A **wound** is a disruption of the integrity and function of tissues in the body (Baranoski, 2012). It is imperative for the nurse to know that *all wounds are not created equal.* Understanding the etiology of a wound is important because the treatment for it varies, depending on the underlying disease process.

There are many ways to classify wounds. Wound classification systems describe the status of skin integrity, cause of the wound, severity or extent of tissue injury or damage, cleanliness of the wound (Table 48-1), and descriptive qualities of the wound tissue such as color (Figure 48-5). Wound classification enables a nurse to understand the risks associated with a wound and implications for healing.

Process of Wound Healing. Wound healing involves integrated physiological processes. The tissue layers involved and their capacity for regeneration determine the mechanism for repair for any wound (Doughty and Sparks-Defriese, 2016).

Wounds can be classified by the extent of tissue loss: partial-thickness wounds that involve only a partial loss of skin layers (the epidermis and superficial dermal layers) and full-thickness wounds

TABLE 48-1 Wound Classification

Description	Causes	Implications for Healing
Onset and Duration		
Acute		
Wound that proceeds through an orderly and timely reparative process that results in sustained restoration of anatomical and functional integrity	Trauma Surgical incision	Wound edges are clean and intact.
Chronic		
Wound that fails to proceed through an orderly and timely process to produce anatomical and functional integrity	Vascular compromise, chronic inflammation, or repetitive insults to tissue (Doughty and Sparks-Defriese, 2016)	Continued exposure to insult impedes wound healing.
Healing Process		
Primary Intention		
Wound that is closed	Surgical incision Wound that is sutured or stapled	Healing occurs by epithelialization; heals quickly with minimal scar formation.
Secondary Intention		
Wound edges not approximated	Pressure ulcers, surgical wounds that have tissue loss or contamination	Wound heals by granulation tissue formation, wound contraction, and epithelialization.
Tertiary Intention		
Wound that is left open for several days; then wound edges are approximated (see Figure 48-4, *C*)	Wounds that are contaminated and require observation for signs of inflammation	Closure of wound is delayed until risk of infection is resolved (Doughty and Sparks-Defriese, 2016).

FIGURE 48-5 Wounds classified by color assessment. **A,** Black wound. **B,** Yellow wound. **C,** Red wound. **D,** Mixed-color wound. (**A** and **D** Courtesy Scott Health Care—A Mölnlycke Company, Philadelphia, PA; **B** and **C** from Bryant RA, Nix DP, editors: *Acute and chronic wounds: current management concepts,* ed 5, St Louis, 2016, Elsevier.)

that involve total loss of the skin layers (epidermis and dermis) (Doughty and Sparks-DeFriese, 2016). Partial-thickness wounds are shallow in depth, moist, and painful; and the wound base generally appears red. A full-thickness wound extends into the subcutaneous layer, and the depth and tissue type varies, depending on body location. The significance of determining if a wound is a partial or full thickness lies in the mechanism of healing. A partial-thickness wound heals by regeneration; and a full-thickness wound heals by forming new tissue, a process that can take longer than the healing of a partial-thickness wound.

A clean surgical incision is an example of a wound with little tissue loss. The surgical incision heals by **primary intention** (Figure 48-6, *A)*. The skin edges are **approximated,** or closed, and the risk of infection is low. Healing occurs quickly, with minimal scar formation, as long as infection and secondary breakdown are prevented (Doughty and Sparks-Defriese, 2016). In contrast, a wound involving loss of tissue such as a burn, pressure ulcer, or severe laceration heals by **secondary intention**. The wound is left open until it becomes filled by scar tissue. It takes longer for a wound to heal by secondary intention; thus the chance of infection is greater. If scarring from secondary intention is severe, loss of tissue function is often permanent (see Figure 48-6, *B)*.

Wound Repair.   Partial-thickness wounds are shallow, involving loss of epidermis and possible loss of dermis. These wounds heal by regeneration because epidermis regenerates. An example of a partial-thickness wound is a scrape or an abrasion. Full-thickness wounds extend into the dermis and heal by scar formation because deeper structures do not regenerate. Pressure ulcers are an example of full-thickness wounds.

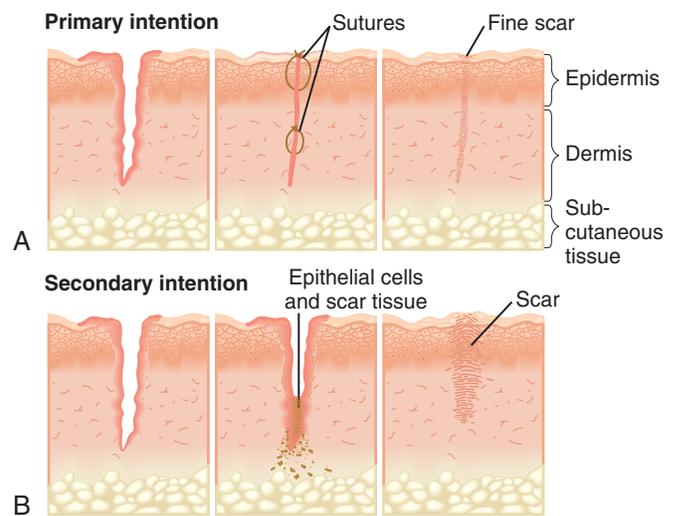
Partial-Thickness Wound Repair.   Three components are involved in the healing process of a partial-thickness wound: inflammatory response, epithelial proliferation (reproduction) and migration, and reestablishment of the epidermal layers.


FIGURE 48-6 A, Wound healing by primary intention such as a surgical incision. Wound healing edges are pulled together and approximated with sutures or staples, and healing occurs by connective tissue deposition. **B,** Wound healing by secondary intention. Wound edges are not approximated, and healing occurs by granulation tissue formation and contraction of the wound edges. (From Black JM, Hawks JH: *Medical-surgical nursing: clinical management for positive outcomes,* ed 8, St Louis, 2009, Mosby.)

Tissue trauma causes the *inflammatory response,* which in turn causes redness and swelling to the area with a moderate amount of serous exudate. This response generally is limited to the first 24 hours after wounding. The epithelial cells begin to regenerate, providing new cells to replace the lost cells. The *epithelial proliferation and migration* start at both the wound edges and the epidermal cells lining the

epidermal appendages, allowing for quick resurfacing. Epithelial cells begin to migrate across a wound bed soon after the wound occurs. A wound left open to air can resurface within 6 to 7 days, whereas one that is kept moist can resurface in 4 days. The difference in the healing rate is related to the fact that epidermal cells only migrate across a moist surface. In a dry wound the cells migrate down into a moist level before migration can occur (Doughty and Sparks-Defriese, 2016). New epithelium is only a few cells thick and must undergo *reestablishment of the epidermal layers.* The cells slowly reestablish normal thickness and appear as dry, pink tissue.

Full-Thickness Wound Repair. The four phases involved in the healing process of a full-thickness wound are hemostasis, inflammatory, proliferative, and maturation.

Hemostasis. A series of events designed to control blood loss, establish bacterial control, and seal the defect occurs when there is an injury. During **hemostasis** injured blood vessels constrict, and platelets gather to stop bleeding. Clots form a **fibrin** matrix that later provides a framework for cellular repair.

Inflammatory Phase. In the inflammatory stage damaged tissue and mast cells secrete histamine, resulting in vasodilation of surrounding capillaries and movement/migration of serum and white blood cells into the damaged tissues. This results in localized redness, edema, warmth, and throbbing. The inflammatory response is beneficial, and there is no value in attempting to cool the area or reduce the swelling unless the swelling occurs within a closed compartment (e.g., ankle or neck).

Leukocytes (white blood cells) reach a wound within a few hours. The primary-acting white blood cell is the neutrophil, which begins to ingest bacteria and small debris. The second important leukocyte is the monocyte, which transforms into macrophages. The macrophages are the "garbage cells" that clean a wound of bacteria, dead cells, and debris by phagocytosis. Macrophages continue the process of clearing a wound of debris and release growth factors that attract fibroblasts, the cells that synthesize collagen (connective tissue). Collagen appears as early as the second day and is the main component of scar tissue.

In a clean wound the inflammatory phase establishes a clean wound bed. The inflammatory phase is prolonged if too little inflammation occurs, as in a debilitating disease such as cancer or after administration of steroids. Too much inflammation also prolongs healing because arriving cells compete for available nutrients. An example is a wound infection in which the increased metabolic energy requirements present in an infected wound compete for the available calorie intake.

Proliferative Phase. With the appearance of new blood vessels as reconstruction progresses, the proliferative phase begins and lasts from 3 to 24 days. The main activities during this phase are the filling of a wound with granulation tissue, wound contraction, and wound resurfacing by **epithelialization**. Fibroblasts are present in this phase and are the cells that synthesize collagen, providing the matrix for granulation. Collagen mixes with the granulation tissue to form a matrix that supports the reepithelialization. Collagen provides strength and structural integrity to a wound. During this period a wound contracts to reduce the area that requires healing. Finally the epithelial cells migrate from the wound edges to resurface. In a clean wound the proliferative phase accomplishes the following: the vascular bed is reestablished (granulation tissue), the area is filled with replacement tissue (collagen, contraction, and granulation tissue), and the surface is repaired (epithelialization). Impairment of healing during this stage usually results from systemic factors such as age, anemia, hypoproteinemia, and zinc deficiency.

Maturation. Maturation, the final stage of healing, sometimes takes place for more than a year, depending on the depth and extent of the wound. The collagen scar continues to reorganize and gain strength for several months. However, a healed wound usually does not have the tensile strength of the tissue it replaces. Collagen fibers undergo remodeling or reorganization before assuming their normal appearance. Usually scar tissue contains fewer pigmented cells (melanocytes) and has a lighter color than normal skin. In dark-skinned individuals the scar tissue may be more highly pigmented than surrounding skin.

Complications of Wound Healing

Hemorrhage. **Hemorrhage,** or bleeding from a wound site, is normal during and immediately after initial trauma. Hemostasis occurs within several minutes unless large blood vessels are involved or a patient has poor clotting function. Hemorrhage occurring after hemostasis indicates a slipped surgical suture, a dislodged clot, infection, or erosion of a blood vessel by a foreign object (e.g., a drain). Hemorrhage occurs externally or internally. For example, if a surgical suture slips from a blood vessel, bleeding occurs internally within the tissues, and there are no visible signs of blood unless a surgical drain is present. A surgical drain may be inserted into tissues beneath a wound to remove fluid that collects in underlying tissues.

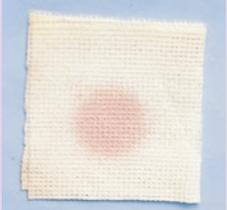
You detect internal bleeding by looking for distention or swelling of the affected body part, a change in the type and amount of drainage from a surgical drain, or signs of hypovolemic shock. A **hematoma** is a localized collection of blood underneath the tissues. It appears as a swelling, change in color, sensation, or warmth that often takes on a bluish discoloration. A hematoma near a major artery or vein is dangerous because pressure from the expanding hematoma obstructs blood flow.

External hemorrhaging is obvious. You observe dressings covering a wound for bloody drainage. If bleeding is extensive, the dressing soon becomes saturated, and frequently blood drains from under the dressing and pools beneath the patient. Observe all wounds closely, particularly surgical wounds, in which the risk of hemorrhage is great during the first 24 to 48 hours after surgery or injury.

Infection. Wound infection is the second most common health care–associated infection (nosocomial) (see Chapter 29). All wounds have some level of bacterial burden; few wounds are infected (Stotts, 2016b). Wound infection is present when the microorganisms invade the wound tissues. The local clinical signs of wound infection can include erythema; increased amount of wound drainage; change in appearance of the wound drainage (thick, color change, presence of odor); and periwound warmth, pain, or edema. A patient may have a fever and an increase in white blood cell count. Laboratory tests such as a wound culture, tissue biopsy, or swab culture can be done to evaluate the wound for infection. Bacterial infections inhibit wound healing.

Some contaminated or traumatic wounds show signs of infection early, within 2 to 3 days. A surgical wound infection usually does not develop until the fourth or fifth postoperative day. A patient will have a fever, tenderness and pain at the wound site, and an elevated white blood cell count. The edges of the wound will appear inflamed. If drainage is present, it is odorous and **purulent,** which causes a yellow, green, or brown color, depending on the causative organism (Table 48-2).

Dehiscence. When an incision fails to heal properly, the layers of skin and tissue separate. This most commonly occurs before collagen formation (3 to 11 days after injury). **Dehiscence** is the partial or total separation of wound layers. A patient who is at risk for poor wound healing (e.g., poor nutritional status, infection) is at risk for dehiscence. Obese patients have a higher risk of wound dehiscence because of the

TABLE 48-2	Types of Wound Drainage
Type	**Appearance**
Serous	Clear, watery plasma
Purulent	Thick, yellow, green, tan, or brown
Serosanguineous	Pale, pink, watery; mixture of clear and red fluid
Sanguineous	Bright red; indicates active bleeding


constant strain placed on their wounds and the poor healing qualities of fat tissue (Pierpont et al., 2014). Dehiscence can happen in abdominal surgical wounds and occurs after a sudden strain such as coughing, vomiting, or sitting up in bed. Patients often report feeling as though something has given way. When there is an increase in serosanguineous drainage from a wound in the first few days after surgery, be alert for the potential for dehiscence.

Evisceration. With total separation of wound layers, **evisceration** (protrusion of visceral organs through a wound opening) occurs. The condition is an emergency that requires surgical repair. When evisceration occurs, a nurse places sterile gauzed soaked in sterile saline over the extruding tissues to reduce chances of bacterial invasion and drying of the tissues. If the organs protrude through the wound, blood supply to the tissues can be compromised. The presence of an evisceration is a surgical emergency. Immediately place damp sterile gauze over the site, contact the surgical team, do not allow the patient anything by mouth (NPO), observe for signs and symptoms of shock, and prepare the patient for emergency surgery.

NURSING KNOWLEDGE BASE

Prediction and Prevention of Pressure Ulcers

A major aspect of nursing care is the maintenance of skin integrity. Consistent, planned skin-care interventions are critical to ensuring high-quality care. Whenever you are in direct contact with a patient, observe the skin for breaks or impaired skin integrity. Impaired skin integrity occurs from prolonged pressure (e.g., from lying in one position, or from rubbing of external devices), fecal or urinary incontinence, and/or immobility, leading to the development of pressure ulcers.

A pressure ulcer is localized injury to the skin and/or underlying tissue, usually over a bony prominence, as a result of pressure or pressure in combination with shear. A number of contributing or confounding factors are also associated with pressure ulcers; the significance of these factors is yet to be explained (NPUAP, EPUAP, PPPIA, 2014).

Risk Assessment. Several instruments are available for assessing patients who are at risk for developing a pressure ulcer. By identifying at-risk patients, you are able to put interventions into place and spare patients with little risk for pressure ulcer development the unnecessary and sometimes costly preventive treatment. Prevention and treatment of pressure ulcers are major nursing priorities. The incidence of pressure ulcers in a facility or agency is an important indicator of quality of care. Evidence exists that a program of prevention guided by risk assessment simultaneously reduces the institutional incidence of pressure ulcers by as much as 60% and brings down the costs of prevention at the same time (Berry et al., 2013). Several risk-assessment scales developed by nurses enable systematic risk assessment of patients. The Braden Scale is the most widely used risk-assessment tool for pressure ulcers and is in the WOCN guidelines (2010) as being a valid tool to use for pressure ulcer risk assessment. The Braden Scale (Table 48-3) was developed on the basis of risk factors in a nursing home population (Braden and Bergstrom, 1994) and is widely used on general patient care units in hospitals. However, the Braden Scale has shown insufficient predictive validity and poor accuracy in discriminating intensive care patients at risk for developing pressure ulcers (Hyun et al., 2013). Research involving critical care patients continues. The Braden Scale contains six subscales: sensory perception, moisture, activity, mobility, nutrition, and friction/shear. The total score ranges from 6 to 23; a lower total score indicates a higher risk for pressure ulcer development (Braden and Bergstrom, 1989). The cutoff score for onset of pressure ulcer risk with the Braden Scale in the general adult population is 18 (Ayello et al., 2012). Research has shown that the cutoff score for onset of risk in intensive care patients is 13 (Hyun et al., 2013).

Prevention. Preventing pressure ulcers is a priority in caring for patients and is not limited to patients with restrictions in mobility. Impaired skin integrity usually is not a problem in healthy, immobilized individuals but is a serious and potentially devastating problem in ill or debilitated patients (WOCN, 2010).

Economic Consequences of Pressure Ulcers. Pressure ulcers are a continual problem in acute and restorative care settings. For adult patients with pressure ulcers, 56.5% were 65 years and older (WOCN, 2010). Paralysis and spinal cord injury are common preexisting conditions among younger adults with primary diagnosis of pressure ulcers. Older adults admitted to acute and long-term facilities are a vulnerable population. In a study examining early intervention of high-risk patients admitted to the emergency department in an acute care facility, early prevention was 81% likely to be cost-effective (Pham, 2011).

TABLE 48-3 Braden Scale for Predicting Pressure Ulcer Risk

Patient's Name _____ Evaluator's Name _____ Date of Assessment _____

Sensory Perception

Ability to respond meaningfully to pressure-related discomfort

1. Completely limited	2. Very limited	3. Slightly limited	4. No impairment
Unresponsive (does not moan, flinch, or grasp) to painful stimuli caused by diminished level of consciousness or sedation *or* Limited ability to feel pain over most of body surface	Responds only to painful stimuli Cannot communicate discomfort except by moaning or restlessness *or* Has sensory impairment that limits ability to feel pain or discomfort over $\frac{1}{2}$ of body	Responds to verbal commands but cannot always communicate discomfort or need to be turned *or* Has some sensory impairment that limits ability to feel pain or discomfort in one or two extremities	Responds to verbal commands Has no sensory deficit that would limit ability to feel or voice pain or discomfort

Moisture

Degree to which skin is exposed to moisture

1. Constantly moist	2. Moist	3. Occasionally moist	4. Rarely moist
Skin kept moist almost constantly by bodily elimination such as perspiration or urine Dampness detected every time patient is moved or turned	Skin often, but not always, moist Necessary to change linen at least once a shift	Skin occasionally moist, requiring an extra linen change approximately once a day	Skin usually dry Required linen changing only at routine intervals

Activity

Degree of physical activity

1. Bedfast	2. Chairfast	3. Walks occasionally	4. Walks frequently
Confined to bed	Ability to walk severely limited or nonexistent Cannot bear own weight and/or must be helped into chair or wheelchair	Walks occasionally during day but for very short distances, with or without help Spends majority of each shift in bed or chair	Walks outside room at least twice a day and inside room at least once every 2 hours during waking hours

Mobility

Ability to change and control body position

1. Completely immobile	2. Very limited	3. Slightly limited	4. No limitations
Does not make even slight changes in body or extremity position without help	Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently	Makes frequent, although slight, changes in body or extremity position independently	Makes major and frequent changes in position without help

Nutrition

Usual food intake pattern

1. Very poor	2. Probably inadequate	3. Adequate	4. Excellent
Never eats a complete meal; rarely eats more than $\frac{1}{3}$ of any food offered; eats two servings or less of protein (meat or dairy products) per day Takes fluids poorly; does not take a liquid dietary supplement *or* Is NPO and/or maintained on clear liquids or IV for more than 5 days	Rarely eats a complete meal and generally eats only about $\frac{1}{2}$ of any food offered Protein intake includes only 3 servings of meat or dairy products per day; occasionally takes a dietary supplement *or* Receives less than optimum amount of liquid diet or tube feeding	Eats over half of most meals; eats a total of four servings of protein (meat, dairy products) each day Occasionally refuses a meal but usually takes a supplement if offered *or* Is on tube feeding or total parenteral nutrition regimen that probably meets most of nutritional needs	Eats most of every meal; never refuses a meal; usually eats a total of four or more servings of meat and dairy products Occasionally eats between meals Does not require supplementation

Friction and Shear

1. Problem	2. Potential problem	3. No apparent problem	**TOTAL SCORE**
Requires moderate-to-maximum help to move; complete lifting without sliding against sheets impossible Frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance Spasticity, contractures, or agitation leads to almost constant friction	Moves feebly or requires minimum assistance; during a move skin probably slides to some extent against sheets, chair, restraints, or other devices Maintains relatively good position in chair or bed most of the time but occasionally slides down	Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move Maintains good position in bed or chair at all times	

TABLE 48-4	Role of Selected Nutrients in Wound Healing		
Nutrient	**Role in Healing**	**Recommendations**	**Sources**
Calories	Fuel for cell energy "Protein protection"	30-35 kcal/kg/day (Individuals who are underweight or have significant unintentional weight loss may need additional calories.)	
Protein	Fibroplasia, angiogenesis, collagen formation and wound remodeling, immune function	1.25-1.5 g protein/kg body weight	Poultry, fish, eggs, beef
Vitamin C (ascorbic acid)	Collagen synthesis, capillary wall integrity, fibroblast function, immunological function, antioxidant	1000 mg/day	Citrus fruits, tomatoes, potatoes, fortified fruit juices
Vitamin A	Epithelialization, wound closure, inflammatory response, angiogenesis, collagen formation Can reverse steroid effects on skin and delayed healing	1600-2000 retinol equivalents per day	Green leafy vegetables (spinach), broccoli, carrots, sweet potatoes, liver
Zinc	Collagen formation, protein synthesis, cell membrane and host defenses	15-30 mg Correct deficiencies No improvement in wound healing with supplementation unless zinc deficient Use with caution—large doses can be toxic May inhibit copper metabolism and impair immune function	Vegetables, meats, legumes
Fluid	Essential fluid environment for all cell function	30-35 mL/kg/day	Use noncaffeinated, nonalcoholic fluids without sugar Water is best—6-8 glasses/day

Adapted from Stotts NA: Nutritional assessment and support. In Bryant RA, Nix DP, editors: *Acute and chronic wounds: current management concepts,* ed 5, St Louis, 2016a, Elsevier.

When a pressure ulcer occurs, the length of stay in a hospital and the overall cost of health care increase. The actual cost of treatment is difficult to estimate. About 1.6 million patients each year in acute care settings develop pressure ulcers, representing a cost of $11 to $17.2 billion to the U.S. health care system (Pieper, 2016). Although it is difficult to identify the exact numbers of pressure ulcers and the number of patients with pressure ulcers, the occurrence of pressure ulcers is costly to patients in terms of disability, pain, and suffering. The occurrence of pressure ulcers is also costly for health care institutions and third-party payers. The Centers for Medicare and Medicaid Services (CMS) implemented a policy effective October 1, 2008 whereby hospitals no longer receive additional reimbursement for care related to eight conditions, including stage III and IV pressure ulcers that occur during a hospitalization. This policy was put in place to provide additional incentives for hospitals to improve quality of care. Using guidelines such as the WOCN Guidelines (WOCN, 2010) helps reduce or eliminate the occurrence of pressure ulcers and prevent the expenses that will not be reimbursed.

Factors Influencing Pressure Ulcer Formation and Wound Healing

Impaired skin integrity resulting in pressure ulcers is primarily the result of pressure. However, additional factors, including shear force, friction, moisture, nutrition, tissue perfusion, infection, and age, increase the patient's risk for pressure ulcer development and poor wound healing.

Nutrition. For patients weakened or debilitated by illness, nutritional therapy is especially important. A patient who has undergone surgery (see Chapter 50) and is well nourished still requires at least 1500 kcal/day for nutritional maintenance. Alternatives such as enteral feedings (see Chapter 45) and parenteral nutrition (see Chapter 45) are available for patients unable to maintain normal food intake.

Normal wound healing requires proper nutrition (Table 48-4). Deficiencies in any of the nutrients result in impaired or delayed healing (Stotts, 2016a). Physiological processes of wound healing depend on the availability of protein, vitamins (especially A and C), and the trace minerals zinc and copper. Collagen is a protein formed from amino acids acquired by fibroblasts from protein ingested in food. Vitamin C is necessary for synthesis of collagen. Vitamin A reduces the negative effects of steroids on wound healing. Trace elements are also necessary; (i.e., zinc for epithelialization and collagen synthesis and copper for collagen fiber linking).

Calories provide the energy source needed to support the cellular activity of wound healing. Protein needs especially are increased and are essential for tissue repair and growth. A balanced intake of various nutrients (i.e., protein, fat, carbohydrates, vitamins, and minerals) is critical to support wound healing. Provide 30 to 35 kcal/kg of body weight for adults with a pressure ulcer who are assessed as being at risk of malnutrition (NPUAP, EPUAP, PPPIA, 2014).

Serum proteins are biochemical indicators of malnutrition (Stotts, 2016a). Serum albumin is probably the most frequently measured of these laboratory parameters. Albumin alone is not sensitive to rapid changes in nutritional status. Transferrin also evaluates protein status,

but alone it does not determine malnutrition. The best measure of nutritional status is prealbumin because it reflects not only what the patient has ingested but also what the body has absorbed, digested, and metabolized (Stotts, 2016a).

Tissue Perfusion. Oxygen fuels the cellular functions essential to the healing process; therefore the ability to perfuse the tissues with adequate amounts of oxygenated blood is critical to wound healing (Doughty and Sparks-Defriese, 2016). Patients with peripheral vascular disease are at risk for poor tissue perfusion because of poor circulation. Oxygen requirements depend on the phase of wound healing (e.g., chronic tissue hypoxia is associated with impaired collagen synthesis and reduced tissue resistance to infection).

Infection. Wound infection prolongs the inflammatory phase; delays collagen synthesis; prevents epithelialization; and increases the production of proinflammatory cytokines, which leads to additional tissue destruction (Stotts, 2016b). Indications that a wound infection is present include the presence of purulent drainage; change in odor, volume, or character of wound drainage; redness in the surrounding tissue; fever; or pain.

Age. Increased age affects all phases of wound healing. A decrease in the functioning of the macrophage leads to a delayed inflammatory response, delayed collagen synthesis, and slower epithelialization.

Psychosocial Impact of Wounds. The psychosocial impact of wounds on the physiological process of healing is unknown. Body image changes often impose a great stress on a patient's adaptive mechanisms. They also influence self-concept (see Chapter 34) and sexuality (see Chapter 35). Factors that affect a patient's perception of a wound include the presence of scars, stitches, drains (often needed for weeks or months), odor from drainage, and temporary or permanent prosthetic devices.

CRITICAL THINKING

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require a nurse to anticipate the information necessary, analyze the data, and make decisions regarding patient care. Critical thinking is always changing. During assessment (Figure 48-7) consider all elements that build toward making appropriate nursing diagnoses.

When caring for patients who have impaired skin integrity and chronic wounds, integrate knowledge from nursing and other disciplines, previous experiences, and information gathered from patients to understand the risk to skin integrity and wound healing. Knowledge of normal musculoskeletal physiology, the pathogenesis of pressure ulcers, pressure ulcer stages, normal wound healing, and the pathophysiology of underlying diseases enables you to have a scientific basis for care. The WOCN (2010) has guidelines for assessment of risk for impaired skin integrity, prevention measures, interventions to promote wound healing, and other standards of practice, which you should use in planning care. Past experience with patients at risk for impaired skin integrity or patients with wounds increases the experiential knowledge base, helping you to identify interventions. Finally you need to be disciplined during assessment to obtain comprehensive and correct data. You also need to be creative. Because chronic wounds are difficult to heal, be diligent in evaluating nursing interventions and determining which interventions are effective and which need modification.

Knowledge
- Pathogenesis of pressure ulcers
- Factors contributing to pressure ulcer formation or poor wound healing
- Factors contributing to wound healing
- Impact of underlying disease process on skin integrity
- Impact of medication on skin integrity and wound healing

Experience
- Caring for patients with impaired skin integrity or wounds
- Observation of normal wound healing

ASSESSMENT
- Identify the patient's risk for developing impaired skin integrity or poor wound healing
- Identify signs and symptoms associated with impaired skin integrity or poor wound healing
- Examine patient's skin for actual impairment in skin integrity

Standards
- Apply intellectual standards of accuracy, relevance, completeness, and precision when obtaining health history regarding skin integrity and wound management
- Knowledge of WOCN (2010), NPUAP, EPUAP, and PPPIA 2014 Clinical Practice Guidelines standards for prevention of pressure ulcers
- Knowledge of standards for assessment of risk for impaired skin integrity and for prevention and treatment

Attitudes
- Use discipline to obtain complete and correct assessment data regarding patient's skin and/or wound integrity
- Demonstrate responsibility for collecting appropriate specimens for diagnostic and laboratory tests related to wound management

FIGURE 48-7 Critical thinking model for skin integrity and wound-care assessment. *WOCN,* Wound, Ostomy, and Continence Nurses Society.

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care.

◆ Assessment

During the assessment process, thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care. Baseline and continual assessment data provide critical information about a patient's skin integrity and the increased risk for pressure ulcer development. Focusing on specific elements such as a patient's level of sensation, movement, and continence status helps guide the skin assessment (Box 48-4).

FIGURE 48-8 Formation of pressure ulcer on heel resulting from external pressure from bed mattress. (Courtesy Janice Colwell, RN, MS, CWOCN, FAAN, Clinical Nurse Specialist, University of Chicago Medicine.)

Through the Patient's Eyes. When patients have acute surgical or traumatic wounds, the wounds sometimes heal promptly and without complications. However, when pressure ulcers or chronic wounds develop, the course of treatments is lengthy and costly. Because a patient and family need to be involved with wound-care management, it is important to know a patient's expectations. Does the patient expect to have home care? Is there the expectation the patient will heal to allow a quick return to work? A patient who has realistic goals and is informed about the length of time for wound healing is more likely to adhere to the specific therapies designed to promote healing and prevent further skin breakdown. Therefore it is important to assess each patient's perception of what is occurring with the wound-healing interventions. For example, why are certain dressings being used and how do they work? As a nurse, you want to determine a patient's and family's understanding of wound assessment; wound interventions; and supportive interventions such as positioning, nutrition, and ambulation.

Skin. Perform skin assessment of a patient when you initiate care and then at a minimum of once a shift (see agency policies). However, high-risk patients have more frequent skin assessments such as every 4 hours. Assess the skin for signs of skin breakdown and/or ulcer development (see Skill 48-1). The neurologically impaired patient; the chronically ill patient in long-term care; the patient with altered mental status; those in the intensive care unit (ICU), oncology, hospice, or orthopedic units; and patients with medical devices have increased potential for developing pressure ulcers.

Assessment for tissue pressure damage includes visual and tactile inspection of the skin. Perform a baseline assessment to determine a patient's normal skin characteristics and any actual or potential areas

of breakdown. Individualize assessment characteristics of a patient's skin, depending on his or her skin tone (NPUAP, EUPAP, PPPIA, 2014, Sommers, 2011). Accurate assessment of patients with darker skin pigmentation is an essential skill for all health care providers (Nix, 2016). Assessment characteristics of darkly pigmented skin are in Boxes 48-2 and 48-3.

Pay particular attention to areas located over bony prominences; next to medical devices; and under casts, traction, splints, braces, collars, or other orthopedic devices. The frequency of pressure checks depends on the schedule of appliance application and the response of the skin to the external pressure (Figure 48-8). Consider adults with medical devices (e.g., tubes, drainage systems, and oxygen devices) to be at risk for pressure ulcers (Black et al., 2010; 2015). Avoid positioning the individual directly onto medical devices (NPUAP, EUPAP, PPPIA, 2014). In addition, carefully assess skin exposed to adhesive tape or other adhesive devices, which cause skin and tissue injury and increase risk for pressure ulcer development (McNichol et al., 2013).

When you note hyperemia, gently palpate the reddened tissue; differentiate whether the skin redness is blanchable or nonblanchable. Blanchable erythema is visible skin redness that becomes white when pressure is applied and reddens when pressure is relieved. It may result from normal reactive hyperemia that should disappear within several hours or from inflammatory erythema with an intact capillary bed. Nonblanchable erythema is visible skin redness that persists with the application of pressure. It indicates structural damage to the capillary bed/microcirculation. This is an indication for a category/stage I pressure ulcer (NPUAP, EUPAP, PPPIA, 2014).

Use visual and tactile inspection over the body areas most frequently at risk for pressure ulcer development (Figure 48-9). For example, when a patient lies in bed or sits in a chair, he or she places body weight heavily on certain bony prominences. Turn the patient in bed to inspect the skin and, once you return a patient to bed from a chair, look at all areas exposed to pressure. Body surfaces subjected to the greatest weight or pressure are at greatest risk for pressure ulcer formation.

Pressure Ulcers. Pressure ulcers have multiple etiological factors. Review the previous section on pp. 1187-1189 for assessment of pressure ulcer staging when one is identified. Assessment for pressure ulcer risk includes using an appropriate predictive measure and assessing a patient's mobility, nutrition, presence of body fluids, and comfort level (see Skill 48-1 on pp. 1221-1223).

Predictive Measures. On admission to acute care, rehabilitation hospitals, nursing homes, home care, and other health care facilities, individuals need to be assessed for risk of pressure ulcer development (WOCN, 2010). Perform pressure ulcer risk assessment systematically (WOCN, 2010). Use an assessment tool such as the Braden Scale (see Table 48-3) or a tool preferred by your agency. The interpretation of the meaning of the total numerical scores differs with each risk-assessment scale relevant to their population. Lower numerical scores on the Braden Scale indicate that the patient is at high risk for skin breakdown. A benefit of the predictive instruments is to increase a nurse's early detection of patients at greater risk for ulcer development. Once you identify these patients, institute appropriate interventions to maintain skin integrity and implement prevention strategies (WOCN, 2010). Perform reassessment for pressure ulcer risk on a scheduled basis.

Mobility. Assessment includes documenting the level of mobility and the potential effects of impaired mobility on skin integrity. Documenting assessment of mobility includes obtaining data regarding the quality of muscle tone and strength. For example, determine whether the patient is able to lift his or her weight off of the sacral area and roll the body to a side-lying position. Some patients have inadequate range of motion to move independently into a more protective position. Finally, assess a patient's activity tolerance to determine if the patient can be transferred to a chair or ambulated more often to relieve pressure from lying down (see Chapter 39).

You must assess mobility as part of baseline data. If a patient has some degree of mobility independence, reinforce the frequency of position changes and measures to relieve pressure. The frequency of position changes is based on ongoing skin assessment and is revised as data change.

Nutritional Status. An assessment of patients' nutritional status is an integral part of the initial assessment data for all patients, especially those at risk for impaired skin integrity (Stotts, 2016a). The Joint Commission (2008, 2015) recommends nutritional assessment within 24 hours of admission. Malnutrition is a risk factor for pressure ulcer development (Litchford et al., 2014). Weigh the patient, and perform this measure more often for at-risk patients. A loss of 5% of usual weight, weight less than 90% of ideal body weight, and a decrease of 10 lbs in a brief period are all signs of actual or potential nutritional problems (Stotts, 2016a). Also assess the patient's appetite and food preferences to determine what food choices might be added to better supplement the diet. Assess the patient's mouth and skin for signs of nutritional deficiencies (see Chapter 45).

Body Fluids. Continual exposure of the skin to body fluids increases a patient's risk for skin breakdown and pressure ulcer formation. Some body fluids such as saliva and serosanguineous drainage are not as caustic to the skin, and the risk of skin breakdown from exposure to these fluids is low. However, exposure to urine, bile, stool, ascitic fluid, and purulent wound exudate carries a moderate risk for skin breakdown, especially in patients who have other risk factors such as chronic illness or poor nutrition. Exposure to gastric and pancreatic drainage has the highest risk for skin breakdown. These fluids have digestive qualities that can irritate and break down the skin quickly. It is important to prevent and reduce the patient's exposure to body fluids; when exposure occurs, provide meticulous hygiene and skin care.

Pain. Significant research has been conducted in the study of pain in surgical patients with wounds. The routine assessment of pain in surgical patients is critical to selecting appropriate pain management therapies and to determine a patient's ability to progress towards recovery (see Chapter 50). Until recently there has been little research about pain and pressure ulcers. The WOCN (2010) has recommended that assessment and management of pain be included in the care of patients with pressure ulcers (NPUAP, EUPAP, PPPIA, 2014). Use standard pain assessment tools to measure pain acuity, and be thorough in assessing the character of a patient's pain (Chapter 44). Maintaining adequate pain control and patient comfort increases the patient's willingness

and ability to increase mobility, which in turn reduces pressure ulcer risk.

Wounds.   Wounds should be assessed on an ongoing basis: at the time of injury, during wound care, when a patient's overall condition changes, and on a regularly scheduled basis. Regardless of the setting, it is important that you initially obtain information regarding the cause and history of the wound, treatment of the wound, wound description, and response to therapy (see Box 48-4).

Emergency Setting. You see wounds in any setting, including clinics, emergency departments, youth camps, or your own backyard. The type of wound determines the criteria for inspection. For example, you do not need to inspect for signs of internal bleeding after an abrasion, but you should inspect in the event of a puncture wound.

When you judge a patient's condition to be stable because of the presence of spontaneous breathing, a clear airway, and a strong carotid pulse (see Chapters 30 and 41), inspect the wound for bleeding. An **abrasion** is superficial with little bleeding and is considered a partial-thickness wound. The wound often appears "weepy" because of plasma leakage from damaged capillaries. A **laceration** sometimes may bleed more profusely, depending on the depth and location of the wound. For example, minor scalp lacerations tend to bleed profusely because of the rich blood supply to the scalp. Lacerations greater than 5 cm (2 inches) long or 2.5 cm (1 inch) deep cause serious bleeding. **Puncture** wounds bleed in relation to the depth, size, and location of the wound (e.g., a nail puncture does not cause as much bleeding as a knife wound). The primary dangers of puncture wounds are internal bleeding and infection.

Inspect wounds for foreign bodies or contaminant material. Most traumatic wounds are dirty. Soil, broken glass, shreds of cloth, and foreign substances clinging to penetrating objects sometimes become embedded in a wound.

The size and depth of a wound are the next steps in assessment. Use a disposable wound-measuring device to measure wound width and length. This approach offers a uniform, consistent method for measuring wound length and width to facilitate meaningful comparisons of wound status across time (EPUAP, NPUAP PPPIA, 2014). Measure depth by using a cotton-tipped applicator in the wound bed (see Skill 48-2). A deep laceration requires suturing. A large, open wound may expose bone or tissue that needs to be protected.

When an injury is a result of trauma from a dirty penetrating object, determine when the patient last received a tetanus toxoid injection. Tetanus bacteria reside in soil and in the gut of humans and animals. A tetanus antitoxin injection is necessary if the patient has not had one within 10 years.

Stable Setting. When a patient's condition is stabilized (e.g., after surgery or treatment), assess the wound to determine progress toward healing. If the wound is covered by a dressing and the health care provider has not ordered it changed, do not inspect it directly unless you suspect serious complications such as a large volume of bright red bleeding, excessive odor, or severe pain under the dressing. In such a situation inspect only the dressing and any external drains. If the health care provider prefers to change the dressing, he or she should assess the wound at least daily. When removing dressings, take care to avoid accidental removal or displacement of underlying drains. Because removal of dressings can be painful, consider giving an analgesic at least 30 minutes before exposing a wound. Assess the wound thoroughly using standard measurements.

Wound Appearance. A surgical incision healing by primary intention should have clean, well-approximated edges. Crusts often form along wound edges from exudate. A puncture wound is usually a small, circular wound with the edges coming together toward the center. If a

TABLE 48-5   Assessment of Abnormal Healing in Primary- and Secondary-Intention Wounds

Primary Intention Wounds	Secondary Intention Wounds
Incision line poorly approximated	Pale or fragile granulation tissue, granulation tissue bed excessively dry or moist
Drainage present more than 3 days after closure	Purulent exudate present
Inflammation increased in first 3-5 days after injury	Necrotic or slough tissue present in wound base
No epithelialization of wound edges by day 4	Epithelialization not continuous. Fruity, earthy, or putrid odor present. Presence of fistula(s), tunneling, undermining

Modified from Stotts NA, Cavanaugh CE: Assessing the patient with a wound, *Home Health Nurse* 17(1):27, 1999.

wound is open, the edges are separated, and you inspect the condition of tissue at the wound base. The outer edges of a wound normally appear inflamed for the first 2 to 3 days, but this slowly disappears. Within 7 to 10 days a normally healing wound resurfaces with epithelial cells, and edges close. Table 48-5 lists assessment characteristics for abnormal wound healing in primary and secondary wounds. If infection develops, the area directly surrounding the wound becomes brightly inflamed and swollen.

Skin discoloration usually results from bruising of interstitial tissues or hematoma formation. Blood collecting beneath the skin first takes on a bluish or purplish appearance. Gradually, as the clotted blood is broken down, shades of brown and yellow appear.

Character of Wound Drainage. Note the amount, color, odor, and consistency of wound drainage. The amount of drainage depends on the type of wound. For example, drainage is minimal after a simple appendectomy. In contrast, it is moderate for 1 to 2 days after drainage of a large abscess. When you need an accurate measurement of the amount of drainage within a dressing, weigh the dressing and compare it with the weight of the same dressing that is clean and dry. The general rule is that 1 g of drainage equals 1 mL of volume of drainage. Another method of quantifying wound drainage is to chart the number of dressings used and the frequency of change. An increase or decrease in the number or frequency of dressings indicates a relative increase or decrease in wound drainage.

The color and consistency of drainage vary, depending on the components. Types of drainage include: **serous**, **sanguineous**, **serosanguineous**, and purulent (see Table 48-2). If the drainage has a pungent or strong odor, you should suspect an infection. Describe the appearance of the wound according to characteristics observed. An example of an accurate recording follows:

Abdominal incision in the RLQ is 5 cm in length; edges well approximated without inflammation or exudate. 1.2 cm diameter circle of serous drainage present on one 4 × 4 gauze changed every 8 hours.

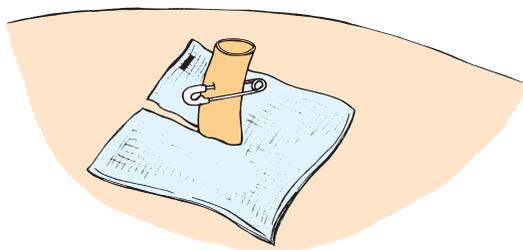
Drains. The surgeon inserts a drain into or near a surgical wound if there is a large amount of drainage. Some drains are sutured in place. Exercise caution when changing a dressing around drains that are not sutured in place to prevent accidental removal. A Penrose drain lies under a dressing; at the time of placement a pin or clip is placed through the drain to prevent it from slipping farther into a wound


FIGURE 48-10 Penrose drain with dressing.
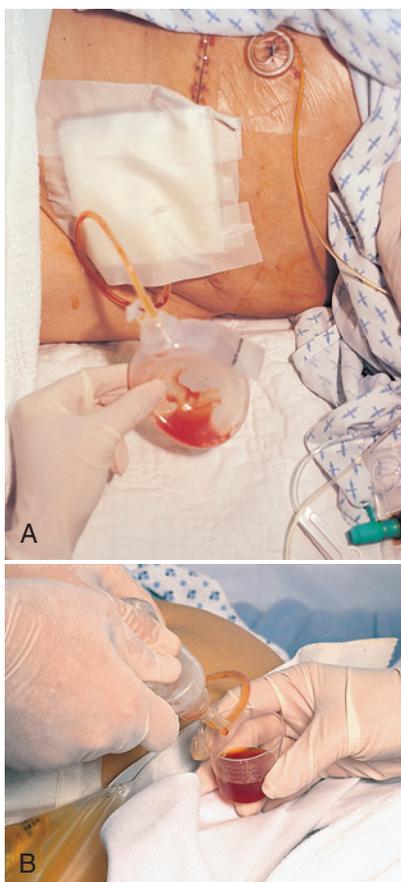

FIGURE 48-11 Jackson-Pratt drainage device. **A,** Drainage tube and reservoir. **B,** Emptying drainage reservoir.

(Figure 48-10). It is usually the health care provider's responsibility to pull or advance the drain as drainage decreases to permit healing deep within the drain site. The wound will heal from the inside out.

Assess the number and type of drains, drain placement, character of drainage, and condition of collecting equipment. Observe the security of the drain and its location with respect to the wound. Next note the character of drainage. If there is a collecting device, measure the drainage volume. Because a drainage system needs to be patent, look for drainage flow through and around the tubing. A sudden decrease in drainage through the tubing may indicate a blocked drain, and you need to notify the health care provider. When a drain is connected to suction, assess the system to be sure that the pressure ordered is being exerted. Evacuator units such as a Hemovac or Jackson-Pratt (Figure 48-11) exert a constant low pressure as long as the suction device (bladder or container) is fully compressed. These types of drainage devices are often referred to as *self-suction*. When the evacuator device is unable to maintain a vacuum on its own, notify the surgeon, who

then orders a secondary vacuum system (such as wall suction). If fluid accumulates within the tissues, wound healing does not progress at an optimal rate, and this increases the risk of infection.

Wound Closures. Surgical wounds are closed with staples, sutures, or wound adhesives. A frequent skin closure is the stainless-steel staple. The staple provides more strength than nylon or silk sutures and tends to cause less irritation to tissue. Look for irritation with redness around staple or suture sites, and note whether closures are intact. Normally for the first 2 to 3 days after surgery the skin around sutures or staples is edematous because of the normal inflammatory response.

Dermabond is a liquid tissue adhesive that forms a strong bond across approximated wound edges, allowing normal healing to occur below. It can be used to replace small sutures for incisional repair. A vial containing the Dermabond solution is used to apply the product to approximated tissue. The wound edges are held together until the solution dries, providing an adhesive closure. Tissue adhesives take less time to apply, have lower risk of infection, have comparable tensile strength as sutures, and also provide less pain and anxiety (Januchowski and Ferguson, 2014).

Palpation of Wound. When inspecting a wound, observe for swelling or separation of wound edges. While wearing gloves, lightly press the wound edges, detecting localized areas of tenderness or drainage collection. If pressure causes fluid to be expressed, note the character of the drainage. The patient is normally sensitive to palpation of wound edges. Extreme tenderness indicates infection.

Wound Cultures. If you detect purulent or suspicious-looking drainage, report to the health care provider because a specimen of the drainage may need to be obtained for culture. Never collect a wound culture sample from old drainage. Resident colonies of bacteria flora from the skin grow within exudate and are not always the true causative organisms of a wound infection. Clean a wound first with normal saline to remove skin flora. Aerobic organisms grow in superficial wounds exposed to the air, and anaerobic organisms tend to grow within body cavities. Use a different method of specimen collection for each type of organism per agency policy (Box 48-5).

Gram stains of drainage are often performed as well. This test allows the health care provider to order appropriate treatment earlier than when only cultures are done. No additional specimens are usually required. The microbiology laboratory needs only to be notified to perform the additional test.

The gold standard of wound culture is tissue biopsy. A health care provider or wound-care specialist with special training obtains the biopsy (Stotts, 2016b).

Psychosocial. Assess how the wound is influencing the patient's self-perception and socialization. Ask the patient to describe how the wound affects his or her view of self. Does the patient have unwarranted fears that the wound will not heal? Does a chronic wound interfere with the patient's willingness to participate in social activities at home? Does it affect the patient's ability to continue working? Make sure that the patient's personal and social resources for adaptation are a part of your assessment. Is there a family caregiver who is able to assist with wound care in the home?

◆ Nursing Diagnosis

Assessment reveals clusters of data to indicate whether a problem-focused diagnosis of *Impaired Skin Integrity* or a risk diagnosis of *Risk for Impaired Skin Integrity* exists. In addition, the assessment data provides information about the related factor. For example, a postoperative patient has purulent drainage from a surgical wound and reports tenderness around the area of the wound. These data support a nursing diagnosis of *Impaired Skin Integrity* related to infection (Box 48-6).

BOX 48-5   Recommendations for Standardized Techniques for Wound Cultures*

Needle Aspiration Procedure
- Clean intact skin with a disinfectant solution to remove skin flora. Allow to dry.
- Use a 10-mL disposable syringe with a 22-gauge needle, pulling 0.5 mL of air into the syringe.
- Insert the needle through intact skin next to the wound; withdraw plunger and apply suction to the 10-mL mark.
- Move the needle back and forward at different angles for two to four explorations.
- Remove and safely discard the needle, expel the excess air from the syringe, and cap and prepare the syringe for the laboratory (Stotts, 2016b).

Quantitative Swab Procedure
- Clean the wound surface with a nonantiseptic solution to remove skin flora. Allow to dry.
- Use a sterile swab from a culturette tube (Figure 48-12).
- Moisten the swab with normal saline.
- Rotate the swab in 1 cm^2 (0.4 in^2) of clean tissue in the open wound. Apply pressure to the swab to elicit tissue fluid (Stotts, 2016b). Insert the tip of the swab into the appropriate sterile container, label, and transport to the laboratory.

Modified from Stotts NA: Wound infection: diagnosis and management. In Bryant RA, Nix DP, editors: *Acute and chronic wounds: current management concepts,* ed 5, St Louis, 2016, Elsevier.
*Check agency policy to determine need to obtain health care provider order.

FIGURE 48-12 Wound culturette tube.

After completing an assessment of a patient's wound, the nurse identifies nursing diagnoses that direct the interventions that will be needed to support wound healing and prevent complications. Multiple nursing diagnoses are associated with impaired skin integrity and wounds:
- *Risk for Infection*
- *Imbalanced Nutrition: Less Than Body Requirements*
- *Acute or Chronic Pain*
- *Impaired Physical Mobility*
- *Impaired Skin Integrity*
- *Risk for Impaired Skin Integrity*
- *Ineffective Peripheral Tissue Perfusion*
- *Impaired Tissue Integrity*

Some patients are at risk for poor wound healing because of the presence of previously defined conditions that impair healing. Thus, even

BOX 48-6   Nursing Diagnostic Process
Impaired Skin Integrity Related to Infection

Assessment Activities	Defining Characteristics
Inspect surface of wound and periwound skin.	Break in skin integrity Yellow, foul-smelling drainage from wound Edges of wound red and warm, not approximated Macerated periwound area
Inspect wound for signs of healing.	Brown-red or beige drainage 5 days after surgery Edges of wound not approximated
Palpate wound and ask patient if there is tenderness.	Patient expresses pain on palpitation Periwound edema
Obtain patient's temperature, heart rate, white blood cell count.	Patient febrile, heart rate 125 beats/min, leukocyte (white blood cell) count 12,000/mm^3

though a patient's wound appears normal, the nurse identifies nursing diagnoses such as *Impaired Nutrition* or *Ineffective Peripheral Tissue Perfusion* that direct nursing care toward support of wound repair.

The nature of a wound can cause problems unrelated to wound healing. An alteration in comfort with the diagnosis of *Acute Pain* and *Impaired Mobility* have implications for a patient's eventual recovery. For example, a large abdominal incision causes enough pain to interfere with the patient's ability to turn in bed effectively, making him or her at risk for impaired skin integrity.

◆ Planning

After identifying nursing diagnoses, develop a plan of care for a patient who has the problem-focused or risk diagnosis for *Impaired Skin Integrity*. During planning synthesize information from multiple resources (Figure 48-13). Critical thinking ensures that a patient's plan of care integrates all that you know about the individual and key critical thinking elements. Professional standards are especially important to consider when you develop a plan of care.

Patients who have large, chronic wounds or infected wounds have multiple nursing care needs. A concept map helps to individualize care for a patient who has multiple health problems and related nursing diagnoses (Figure 48-14). This map helps you use critical thinking skills to organize complex patient assessment data into related nursing diagnoses with the patient's chief medical diagnosis. As you identify links between the nursing diagnoses and the chief medical diagnosis, the concept map also links potential interventions that apply to the patient's health care needs.

Goals and Outcomes.   Nursing care is based on a patient's identified needs and priorities. You establish goals and expected outcomes, and from the goals you plan interventions according to the risk for pressure ulcers or the type and severity of the wound and the presence of any complications such as infection, poor nutrition, peripheral vascular diseases, or immunosuppression that can affect wound healing (see the Nursing Care Plan). A goal frequently identified when working with a patient with a wound is to see the wound progressing toward healing within a 2-week period. The outcomes of this goal can include the following:
- Increase in the percentage of granulation tissue in the wound base

Knowledge
- Role of other health care professionals in caring for patients with wounds
- Effect of specific wound care treatment options
- Effect of selected pressure redistribution devices on skin integrity

Experience
- Previous patient responses to planned nursing therapies for improving skin integrity and wound healing (what worked and what did not work)

PLANNING
- Select nursing interventions to promote improved skin integrity and/or wound healing
- Consult with health care professionals such as nutritionists and wound care specialists
- Involve the patient and family in using interventions

Standards
- Individualize therapy to patient's skin integrity and wound management needs
- Use therapies consistent with WOCN (2010) guidelines for treatment of wounds and pressure ulcers

Attitudes
- Use creativity to plan interventions to promote skin integrity and wound healing
- Demonstrate responsibility in planning nursing interventions consistent with the patient's skin care needs and WOCN (2010) guidelines

FIGURE 48-13 Critical thinking model for skin integrity and wound-care planning. *WOCN,* Wound, Ostomy, and Continence Nurses Society.

- No further skin breakdown
- Increase in caloric intake by 10%

These outcomes are reasonable if the overall goal for the patient is to heal the wound. Plan therapies according to the severity and type of wound and the presence of any complicating conditions (e.g., infection, poor nutrition, immunosuppression, and diabetes) that affect wound healing. Other goals of care for patients with wounds include the following: promoting wound hemostasis, preventing infection, promoting wound healing, maintaining skin integrity, gaining comfort, and promoting health.

Setting Priorities. Establish nursing care priorities in wound care on the basis of the comprehensive patient assessment and goals and established outcomes. These priorities also depend on whether the patient's condition is stable or emergent. An acute wound needs immediate intervention; whereas in the presence of a chronic, stable wound, the patient's hygiene and education on wound care is more important. When there is a risk for pressure ulcer development, preventive interventions such as skin-care practices, elimination of shear, and positioning are high priorities. Promotion of wound healing is a major nursing priority; and the type of wound care administered depends on the type, size, and location of the wound and overall treatment goals.

Other patient factors to consider when establishing priorities include patient preferences, daily activities, and family factors. These factors are important, regardless of the setting for health care. The priorities of care may not vary from outpatient, home, acute care, or restorative care settings.

Teamwork and Collaboration. With early discharge from health care settings, it is important to consider a patient's plan for discharge. Anticipating the patient's discharge wound-care needs and related equipment and resources such as referral to a home care agency or outpatient wound-care clinic helps to improve not only wound healing but also the patient's level of independence. Patients and their family caregivers often need to continue the objectives of wound management after discharge (Box 48-7). Carefully consider the ability of a family caregiver and the amount of time needed to change a particular dressing when selecting a dressing for the patient to use after discharge. For example, in the home setting a patient's spouse may choose more expensive dressing materials to reduce the frequency of dressing

---

◎ NURSING CARE PLAN

Impaired Skin Integrity

ASSESSMENT

Mrs. Stein, who is 76 years of age, is 7 days postoperative for an elective total hip replacement. She developed redness and oozing of foul-smelling tan-colored drainage from the hip incision on postoperative day 4. Significant medical history includes osteoarthritis and mild hypertension. Her hospital stay has been prolonged because of the development of a lower-extremity blood clot. Because of surgical pain at the incision site and her lower extremity, she does not turn on her own or transfer easily from her bed to the chair. On day 7 she notes pain at the incision and complains of a painful, burning sensation in the sacral region. She is continent of urine and stool but continues to "scoot" over to the side of the bed when preparing for bed-to-chair transfers.

Assessment Activities	Findings/Defining Characteristics*
Obtain an oral temperature.	Patient has elevated temperature and is diaphoretic.
Ask Mrs. Stein how the surgical site or anything else limits her mobility.	She relates that her hip always aches **limiting movement** and her lower leg is sore and the pain increases on movement.
	She tells you that she prefers to **keep the hip and leg immobile** to keep the pain level down.
	Position of comfort is supine, and **Mrs. Stein resists position changes.**
Perform a total body skin assessment, paying special attention to the surgical incision, lower extremities, and sacral area.	

Continued

◎ NURSING CARE PLAN

Impaired Skin Integrity—cont'd

Assessment Activities	*Findings/Defining Characteristics**
Sacral area.	There is a **partial-thickness ulcer directly over the sacral area.**
	Patient has **nonblanchable erythema** around the open sacral area; this **area does not blanch on palpation.**
Left hip, surgical incision.	**Small openings between staples oozing tan, foul-smelling fluid. Periwound area red and warm.**

Defining characteristics are shown in bold type.

NURSING DIAGNOSIS: Impaired skin integrity related to pressure, friction, and shearing forces over sacral bony prominence and infectious drainage from surgical site

PLANNING

Goals	*Expected Outcomes (NOC)†*
	Tissue Integrity: Skin and Mucous Membranes
Injury to Mrs. Stein's skin and underlying tissue resulting from pressure, friction, and shear over the bony prominence will be reduced within 2 to 4 weeks.	Mrs. Stein has intact skin integrity in the area of nonblanching erythema.
	Mrs. Stein's sacral ulcer shows signs of healing.
	Mrs. Stein maintains intact skin over other pressure points.
Red area around hip wound and tan-colored drainage will be absent within 5 days.	Left hip wound demonstrates signs of healing.
	Immobility Consequences: Physiological
Mrs. Stein's ability to tolerate position changes and correctly change positions will improve within 2 to 4 weeks.	Hyperemia is not present at any pressure points.
	Hyperemia in sacral region has a decrease in nonblanchable pressure areas.

†Outcome classification labels from Moorhead S et al: *Nursing outcomes classification (NOC),* ed 5, St Louis, 2013, Mosby.

INTERVENTIONS (NIC)‡

	RATIONALE
Pressure Management	
Order and place on Mrs. Stein's bed a pressure redistribution surface. Help Mrs. Stein with repositioning every 90 minutes as her condition allows. Use a drawsheet when helping to reposition.	Repositioning reduces the duration and magnitude of pressure over vulnerable areas of the body and contributes to comfort, hygiene, dignity, and functional ability (Bryant and Nix, 2016).
	Repositioning is still required for pressure redistribution and comfort when a support surface is in use.
	Use a lift or transfer sheet to minimize friction and/or shear when repositioning, keeping bed linens smooth and unwrinkled (NPUAP, EPUAP, PPPIA, 2014).
Elevate head of bed no more than 30 degrees. Hip patient may not be allowed to turn in to 30-degree lateral position.	If sitting in bed is necessary, avoid head-of-bed elevation or a slouched position that places pressure and shear on the sacrum and coccyx (NPUAP, EPUAP, PPPIA, 2014).
Keep skin dry and clean; avoid rubbing or massaging around the open area.	The presence of skin damage from moisture increases the risk of pressure ulceration (Colwell et al., 2011; NPUAP, EPUAP, PPPIA, 2014). Rubbing or massaging areas of nonblanching erythema causes further tissue damage (WOCN, 2010).
Use moisture barrier ointment over the ulcer at least 3 times a day to decrease friction and provide moisture to the open tissue.	An ointment covers the area, providing base of ulcer with moisture, which encourages healing. Ointment prevents sheets from rubbing on area, thus decreasing the friction (Rolstad et al., 2016).
Wound Care	
Irrigate wound with saline solution twice per day per wound-care provider's order.	Cleanse wound and surrounding area of wound debris and exudate.
Apply dressing (i.e., gauze moistened with solution twice a day after irrigation) according to wound-care provider's order.	Provides appropriate topical therapy to wound, placing wound in best environment for healing (Rolstad et al., 2016).
At frequent intervals evaluate patient's pain level and offer pain medication as indicated by assessment.	Provides patient with pain reduction/relief, allowing for greater mobility and comfort (Krazner, 2016).

‡Intervention classification labels from Bulechek GM et al: *Nursing interventions classification (NIC),* ed 6, St Louis, 2013, Mosby.

EVALUATION

Nursing Actions	*Patient Response/Findings*	*Achievement of Outcome*
Perform daily total body skin and wound assessments. Chart results.	No new skin breakdown noted.	No other areas of pain or discomfort are reported.
	Decreased redness at the sacral area.	Decreased or absence of pain at sacral site is reported.
	Presence of reepithelialization in sacral area.	Ulcer in sacral area is healed.
	Reduction in hip wound, periwound redness, and amount of wound drainage.	Surgical incision is no longer open; no drainage and no periwound redness.
Palpate reddened area around sacrum.	Sacral area begins to show signs of reactive hyperemia and blanching following palpation.	Sacral region is improving; no break in epidermis.
	Other pressure points have reactive hyperemia and blanching.	Other pressure points remain intact.

CONCEPT MAP

Nursing diagnosis: Impaired skin integrity related to limited mobility
- Pressure ulcer over sacral area
- Reactive hyperemia noted on inspection and palpation
- Partial thickness ulcer over sacral area, stage II
- Reddened periwound skin

Interventions
- Keep skin clean and dry
- Apply moisture barrier to area at least 3 times daily
- Perform an ongoing wound and risk assessment
- Apply dressing to support moist wound healing

Nursing diagnosis: Risk for infection
- Surgical incision on left hip
- Reddened periwound tissue
- Foul drainage
- Poor wound healing; open areas between staples

Interventions
- Irrigate and cleanse hip incision with normal saline twice daily
- Pack open areas of wound with gauze moistened with antibiotic solution as ordered
- Obtain wound culture as needed

Primary health problem: Postsurgical total hip replacement, surgical wound drainage, sacral pressure ulcer
Priority assessments: Condition of surgical incision, pressure ulcer status, and pain levels

Nursing diagnosis: Impaired physical mobility related to incisional pain
- Complains of incisional pain and resists assisted movement
- Does not assist with moving in bed; skin is subject to shear

Interventions
- Provide analgesic 30 minutes before positioning and wound care
- Reposition patient at least every 90 minutes
- When patient is lying down, position in the 30-degree lateral position
- Instruct patient how not to slide over sheets during a transfer
- Demonstrate correct repositioning techniques

——— Link between medical diagnosis and nursing diagnosis   - - - - Link between nursing diagnoses

FIGURE 48-14 Concept map for Mrs. Stein.

changes. It is important that you and the patient work together to establish ways of maintaining patient involvement in nursing care to promote wound healing, whether the patient is in the hospital or at home.

◆ Implementation

Health Promotion. Perhaps the most effective intervention for problems with skin integrity and wound care is prevention. Prompt identification of high-risk patients and their risk factors helps to identify the interventions needed to prevent pressure ulcers.

Prevention of Pressure Ulcers. Nursing interventions for patients who are immobile or have other risk factors for pressure ulcers focus

on prevention. Table 48-6 describes basic nursing care measures for preventing ulcers based on a patient's risk factors.

Prevention minimizes the impact that risk factors or contributing factors have on pressure ulcer development. Three major areas of nursing interventions for prevention of pressure ulcers are: (1) skin care and management of incontinence; (2) mechanical loading and support devices, which include proper positioning and the use of therapeutic surfaces; and (3) education (WOCN, 2010).

Topical Skin Care and Incontinence Management. When you clean the skin, avoid soap and hot water. Use cleaners with nonionic surfactants that are gentle to the skin (WOCN, 2010). Many types of products are available for skin care, and you need to match their use

BOX 48-7   Home Care Recommendations

Ulcer/Wound Assessment

Assessment and documentation of a pressure ulcer needs to occur at least weekly unless there is evidence of deterioration, in which case the nurse needs to reassess both the pressure ulcer and the patient's overall management immediately. In the home setting this requires the help of the patient and family because weekly assessment is not always feasible.

Psychosocial Assessment and Management

- Assess the patient's resources (e.g., availability and skill of caregivers, finances, equipment). A successful treatment program requires adequate caregiver and equipment resources.
- Assess family caregivers for their ability to comprehend and implement the treatment requirements.
- Assess family caregivers for their level of strength and endurance.
- Consider economic factors because they often limit the supply and availability of equipment and opportunities to relieve caregivers.
- Use an approach that focuses on the psychosocial and physical factors affecting wound care.

Ulcer Care Dressings

- Consider family caregiver time and ability when selecting a dressing.
- In the home setting some family caregivers choose dressing materials manufactured to reduce the frequency of dressing changes.

Infection Control

- Clean dressings, as opposed to sterile ones, are recommended for home use until research demonstrates otherwise. This recommendation is in keeping with principles regarding nosocomial infections and with past success of clean urinary catheterization in the home setting, and it takes into account the expense of sterile dressings and the dexterity required for application. The family caregiver can use the "no-touch" technique for dressing changes. This technique is a method of changing surface dressings without touching the wound or the surface of any dressing that might be in contact with the wound. Adherent dressings should be grasped by the corner and removed slowly, whereas gauze dressings can be pinched in the center and lifted off.
- Contaminated dressings in the home should be disposed of in a manner consistent with local regulations. The Environmental Protection Agency recommends placing soiled dressings in securely fastened plastic bags before adding them to other household trash. However, local regulations vary, and home care agencies and patients need to follow procedures that are consistent with local laws.

Modified from Agency for Health Care Policy and Research, Panel for the Treatment of Pressure Ulcers in Adults: *Treatment of pressure ulcers,* Clinical Practice Guideline No. 15, AHCPR Pub No. 95-0653, Rockville, MD, 1994, Agency for Health Care Policy and Research, Public Health Service, US Department of Health and Human Services.

TABLE 48-6   Quick Guide to Pressure Ulcer Prevention

Risk Factor	Nursing Interventions
Decreased sensory perception	Provide pressure-redistribution surface. Be sure to include protection for pressure points from medical devices such as oxygen tubing, feeding tubes, and casts (Black et al., 2015; Fletcher, 2012).
Moisture	Following each incontinent episode, clean area with no-rinse perineal cleaner and protect skin with moisture-barrier ointment (Rolstad et al., 2016). Keep skin dry and free of maceration (Gray et al., 2011; Colwell et al., 2011). Turn patient off of at-risk areas often.
Friction and shear	Reposition patient using drawsheet or a transfer board surface. Provide trapeze to facilitate movement in bed. Position patient at a 30-degree lateral turn and limit head elevation to 30 degrees (see Figure 48-15).
Decreased activity/mobility	Establish and post individualized turning schedule.
Poor nutrition	Provide adequate nutritional and fluid intake; help with intake as necessary. Consult dietitian for nutritional assessment and recommended nutrients.

It is helpful to use the expertise of an advanced practice nurse with a focus on wound care or management of incontinence while caring for at-risk patients. Methods for controlling or containing incontinence vary. Bowel incontinence can sometimes be better managed with proper diet and medications. Urinary incontinence is treated with behavioral techniques, medication, and surgery. Behavioral techniques help patients learn ways to control their bladder and sphincter muscles. Two examples are bladder and habit training, also called *timed voiding*.

Consider using absorbent pads and garments only after trying these measures. Although controversial, absorbent products such as absorptive underpads and garments are sometimes part of the treatment plan for an incontinent patient. Use only products that wick moisture away from the patient's skin (WOCN, 2010).

Positioning. Positioning interventions redistribute pressure and **shearing force** to the skin. Elevating the head of the bed to 30 degrees or less decreases the chance of pressure ulcer development from shearing forces (WOCN, 2010). Change the immobilized patient's position according to tissue tolerance, level of activity and mobility, general medical condition, overall treatment objectives, skin condition, and comfort (NPUPA, EUPAP, PPPIA, 2014). A standard turning interval of $1\frac{1}{2}$ to 2 hours does not always prevent pressure ulcer development. Consider repositioning the patient at least every 2 hours if allowed by his or her overall condition. When repositioning, use positioning devices to protect bony prominences (WOCN, 2010). The WOCN guidelines (2010) recommend a 30-degree lateral position (Figure 48-15), which should prevent positioning directly over the bony prominence. To prevent shear and friction injuries, use a transfer device to lift rather than drag the patient when changing positions (see Chapter 39).

For patients at risk for skin breakdown who are able to sit in a chair, limit the amount of time they sit to 2 hours or less at any given time. In the sitting position the pressure on the ischial tuberosities is greater than in the supine position. In addition, teach the patient to shift weight every 15 minutes while sitting (WOCN, 2010). Shifting weight

to the specific needs of the patient. After you clean the skin and make sure that it is completely dry, apply moisturizer to keep the epidermis well lubricated but not oversaturated.

Make an effort to control, contain, or correct incontinence, perspiration, or wound drainage (see Chapters 46 and 47). Patients who have fecal incontinence and who are also receiving enteral tube feeding provide a management challenge. Often the feedings can result in diarrhea. When patients have an incontinent episode, gently clean the area, dry, and apply a thick layer of moisture barrier to the exposed areas. A moisture barrier protects the skin from excessive moisture and bacteria found in the urine or stool.

FIGURE 48-15 Thirty-degree lateral position at which pressure points are avoided. (Adapted from Bryant RA, Nix DP, editors: *Acute and chronic wounds: current management concepts,* ed 5, St Louis, 2016, Elsevier.)

QSEN **QSEN: BUILDING COMPETENCY IN EVIDENCE-BASED PRACTICE** The nurses on an orthopedic unit are concerned about patients who develop skin breakdown after hip-replacement surgery. The nurses would like to implement a new evidence-based postoperative positioning protocol with the goal of preventing pressure ulcer development. What is the nurses' PICO question, and what topics should the nurses include in the evidence-based literature review?

ⓔ *Answers to QSEN Activities can be found on the Evolve website.*

---

provides short-term relief on the ischial tuberosities. Also have him or her sit on foam, gel, or an air cushion to redistribute weight away from the ischial areas. Rigid and donut-shaped cushions are contraindicated because they reduce blood supply to the area, resulting in wider areas of ischemia (WOCN, 2010).

After repositioning the patient, reassess the skin. Remember to use caution when evaluating early signs of tissue ischemia in darkly pigmented skin. For patients with light-toned skin, observe for **reactive hyperemia** and blanching. Never massage reddened areas. Massaging reddened areas increases the breakdown of the capillaries in the underlying tissues and leads to the risk of tissue injury and pressure ulcer formation (WOCN, 2010).

Support Surfaces (Therapeutic Beds and Mattresses). Support surfaces are "specialized devices for pressure redistribution designed for management of tissue loads, microclimate, and/or other therapeutic functions (i.e., any mattress, integrated bed system, mattress replacement, overlay, seat cushion, or seat cushion overlay)" (NPUAP, EUPAP, PPPIA, 2014). Support surfaces reduce the hazards of immobility to the skin and musculoskeletal system. However, none eliminates the need for meticulous nursing care. No single device completely eliminates the effects of pressure on the skin.

When selecting support surfaces, consider a patient's unique needs. Knowledge about support-surface characteristics (Table 48-7) helps you in clinical decision making. In selecting a support surface, know the patient's risks and the purpose for the support surface; a flow chart is often helpful (Figure 48-16). Teach patients and families the reason for and proper use of the devices (Box 48-8). Some common errors with support surfaces are placing the wrong side of the support surface toward the patient, not plugging powered support surfaces into the electrical source, not turning on the power source for powered support surfaces, failing to place a hand between the metal bedframe and the

mattress to determine if the patient sinks to the point of touching the bedframe for some support surfaces, and improperly inflating some support surfaces. When used correctly, these support services help redistribute pressure to the patients skin who are at risk for or have skin breakdown.

Acute Care

Management of Pressure Ulcers. Treatment of patients with pressure ulcers requires a holistic approach that uses the expertise of several multidisciplinary health care professionals (WOCN, 2010). In addition to the nurse, the health care provider, the wound-care nurse specialist, physical therapist, occupational therapist, nutritionist, and pharmacist are involved. Aspects of pressure ulcer treatment include local care of the wound and supportive measures such as adequate nutrients and redistribution of pressure (see Skill 48-2 on pp. 1224-1226).

Before treating a pressure ulcer, reassess the wound for location, stage, size, tissue type and amount, exudate, and surrounding skin condition (Nix, 2016). Acute wounds require close monitoring (every 8 hours). Chronic wound assessment occurs less frequently. Depending on the topical management system, evaluate the wound with every dressing change, usually not more than 1 time per day.

The use and documentation of a systematic approach to monitor progress of an actual pressure ulcer leads to better decision making and optimum outcomes (Nix, 2016). Several healing and documentation tools are available to document wound assessments over time. Using a tool helps link assessment to outcomes so an evaluation of the plan of care follows objective criteria (Nix, 2016). For example, the Bates-Jensen Wound Assessment Tool (Harris et al., 2010) addresses 15 wound characteristics. You score individual items and calculate the sum total, providing an overall indication of wound status. The scoring helps to evaluate whether the goals of the wound management are effective.

Wound Management. Maintenance of a physiological local wound environment is the goal of effective wound management (Rolstad et al., 2016). To maintain a healthy wound environment, you need to address the following objectives: prevent and manage infection, clean the wound, remove nonviable tissue, maintain the wound in a moist environment, eliminate dead space, control odor, eliminate or minimize pain, and protect the wound and periwound skin (Ramundo, 2016).

A wound does not move through the phases of healing if infected. Preventing wound infection includes cleaning and removing nonviable tissue. Clean pressure ulcers *only with noncytotoxic wound cleaners* such

TABLE 48-7   Support Surfaces

Categories and Definitions	Mechanism of Action	Indications	Examples of Manufacturers' and Product Names
Low-Air-Loss Air circulated through a mattress/overlay that is covered by a water-vapor permeable cover Available as a mattress placed directly on the existing bedframe or an overlay placed directly on top of an existing surface	Pressure redistribution Maintains a constant and slight air movement against the skin to prevent buildup of moisture and skin breakdown Provides a flow of air to help manage the heat and humidity of the skin	Prevention or treatment of skin breakdown	Hill Rom/Synergy Air Elite
Nonpowered Any support surface not requiring or using external sources of energy for operation *Examples:* Foam, interconnected air-filled cells	Reduces pressure by lowering mean interface pressure between patient's tissue and mattress Pressure redistribution Air moves to and from cells as body position changes	Prevention or treatment of skin breakdown	ROHO/ Dry Flotation Mattress, Gaymar Industries/Sof-Care
Air-Fluidized Beds Surfaces that change load distribution properties when powered and when patient is in contact with the surface	Uses air and fluid support to provide pressure redistribution via a fluidlike medium created by forcing air through beads as characterized by immersion and envelopment (NPUAP, EPUAP, PPPIA, 2014)	Prevention or treatment of skin breakdown May also be used to protect newly flapped or grafted surgical sites and for patients with excessive moisture	Hill Rom/Clinitron
Lateral Rotation Provides passive motion turning the patient from side to side on a low–air loss surface	Passive motion provides pressure relief and mobilization of respiratory secretions A feature of a support surface that provides rotation about a longitudinal axis as characterized by degree of patient turn, duration, and frequency	Treatment and prevention of pulmonary, venous stasis, and urinary complications associated with immobility	Hill Rom/TotalCare SpO2RT

as normal saline or commercial wound cleaners. Noncytotoxic cleaners do not damage or kill fibroblasts and healing tissue (Rolstad et al., 2016). Some commonly used cytotoxic solutions are Dakin's solution (sodium hypochlorite solution), acetic acid, povidone-iodine, and hydrogen peroxide. These are not to be used in clean, granulating wounds.

Irrigation is a common method of delivering a wound-cleansing solution to the wound. Wound irrigation debrides necrotic tissue with pressure that can remove debris from the wound bed without damaging healthy issues (Ramundo, 2016). One method to ensure an irrigation pressure within the correct range is to use a 19-gauge angiocatheter and a 35-mL syringe that delivers saline to a pressure ulcer at 8 psi (Figure 48-17).

Debridement is the removal of nonviable, necrotic tissue. Removal of necrotic tissue is necessary to rid the wound of a source of infection, enable visualization of the wound bed, and provide a clean base necessary for healing.

The method of debridement depends on which is most appropriate for a patient's condition and goals of care (WOCN, 2010). It is important to remember that during the debridement process some normal wound observations include an increase in wound exudate, odor, and size. You need to assess and prevent or effectively manage pain that occurs with debridement (WOCN, 2010). Plan to administer an ordered analgesic 30 minutes before debridement.

Methods of debridement include mechanical, autolytic, chemical, and sharp/surgical. Autolytic debridement is the removal of dead tissue via lysis of necrotic tissue by the white blood cells and natural enzymes of the body (Ramundo, 2016). You accomplish this by using dressings that support moisture at the wound surface. If the wound base is dry, use a dressing that adds moisture; if there is excessive exudate, use a dressing that absorbs the excessive moisture while maintaining moisture at the wound bed. Some examples of these dressings are transparent film and hydrocolloid dressings.

You can accomplish chemical debridement with the use of a topical enzyme preparation, Dakin's solution, or sterile maggots. Topical enzymes induce changes in the substrate, resulting in the breakdown of necrotic tissue (Ramundo, 2016). Depending on the type of enzyme used, the preparation either digests or dissolves the tissue. These preparations require a health care provider's order. Dakin's solution breaks down and loosens dead tissue in a wound. Apply the solution to gauze and apply to the wound. Sterile maggots are used in a wound because it is thought that they ingest the dead tissue.

Skin and risk assessment performed

Patient not at risk

Patient at high risk, and skin is intact

Patient at high risk and has impaired skin integrity

- Standard nursing care

- Use higher-specification foam mattresses rather than standard hospital foam mattress.
- Use an active support surface (overlay or mattress) when frequent manual repositioning is not possible.
- To reduce the risk of heel breakdown, use a pillow under the calves so heels are elevated.
- Use a pressure-redistributing seat cushion for patient sitting in a chair when mobility is reduced, and limit the time patient spends seated in a chair without pressure relief.

Stage I or II Pressure Ulcer
- Use higher-specification foam or similar nonpowered redistribution support surfaces.
- Avoid prolonged head-of-bed elevation and a slouched position that places pressure and shear on the sacrum and coccyx.
- If sitting in a chair is necessary for patients with pressure ulcers of the sacrum/coccyx or ischia, limit sitting to 3 times per day in periods of 60 minutes or less. Consult seating specialist for the appropriate seating surface.

Stage II, Stage IV, and Unstageable Pressure Ulcer(s)
- Avoid prolonged head-of-bed elevation and a slouched position that places pressure and shear on the sacrum and coccyx.
- Consider one of the following support surfaces: low-air-loss, alternating pressure, or air-fluidized surface.
- Consider the use of a wheelchair cushion for use in a patient with a sacral/coccyx pressure ulcer.

FIGURE 48-16 Considerations for choosing the appropriate support surface. (Modified from WOCN: *Guideline for prevention and management of pressure ulcers,* 2010, Mt Laurel, NJ; and National Pressure Ulcer Advisory Panel (NPUAP) and European Pressure Ulcer Advisory Panel (EPUAP): *International guideline for prevention and treatment of pressure ulcers,* Washington DC, 2009, National Pressure Ulcer Advisory Panel.)

BOX 48-8   PATIENT TEACHING

Pressure-Redistribution Surfaces

Objective
- Patient and family caregiver will describe understanding of the purposes and basic operations of the pressure-redistribution surface.

Teaching Strategies
- Explain the reasons for the pressure-redistribution surface.
- Explain the need to maintain proper body mechanics while using the pressure-redistribution surface. Demonstrate technique.
- Discuss possible patient sensations associated with the device.
- Instruct that minimal layers of linens should be placed over the pressure redistribution surface.
- Educate in the use and care of the pressure-redistribution surface (WOCN, 2010) (based on manufacturer guidelines).
- Explain common errors in use of support surfaces.
- Explain additional pressure-redistribution measures (e.g., turning, avoidance of friction, 30-degree lateral position).

Evaluation
- Patient and family caregiver will state basic purposes for the pressure-redistribution surface.
- Patient and family caregiver will discuss possible sensations associated with the support surface.
- Patient and family caregiver will be able to describe the function of the pressure-redistribution surface.
- Patient and family caregiver will be able to demonstrate turning/repositioning techniques and proper use of the pressure-redistribution surface.

FIGURE 48-17 Wound irrigation.

Surgical debridement is the removal of devitalized tissue with a scalpel, scissors, or other sharp instrument. Physicians and, in some states, trained advanced practice nurses perform surgical debridement of an ulcer or wound. Nurses should check the Nurse Practice Act for their state to see if surgical debridement is a nursing function. It is the quickest method of debridement. It is usually indicated when the patient has signs of cellulitis or sepsis. Other methods of mechanical debridement are wound irrigation (high-pressure irrigation and pulsatile high-pressure lavage) and whirlpool treatments (Ramundo, 2016).

A moist environment supports the movement of epithelial cells and facilitates wound closure. A wound that has excessive exudate (drainage) provides an environment that supports bacterial growth, macerates the periwound skin, and slows the healing process. If excessive

wound exudate is present, evaluate the volume, consistency, and odor of the drainage to determine if an infection is present.

Remember, the wound will not heal unless the contributory factors are controlled or eliminated. Therefore it is critically important for you to address the causative factors (e.g., shear, friction, pressure, and moisture), or it is unlikely that the wound will heal despite topical therapy (Rolstad et al., 2016).

The treatment plan needs to be altered as a wound heals. For example, a transparent film dressing is used initially to autolytically debride (liquefy the tissue using body moisture) a necrotic wound. Once the wound is cleaned of necrotic tissue, discontinue the transparent film dressing; and, on the basis of the wound base characteristics, choose a new dressing. A wound with excessive drainage requires a dressing with a high absorptive capacity. Continued reassessment is key to supporting the wound as it moves through the phases of wound healing.

Protection. Protecting a wound from further injury is key. A strategy to prevent surgical wound dehiscence is to place a folded thin blanket or pillow over an abdominal wound so a patient can splint the area during coughing. Because coughing increases the intraabdominal pressure, the patient applies light but firm pressure over the wound when coughing to support the healing tissue. A patient may also wear an abdominal binder to make movement less uncomfortable and to provide support for the abdomen and surgical site. Teach the patient this technique and keep the splint within hand's reach.

Education. Education of the patient and caregivers is an important nursing function (Rolstad et al., 2016). A variety of educational tools, including videotapes and written materials, are available for you to use when teaching patients and caregivers/family to prevent and treat pressure ulcers and care for wounds. The U.S. National Library of Medicine has an excellent website with information on the prevention of pressure ulcers (https://www.nlm.nih.gov/medlineplus/ency/patientinstructions/000147.htm).

Understanding and assessing the experience of the patient and support person are also important dimensions in the treatment of people with pressure ulcers (WOCN, 2010). Clinicians are only just now exploring through research the caregiver's perspective of the concerns and issues faced by frail older spouses caring for their loved ones with pressure ulcers. You need to plan interventions to meet the identified psychosocial needs of patients and their support people (WOCN, 2010).

Nutritional Status. Nutritional support of a patient with a wound is based on the appreciation that nutrition is fundamental to normal cellular integrity and tissue repair (Stotts, 2016a). Early intervention is necessary to correct inadequate nutrition and support healing. Refer patients with pressure ulcers to a registered dietitian for early intervention involving therapeutic diets or enteral or parenteral nutrition (see Chapter 45). If a patient's oral intake is inadequate, enteral nutrition is a likely choice. The dietitian will recommend an individualized energy intake (calories) on the basis of underlying medical condition and level of activity. You will provide 30 to 35 calories/kg of body weight for individuals with a pressure ulcer who are assessed to be at risk for malnutrition. Increased caloric intake helps replace subcutaneous tissue. Patients will also receive vitamin and mineral supplements if suspected or known deficiencies exist. Vitamin C promotes collagen synthesis, capillary wall integrity, fibroblast function, and immunological function.

Patients with pressure ulcers who are underweight or losing weight need enhanced protein supplementation (WOCN, 2010). A patient can lose as much as 50 g of protein per day from an open, high exudative pressure ulcer. Although the recommended intake of protein for adults is 0.8 g/kg/day, a higher intake up to 1.8 g/kg/day is necessary

for healing. Increased protein intake helps rebuild epidermal tissue (NPUAP, EUPAP, PPPIA, 2014). Evaluation of weight, laboratory values, and skin parameters reflect changes in status and effects of nutritional interventions (Stotts, 2016a).

First Aid for Wounds. Use first-aid measures for wound protection and management in an emergency situation. Under stable conditions a variety of interventions ensure wound healing. When a patient suffers a traumatic wound, first-aid interventions include stabilizing cardiopulmonary function (see Chapter 41), promoting hemostasis, cleaning the wound, and protecting it from further injury.

Hemostasis. After assessing the type and extent of a wound, control bleeding by applying direct pressure with a sterile or clean dressing such as a washcloth. After bleeding subsides, an adhesive bandage or gauze dressing taped over the laceration allows skin edges to close and a blood clot to form. If a dressing becomes saturated with blood, add another layer of dressing, continue to apply pressure, and elevate the affected part. Avoid further disruption of skin layers. Serious lacerations need to be sutured by a health care provider. Pressure dressings used during the first 24 to 48 hours after trauma help maintain hemostasis.

Normally allow a puncture wound to bleed to remove dirt and other contaminants such as saliva from a dog bite. When a penetrating object such as a knife blade is present, *do not remove the object.* The presence of the object provides pressure and controls some bleeding. Removal causes massive, uncontrolled bleeding. Except for skull injuries, apply pressure around the penetrating object but not on it and transport the patient to an emergency facility.

Cleaning. The process of cleaning a wound involves selecting an appropriate cleaning solution and using a mechanical means of delivering that solution without causing injury to the healing wound tissue (WOCN, 2010). Gently cleaning a wound removes contaminants that serve as sources of infection. However, vigorous cleaning using a method with too much mechanical force causes bleeding or further injury. For abrasions, minor lacerations, and small puncture wounds, first rinse the wound with normal saline and lightly cover the area with a dressing. When a laceration is bleeding profusely, only brush away surface contaminants and concentrate on hemostasis until the patient can be cared for in a clinic or hospital.

According to the WOCN guidelines (2010), normal saline is the preferred cleaning agent. It is physiologically neutral and does not harm tissue. Normal saline keeps the wound surface moist to promote the development and migration of epithelial tissue. Gentle cleansing with normal saline and application of moist saline dressings are commonly used for healing wounds.

Protection. Regardless of whether bleeding has stopped, protect a traumatic wound from further injury by applying sterile or clean dressings and immobilizing the body part. A light dressing applied over minor wounds prevents entrance of microorganisms.

Dressings. The more extensive a wound, the larger the dressing required. For example, a bulky dressing applied with pressure minimizes movement of underlying tissues and helps immobilize the entire body part. A bandage or cloth wrapped around a penetrating object should immobilize it adequately.

Alternative dressings are available to cover and protect certain types of wounds such as large wounds, wounds with drainage tubes or suction catheters in the wound, and wounds that need frequent changing because of excessive drainage. In the home setting a clean towel or diaper is often the best secondary dressing. Pouches or special wound collection systems cover wounds with excessive drainage and collect the drainage. Some of the collection systems have a plastic window on the front of the wound pouch, allowing you to change the packing without removing the pouch from the skin.

The use of dressings requires an understanding of wound healing. A variety of dressing materials are available commercially. The correct dressing selection facilitates wound healing (Rolstad et al., 2016). The dressing type depends on the assessment of the wound and the phase of wound healing. When you identify the objectives for the wound care, the dressing choice becomes clear. A wound that requires infection management requires a different set of dressings than one requiring the removal of nonviable tissue.

For surgical wounds that heal by primary intention, it is common to remove dressings as soon as drainage stops. In contrast, when dressing a wound healing by secondary intention, the dressing material becomes a means for providing moisture to the wound or helping in debridement.

Purposes of Dressings. A dressing serves several purposes:
- Protects a wound from microorganism contamination
- Aids in hemostasis
- Promotes healing by absorbing drainage and debriding a wound
- Supports or splints a wound site
- Promotes thermal insulation of a wound surface
- Provides a moist environment

When the skin is broken, a dressing helps reduce exposure to microorganisms. However, when drainage is minimal, the healing process forms a natural fibrin seal that eliminates the need for a dressing. Wounds with extensive tissue loss always need a dressing.

Pressure dressings promote hemostasis. Applied with elastic bandages, a pressure dressing exerts localized downward pressure over an actual or potential bleeding site. It eliminates dead space in underlying tissues so wound healing progresses normally. Check pressure dressings to be sure that they do not interfere with circulation to a body part. Assess skin color, pulses in distal extremities, the patient's comfort, and changes in sensation. Pressure dressings are not removed routinely.

The primary function of a dressing on a healing wound is to absorb drainage. Most surgical gauze dressings have three layers: a contact or primary layer, an absorbent layer, and an outer protective or secondary layer. The contact dressing covers the incision and then overlaps and covers part of the adjacent skin. Fibrin, blood products, and debris adhere to its surface. A problem occurs if wound drainage dries, causing the dressing to stick to the suture line. Improperly removing a dressing disrupts the healing epidermal surface. If a gauze dressing sticks to a surgical incision, lightly moisten it with saline solution. This saturates the dressing and loosens it from the incisional area, thus preventing trauma to the incisional area during removal.

The dressing technique varies, depending on the goal of the treatment plan for a wound. For example, if the goal is to maintain a moist environment to promote wound healing, it is important to not let the saline-moistened gauze dressing become dry and stick to the wound. This is in direct contrast to the dressing technique that you use if the goal of care is to mechanically debride the wound using a saline moist-to-dry dressing. When wounds such as a necrotic wound require debriding, a moist-to-dry dressing technique can be considered. You place the moist dressing (contact dressing) over the wound bed, cover with a clean gauze and allow the contact layer to dry. In this case the contact dressing is allowed to dry so it sticks to underlying tissue and debrides the wound during removal. This type of debridement is nonselective and can remove viable tissue; it is recommended for debridement in a necrotic wound (Ramundo, 2016).

Dressings applied to a draining wound require frequent changing to prevent microorganism growth and skin breakdown. Bacteria grow readily in the dark, warm, moist environment under a dressing. Skin surfaces become macerated and irritated. Minimize periwound skin breakdown by keeping the skin clean and dry and reducing the use of

---

BOX 48-9 **Dressing Considerations**

- Clean the wound and periwound area at each dressing change, minimizing trauma to the wound (WOCN, 2010).
- Use a dressing that continuously provides a moist environment.
- Perform wound care using topical dressings as determined by a thorough assessment.
- No specific studies have proven an optimal dressing type for pressure ulcers (WOCN, 2010).
- Choose a dressing that keeps the periwound skin dry while keeping the ulcer bed moist.
- Choose a dressing that controls exudate but does not desiccate the ulcer bed.
- The type of dressing may change over time as the pressure ulcer heals or deteriorates. The wound should be monitored at every dressing change and regularly assessed to determine whether modifications in the dressing type are needed (WOCN, 2010).
- Consider caregiver time, ease of use, availability, and cost when selecting a dressing.

---

tape. The absorbent dressing inner layer serves as a reservoir for secretions. The wicking action of woven gauze dressings pulls excess drainage into the dressing and away from the wound. The final outer layer of the dressing helps prevent bacteria and other external contaminants from reaching the wound surface. Usually the outer dressing is made of a thicker dressing material. Apply adhesives to this layer to secure the dressings.

A dressing needs to support a moist wound environment if the wound is healing by secondary intention. A moist wound base facilitates the movement of epithelialization, thus allowing the wound to resurface as quickly as possible.

Types of Dressings. Dressings vary by type of material and mode of application (moist or dry) (see Skill 48-3 on pp. 1226-1230). They need to be easy to apply, comfortable, and made of materials that promote wound healing. The WOCN guidelines (2010) are helpful when selecting dressings based on the goal of wound treatment (Box 48-9). To avoid causing damage to the periwound skin, it is important that the dressing technique that you use to treat pressure ulcers and other wounds is not excessively moist (Box 48-10).

Most pressure ulcers require dressings. The type of dressing is usually based on the stage of the pressure ulcer, the type of tissue in the wound, and the function of the dressing (Table 48-8). Before placing a dressing on a pressure ulcer, it is important based on the nursing diagnosis to understand the goal of the treatment, the mechanism of action of the dressing, and principles of wound care.

Gauze sponges are the oldest and most common dressing. They are absorbent and are especially useful in wounds to wick away wound exudate. Gauze is available in different textures and various lengths and sizes; the 4 × 4 is the most common size. Gauze can be saturated with solutions and used to clean and pack a wound. When used to pack a wound, the gauze is saturated with the solution (usually normal saline), wrung out (leaving the gauze only moist), unfolded, and lightly packed into the wound. Unfolding the dressing allows easy wicking action. The purpose of this type of dressing is to provide moisture to the wound yet to allow wound drainage to be wicked into the dry cover gauze pad.

Another type of dressing is a self-adhesive, transparent film that traps moisture over a wound, providing a moist environment (Figure 48-18). The transparent film dressing is ideal for small superficial wounds such as a Stage I pressure ulcer or a partial-thickness wound.

BOX 48-10   EVIDENCE-BASED PRACTICE

Moisture-Associated Skin Damage

PICO Question: In patients with pressure ulcers or chronic wounds, which wound care interventions prevent moisture-associated skin damage in the periwound area?

Evidence Summary

Appropriate wound management to support healing is critical for patients with pressure ulcers and other chronic wounds. Advances in wound healing document the benefit of a moist wound environment and the accepted practice of moist wound healing. But when moisture is present in excess and allowed to sit on the periwound skin, it leads to damaging maceration. Maceration is defined as a softening of tissues by soaking until connective fibers can be teased apart (Colwell et al., 2011). This condition is classified as moisture-associated skin damage (MASD)—the inflammation and erosion of the skin caused by prolonged exposure to various sources of moisture and its contents, including urine, stool, perspiration, wound exudate, mucus, or saliva. Exudate is created by the normal inflammatory process of wound healing. However, when high volumes of exudate occur, it poses clinical difficulties, and healing may be affected as the overhydrated skin becomes macerated, potentially leading to skin breakdown.

Interventions that focus on preventive steps include use of a dressing that absorbs excessive moisture while maintaining a moist wound bed (Colwell et al., 2011), selection of the right dressing and size to absorb the wound exudate, the appropriate frequency of dressing change, and use of a skin protectant on the periwound skin (Guest et al., 2011)

Application to Nursing Practice

- Use of a skin protectant (no-sting film barrier, petrolatum-based or zinc-based protectant) helps to prevent periwound skin maceration (Gray and Weir, 2007; Guest et al., 2011).
- Enzymatic debridement is the topical application of enzymes over the necrotic tissue. The only enzyme available in the United States is collagenase. Collagenase digests the necrotic tissue by dissolving the collagen in the dead tissue (NPUAP, EPUAP, PPPIA, 2014).
- Assess the wound and surrounding skin for irritation, itching, burning, or drainage amount. These symptoms are exacerbated during dressing changes or stomal pouching (Gray et al., 2013).
- Prevent peristomal MASD by selecting a pouching system with an effective seal between peristomal skin and fecal material (Gray et al., 2013).
- Make changes in dressing material and frequency of dressing change on the basis of the amount of wound drainage (Rolstad et al., 2016).
- Assess perineal skin for incontinence-related dermatitis, which is an early sign of MASD. When needed, use a moisture barrier in addition to frequent perineal hygiene (Voegeli, 2012).

FIGURE 48-18 Transparent film dressing.

necrotic wounds; they are available in a variety of sizes and shapes. This type of dressing has the following functions:

- Absorbs drainage through the use of exudate absorbers in the dressing
- Maintains wound moisture
- Slowly liquefies necrotic debris
- Is impermeable to bacteria and other contaminants
- Is self-adhesive and molds well
- Acts as a preventive dressing for high-risk friction areas
- May be left in place for 3 to 5 days, minimizing skin trauma and disruption of healing

The hydrocolloid dressing is useful on shallow-to–moderately deep dermal ulcers. Hydrocolloid dressings cannot absorb the amount of drainage from heavily draining wounds, and some are contraindicated for use in full-thickness and infected wounds. Most hydrocolloids leave a residue in the wound bed that is easy to confuse with purulent drainage.

Hydrogel dressings are gauze or sheet dressings impregnated with water or glycerin-based amorphous gel. This type of dressing hydrates wounds and absorbs small amounts of exudate. Hydrogel dressings are for partial-thickness and full-thickness wounds, deep wounds with some exudate, necrotic wounds, burns, and radiation-damaged skin. They can be very useful in painful wounds because they are very soothing to a patient and do not adhere to the wound bed and thus cause little trauma during removal. A disadvantage is that some hydrogels require a secondary dressing and you must take care to prevent periwound maceration. Hydrogels come in a sheet dressing or a tube; thus you are able to squirt the gel directly into the wound base. Hydrogel has the following advantages:

- Is soothing and can reduce wound pain
- Provides a moist environment
- Debrides necrotic tissue (by softening the necrotic tissue)
- Does not adhere to the wound base and is easy to remove

Many other types of dressings are available. Foam and alginate dressings are for wounds with large amounts of exudate and those that need packing. Foam dressings are also used around drainage tubes to absorb drainage. Calcium alginate dressings are manufactured from seaweed and come in sheet and rope form. The alginate forms a soft gel when in contact with wound fluid. These highly absorbent dressings are for wounds with an excessive amount of drainage and do not cause trauma when removed from the wound. *Do not use these in dry wounds, and they require a secondary dressing.* Several manufacturers produce composite dressings, which combine two different dressing types into one dressing. Research is ongoing regarding which type of dressing is best for which type of wound.

Changing Dressings. To prepare for changing a dressing, you need to know the type of dressing, the presence of underlying drains or

Use a film dressing as a secondary dressing and for autolytic debridement of small wounds. It has the following advantages:

- Adheres to undamaged skin
- Serves as a barrier to external fluids and bacteria but still allows the wound surface to "breathe" because oxygen passes through the transparent dressing (Guest et al., 2011)
- Promotes a moist environment that speeds epithelial cell growth
- Can be removed without damaging underlying tissues
- Permits viewing a wound
- Does not require a secondary dressing

Hydrocolloid dressings are dressings with complex formulations of colloids and adhesive components. They are adhesive and occlusive. The wound contact layer of this dressing forms a gel as wound exudate is absorbed and maintains a moist healing environment. Hydrocolloids support healing in clean granulating wounds and autolytically debride

TABLE 48-8 Dressings by Pressure Ulcer Stage

Pressure Ulcer Category/Stage	Pressure Ulcer Status	Dressing	Comments*	Expected Change	Adjuvants
I	Intact	None	Allows visual assessment	Resolves slowly without epidermal loss over 7-14 days	Turning schedule Support hydration Nutritional support
		Transparent dressing	Protects from shear and friction		
		Hydrocolloid	Does not always allow visual assessment		Pressure-redistribution surface or chair cushion
II	Clean	Composite film	Limits shear	Heals through reepithelialization	Turning schedule Support hydration Nutritional support Manage incontinence
		Hydrocolloid	Change when seal of dressing breaks; maximal wear time 7 days		
		Hydrogel	Provides a moist environment		
III	Clean	Hydrocolloid	Must change when seal of dressing breaks; maximal wear time 7 days	Heals through granulation and reepithelialization	See previous stages; evaluate pressure-redistribution needs
		Hydrogel covered with foam dressing	Applied over wound to protect and absorb moisture		
		Calcium alginate	Used with significant exudate; must cover with secondary dressing		
		Gauze	Used with normal saline or other prescribed solution; must unfold to make contact with wound		
IV	Clean	Hydrogel covered with foam dressing	Applied over wound to protect and absorb moisture	Heals through granulation and reepithelialization	Surgical consultation often necessary for closure
		Calcium alginate	Used with significant exudate; must cover with secondary dressing		
		Gauze	Used with normal saline or other prescribed solution; must unfold to make contact with wound; fill all dead space with gauze		
Unstageable	Wound covered with eschar	Adherent film	Facilitates softening of eschar	Eschar lifts at edges as debridement progresses	See previous stages; surgical consultation sometimes considered for debridement
		Gauze plus ordered solution	Delivers solution and softens eschar	Eschar softens	
		Enzymes	Facilitate debridement	Eschar softens	
		None	If eschar is dry and intact, no dressing used, allowing eschar to act as physiological cover; may be indicated for treatment of heel eschar		

*As with all occlusive dressings, wound should *not* be clinically infected.

tubing, and the type of supplies needed for wound care. Poor preparation causes a break in aseptic technique (see Chapter 29) or accidental dislodging of a drain. Your judgment in modifying a dressing-change procedure is important during wound care, particularly if the character of a wound changes. Notifying the health care provider of any change is essential.

Sometimes (e.g., with chronic nonsurgical wounds) you will use clean medical aseptic technique for a dressing change. The clean technique refers to the fact that the nurse maintains medical versus sterile asepsis (Chapter 29). You will wear clean gloves, but the dressing materials are in sterile packages and are carefully placed over the wound. Deep wounds that require irrigation are usually irrigated with a sterile

solution. A complete patient and wound history is essential in determining when a clean dressing technique is appropriate. For example, chronic pressure ulcer wounds use a clean technique. On the other hand, a fresh surgical wound may require sterile technique, which requires the use of sterile gloves so as not to introduce microorganisms into a healing wound.

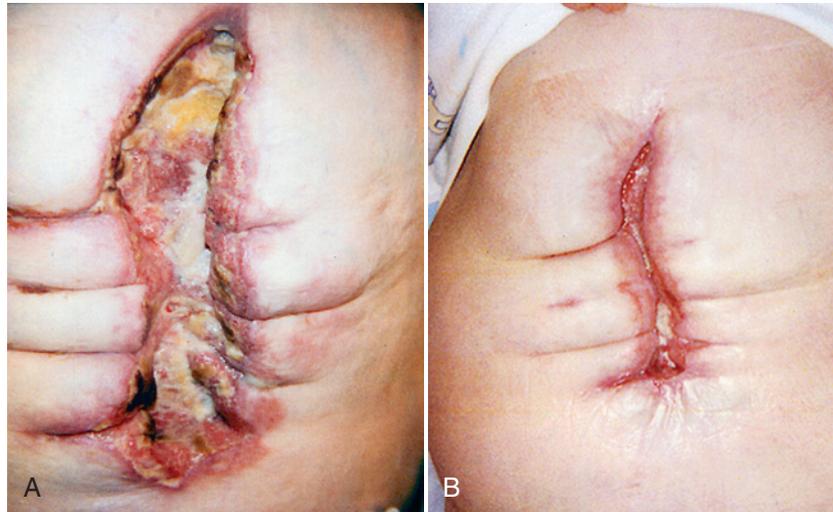
A health care provider's order for changing a dressing indicates the dressing type, the frequency of changing, and any solutions or ointments to be applied to the wound. An order to "reinforce dressing prn" (add dressings without removing the original one) is common right after surgery, when the health care provider does not want accidental disruption of the suture line or bleeding. The medical or operating


FIGURE 48-19 **A,** Dehisced wound before wound V.A.C. therapy. **B,** Dehisced wound after wound V.A.C. therapy. *V.A.C.,* Vacuum-assisted closure. (Courtesy Kinetic Concepts, [KCI], San Antonio, TX.)

room record usually indicates whether drains are present and from which body cavity they drain. After the first dressing change, describe the location of drains and the type of dressing materials and solutions to use in the patient's care plan. See Skill 48-3 for guidelines to use during a dressing change procedure.

Often it is necessary to teach patients how to change dressings in preparation for home care. In this situation, demonstrate dressing changes to a patient and family and then provide an opportunity for them to practice. Usually wound healing has progressed to the point that risks of complications such as dehiscence or evisceration are minimal. A patient needs to be able to change a dressing independently or with help from a family caregiver before discharge. Contaminated dressings in the home should be disposed of in a manner consistent with local regulations. Skill 48-3 outlines the steps for changing dry and moist dressings.

Packing a Wound. The first step in packing a wound is to assess its size, depth, and shape. These characteristics are important in determining the size and type of dressing used to pack a wound. The dressing needs to be flexible and in contact with the entire wound surface. Make sure that the type of material used to pack the wound is appropriate. Many new dressing materials such as alginates are also used for packing. If gauze is the appropriate dressing material, saturate with the ordered solution, wring out, unfold, and lightly pack into the wound. The entire wound surface needs to be in contact with part of the moist gauze dressing (see Skill 48-3).

It is important to remember not to pack a wound too tightly. Overpacking causes pressure on the wound bed tissue. Pack the wound only until the packing material reaches the surface of the wound; there should never be so much packing material that it extends higher than the wound surface. Packing that overlaps onto the wound edges causes maceration of the skin surrounding the wound.

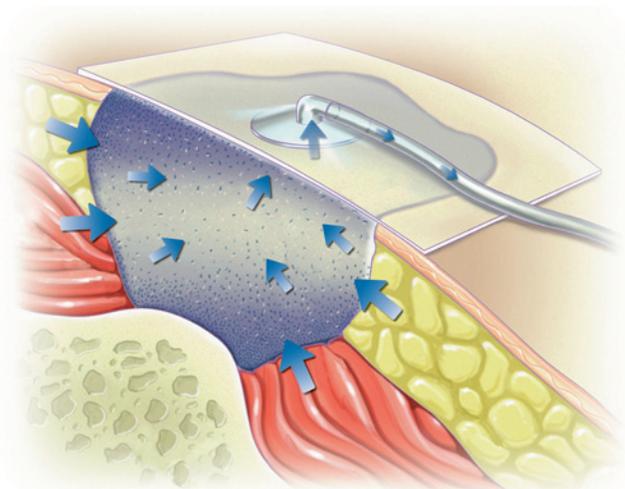
A treatment modality for wounds is negative-pressure wound therapy (NPWT) or vacuum-assisted closure (one brand name is V.A.C.). NPWT is the application of subatmospheric (negative) pressure to a wound through suction to facilitate healing and collect wound fluid (Netsch, 2016). The **vacuum-assisted closure (V.A.C.)** is a device that helps in wound closure by applying localized negative pressure to draw the edges of a wound together (Figure 48-19, *A and B)*. NPWT supports wound healing by edema reduction and fluid removal, macro deformation and wound contraction, and micro deformation and mechanical stretch perfusion. Secondary effects include angiogenesis,


FIGURE 48-20 V.A.C. system using negative pressure to remove fluid from area surrounding wound, reducing edema and improving circulation to area. *V.A.C.,* Vacuum-assisted closure. (Courtesy Kinetic Concepts [KCI], San Antonio, TX.)

granulation tissue formation, and reduction in bacterial bioburden (Netsch, 2016) (Figure 48-20). There have been modifications to the V.A.C. The V.A.C. Instill allows intermittent instillation of fluids into a wound, especially wounds not responding to traditional NPWT (Wolvos, 2013).

NPWT treats acute and chronic wounds (see Skill 48-4 on pp. 1231-1234). The schedule for changing NPWT dressings varies, depending on the type of wound and amount of drainage. Wear time for the dressing is anywhere from 24 hours to 5 days. As a wound heals, granulation tissue lines its surface. The wound has a stippled or granulated appearance. The surface area sometimes increases or decreases, depending on wound location and the amount of drainage removed by the NPWT system. NPWT also enhances the adherence of split-thickness skin grafts. It is placed over a graft intraoperatively, decreasing the ability of the graft to shift and evacuating fluids that build up under it (Netsch, 2016; Xie et al., 2010). An airtight seal must be maintained (Box 48-11).

Securing Dressings. Use tape, ties, or a secondary dressing to secure a dressing over a wound site. The choice of anchoring depends on the wound size and location, the presence of drainage, the frequency of dressing changes, and the patient's level of activity.

You will most often use strips of tape to secure dressings. Nonallergenic paper and silicone tapes minimize skin reactions. Common adhesive tape adheres well to the surface of the skin, whereas elastic adhesive tape compresses closely around pressure bandages and permits more movement of a body part. Skin sensitive to adhesive tape becomes severely inflamed and denuded and in some cases even sloughs when the tape is removed. It is important to assess skin under tape at each dressing change.

Tape is available in various widths such as 1.3, 2.5, 5 and 7.5 cm (½, 1, 2, and 3 inches). Choose the size that secures a dressing sufficiently. For example, a large abdominal wound dressing needs to remain secure over a large area despite frequent stress from movement, respiratory effort, and possibly abdominal distention. Strips of 7.5-cm (3-inch) adhesive better stabilize such a large dressing so it does not continually slip off. When applying tape, ensure that it adheres to several inches of skin on both sides of the dressing and that it is placed across the middle of the dressing. When securing a dressing, press the tape gently. Make sure to exert pressure away from a wound so that tension occurs in both directions away from the wound, minimizing skin distortion and irritation. Never apply tape over irritated or broken skin. Protect irritated skin by using a solid skin barrier and applying the tape over the barrier.

To remove tape safely, loosen the ends and gently pull the outer end parallel with the skin surface toward the wound. Apply light traction to the skin away from the wound as the tape is loosened and removed. The traction minimizes pulling of the skin. Adhesive remover also loosens the tape from the skin. If tape covers an area of hair growth, a patient experiences less discomfort if you pull it in the direction of the hair growth.

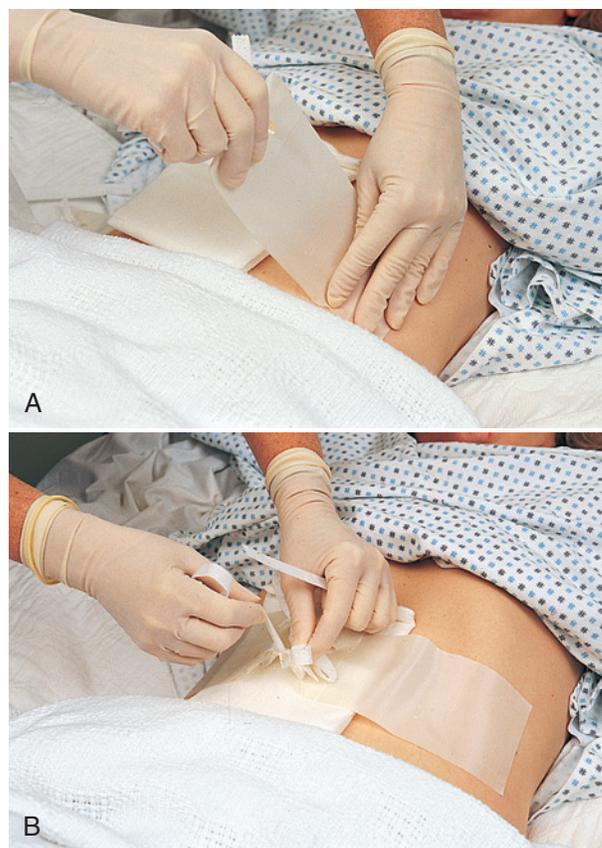
To avoid repeated removal of tape from sensitive skin, secure dressings with pairs of reusable Montgomery ties (Figure 48-21). Each section consists of a long strip; half contains an adhesive backing to apply to the skin, and the other half folds back and contains a cloth tie or a safety pin/rubber band combination that you fasten across a dressing and untie at dressing changes. A large, bulky dressing often requires two or more sets of Montgomery ties. Another method to protect the


FIGURE 48-21 Montgomery ties. **A,** Each tie is placed at side of dressing. **B,** Securing ties encloses dressing.

surrounding skin on wounds that need frequent dressing changes is to place strips of hydrocolloid dressings on either side of the wound edges, cover the wound with a dressing, and apply the tape to the dressing. To provide even support to a wound and immobilize a body part, apply elastic gauze, elastic stretch net, or binders over a dressing.

Comfort Measures. A wound is often painful, depending on the extent of tissue injury; and wound care often requires the use of well-timed analgesia before any wound procedure (Krazner, 2016). Administer analgesic medications 30 to 60 minutes before dressing changes (depending on the time of peak action of a drug). In addition, several techniques are useful in minimizing discomfort during wound care. Carefully removing tape, gently cleaning wound edges, and carefully manipulating dressings and drains minimize stress on sensitive tissues. Careful turning and positioning also reduce strain on a wound.

Cleaning Skin and Drain Sites. Although a moderate amount of wound exudate promotes epithelial cell growth, some health care providers order cleaning a wound or drain site if a dressing does not absorb drainage properly or if an open drain deposits drainage onto the skin. Wound cleaning requires good hand hygiene and aseptic techniques (see Chapter 29). You sometimes use irrigation to remove debris from a wound.

Basic Skin Cleaning. Clean surgical or traumatic wounds by applying noncytotoxic solutions with sterile gauze or by irrigation. The following three principles are important when cleaning an incision or the area surrounding a drain:

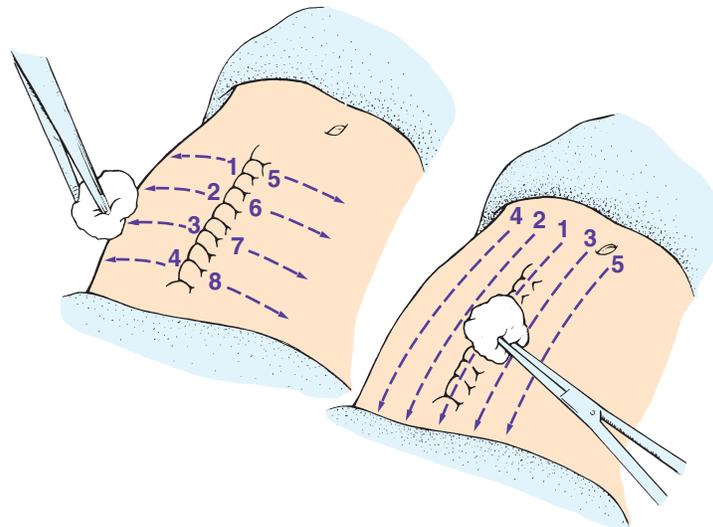
1. Clean in a direction from the least contaminated area such as from a wound or incision to the surrounding skin (Figure 48-22) or from an isolated drain site to the surrounding skin (Figure 48-23).


FIGURE 48-22 Methods for cleaning wound site.
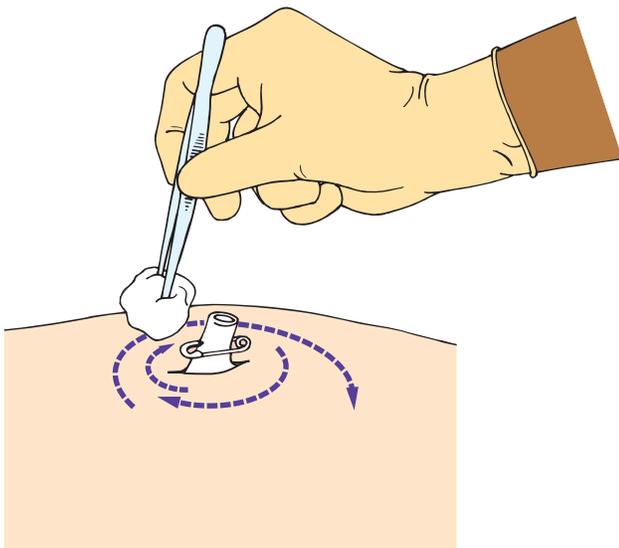

FIGURE 48-23 Cleaning drain site.

FIGURE 48-24 Incision closed with metal staples.

2. Use gentle friction when applying solutions locally to the skin.
3. When irrigating, allow the solution to flow from the least to most contaminated area (see Skill 48-5).

After applying a solution to sterile gauze, clean away from the wound. Never use the same piece of gauze to clean across an incision or wound twice.

Drain sites are a source of contamination because moist drainage harbors microorganisms. If a wound has a dry incisional area and a moist drain site, cleaning moves from the incisional area toward the drain. Use two separate swabs or gauze pads, one to clean from the top of the incision toward the drain and one to clean from the bottom of the incision toward the drain. To clean the area of an isolated drain site, clean around the drain, moving in circular rotations outward from a point closest to the drain. In this situation the skin near the site is more contaminated than the site itself. To clean circular wounds, use the same technique as in cleaning around a drain.

Irrigation. Irrigation is a way of cleaning wounds. Use an irrigating syringe to flush the area with a constant low-pressure flow of solution. The gentle washing action of the irrigation cleanses a wound of exudate and debris. Irrigation is particularly useful for open, deep wounds; wounds involving an inaccessible body part such as the ear canal; or when cleaning sensitive body parts such as the conjunctival lining of the eye.

Wound Irrigations. Irrigation of an open wound requires sterile technique. Use a 35-mL syringe with a 19-gauge soft angiocatheter (Rolstad et al., 2016) to deliver the solution. This irrigation system has a safe pressure and does not damage healing wound tissue. It is important to never occlude a wound opening with a syringe because this results in the introduction of irrigating fluid into a closed space. The pressure of the fluid causes tissue damage, discomfort, and possibly forcing infection or debris into the wound bed. Always irrigate a wound with the syringe tip over but not in the drainage site. Make sure that fluid flows directly into the wound and not over a contaminated area before entering the wound. Skill 48-5 on pp. 1234-1236 lists steps for wound irrigation.

Suture Care. A surgeon closes a wound by bringing the wound edges as close together as possible to reduce scar formation. Proper wound closure involves minimal trauma and tension to tissues with control of bleeding.

Sutures are threads or metal used to sew body tissues together (Figure 48-24). A patient's history of wound healing, the site of surgery, the tissues involved, and the purpose of the sutures determine the suture material used. For example, if a patient has had repeated surgery for an abdominal hernia, the health care provider can choose wire

sutures to provide greater strength for wound closure. In contrast, a small laceration of the face calls for the use of very fine Dacron (polyester) sutures to minimize scar formation.

Sutures are available in a variety of materials, including silk, steel, cotton, linen, wire, nylon, and Dacron. They come with or without sharp surgical needles attached. Steel staples are a common type of outer skin closure that traumatizes tissue less than sutures while providing extra strength.

Sutures are placed within tissue layers in deep wounds and superficially as the final means for wound closure. Deep sutures are usually composed of an absorbable material that disappears over time. Sutures are foreign bodies and thus are capable of causing local inflammation. A surgeon tries to minimize tissue injury by using the finest suture possible and the smallest number necessary.

Policies vary within institutions as to who is able to remove sutures. If it is appropriate that the nurse remove them, a health care provider's order is required. An order for suture removal is not written until the health care provider believes that the wound has closed (usually in 7 days). Special scissors with curved cutting tips or special staple removers slide under the skin closures for suture removal (Figure 48-25). The health care provider usually specifies the number of sutures or staples to remove. If the suture line appears to be healing in certain locations better than in others, some health care providers choose to have only some sutures removed (e.g., every other one).

To remove staples, insert the tips of the staple remover under each wire staple. While slowly closing the ends of the staple remover together, squeeze the center of the staple with the tips, freeing it from the skin (see Figure 48-25).

To remove sutures, first check the type of suturing used (Figure 48-26). With intermittent suturing the surgeon ties each individual suture made in the skin. Continuous suturing, as the name implies, is

a series of sutures with only two knots, one at the beginning and one at the end of the suture line. Retention sutures are placed more deeply than skin sutures, and nurses may or may not remove them, depending on agency policy. The manner in which the suture crosses and penetrates the skin determines the method for removal. *Never pull the visible part of a suture through underlying tissue.* Sutures on the surface of the skin harbor microorganisms and debris. The part of the suture beneath the skin is sterile. Pulling the contaminated part of the suture through tissues can lead to infection. Before taking out the sutures, cleanse the suture line with normal saline. Clip suture materials as close to the skin edge on one side as possible and pull the suture through from the other side (Figure 48-27).

Drainage Evacuation. When drainage interferes with healing, evacuation is achieved by using either a drain alone or a drainage tube with continuous suction. You may apply special skin barriers, including hydrocolloid dressings similar to those used with ostomies (see Chapter 47), around drain sites with significant drainage. The skin barriers are soft material applied to the skin with adhesive. Drainage flows on the barrier but not directly on the skin. **Drainage evacuators** (Figure 48-28) are convenient portable units that connect to tubular drains lying within a wound bed and exert a safe, constant, low-pressure vacuum to remove and collect drainage. Ensure that suction is exerted and that connection points between the evacuator and tubing are intact. The evacuator collects drainage. Assess for volume and character every shift and as needed. When the evacuator fills, measure output by emptying the contents into a graduated cylinder and immediately reset the evacuator to apply suction.

FIGURE 48-28 Setting suction on drainage evacuator. *1,* With drainage port open, raise level on diaphragm. *2,* Push straight down on lever to lower diaphragm. *3,* Closure of port prevents escape of air and creates vacuum pressure.

Bandages and Binders. A simple gauze dressing is often not enough to immobilize or provide support to a wound. Binders and bandages applied over or around dressings provide extra protection and therapeutic benefits by the following:

1. Creating pressure over a body part (e.g., an elastic pressure bandage applied over an arterial puncture site)
2. Immobilizing a body part (e.g., an elastic bandage applied around a sprained ankle)
3. Supporting a wound (e.g., an abdominal binder applied over a large abdominal incision and dressing)
4. Reducing or preventing edema (e.g., a stretch pressure bandage applied to the lower leg)
5. Securing a splint (e.g., a bandage applied around hand splints for correction of deformities)
6. Securing dressings (e.g., elastic webbing applied around leg dressings after a vein stripping)

Bandages are available in rolls of various widths and materials, including gauze, elasticized knit, elastic webbing, flannel, and muslin. Gauze bandages are lightweight and inexpensive, mold easily around contours of the body, and permit air circulation to prevent skin maceration. Elastic bandages conform well to body parts but are also for exerting pressure.

Binders are bandages that are made of large pieces of material to fit a specific body part. Most binders are made of elastic or cotton. An abdominal binder and a breast binder are examples.

Principles for Applying Bandages and Binders. Correctly applied bandages and binders do not cause injury to underlying and nearby body parts or create discomfort for a patient. For example, a chest binder should not be so tight as to restrict chest wall expansion. Before applying a bandage or binder, a nurse's responsibilities include the following:

• Inspecting the skin for abrasions, edema, discoloration, or exposed wound edges
• Covering exposed wounds or open abrasions with a dressing
• Assessing the condition of underlying dressings and changing if soiled
• Assessing the skin of underlying areas that will be distal to the bandage for signs of circulatory impairment (coolness, pallor or cyanosis, diminished or absent pulses, swelling, numbness, and tingling) to provide a means for comparing changes in circulation after bandage application

After applying a bandage, the nurse assesses, documents, and immediately reports changes in circulation, skin integrity, comfort level, and body function (e.g., ventilation or movement). The nurse who applies a bandage loosens or readjusts it as necessary. He or she needs a health care provider's order before loosening or removing a bandage applied by the health care provider. The nurse explains to the patient that any bandage or binder feels relatively firm or tight. Carefully assess a bandage to be sure that it is applied properly and providing therapeutic benefit and replace any soiled bandages.

Binder Application. Binders are especially designed for the body part to be supported. The most common type of binder is the abdominal binder (Box 48-12). An abdominal binder supports large abdominal incisions that are vulnerable to tension or stress as a patient moves or coughs (Figure 48-29). Secure an abdominal binder with safety pins or Velcro strips.

Slings. Slings support arms with muscular sprains or fractures. A commercially manufactured sling consists of a long sleeve that extends above the elbow with a strap that fits around the neck. In the home patients can use a large triangular piece of cloth. The patient sits or lies supine during sling application (Figure 48-30). Instruct him or her to bend the affected arm, bringing the forearm straight across the chest. The open sling fits under the patient's arm and over the chest, with the base of the triangle under the wrist and the point of the triangle at his or her elbow. One end of the sling fits around the back of the patient's neck. Bring the other end up and over the affected arm while supporting the extremity. Tie the two ends at the side of the neck so the knot does not press against the cervical spine. Fold the loose material at the elbow evenly around the elbow and then pin to secure. Always support the lower arm and hand at a level above the elbow to prevent the formation of dependent edema.

Roll Bandage Application. Rolls of bandage secure or support dressings over irregularly shaped body parts. Each roll has a free outer end and a terminal end at the center of the roll. The rolled part of the bandage is its body, and its outer surface is placed against the patient's skin or dressing. Skill 48-6 on pp. 1236-1237 describes the steps for applying an elastic bandage. Use a variety of bandage turns, depending on the body part to be bandaged.

Heat and Cold Therapy

Assessment for Temperature Tolerance. Before applying heat or cold therapies, assess a patient's physical condition for signs of potential intolerance to heat and cold. First observe the area to be treated. Assess the skin, looking for any open areas such as alterations in skin integrity (e.g., abrasions, open wounds, edema, bruising, bleeding, or localized areas of inflammation) that increase a patient's risk for injury. Because a health care provider commonly orders heat and cold applications for traumatized areas, the baseline skin assessment provides a guide for evaluating skin changes that can occur during therapy. Also assess neurological function, testing for sensation to light touch, pinprick, and mild temperature variations (see Chapter 31). Sensory status reveals the ability of a patient to recognize when heat or cold becomes excessive. Assess a patient's mental status to be sure that he or she can correctly communicate any issues with the hot or cold therapy. Level of consciousness influences the ability to perceive heat, cold, and pain. If a patient is confused or unresponsive, the nurse needs to make frequent observations of skin integrity after therapy begins.

Assessment also includes identification of conditions that contraindicate heat or cold therapy. Do not cover an active area of bleeding with a warm application because bleeding will continue. Warm applications are contraindicated when a patient has an acute, localized inflammation such as appendicitis because the heat could cause the

BOX 48-12 **PROCEDURAL GUIDELINES**

Applying a Binder

Delegation Considerations

The skill of applying an abdominal binder can be delegated to nursing assistive personnel (NAP). The nurse is responsible for wound assessment; the evaluation of wound-care interventions and assessment of the patient's ability to breathe deeply, cough effectively, and move independently; and assessment of skin for irritation/abrasion, of incision/wound and dressing, and of comfort level before a binder or sling is applied for the first time. Direct the NAP to:

- Immediately notify the nurse of any change in patient's respiratory status.
- Report any increase in wound drainage to the nurse.
- Report any changes in skin integrity under or adjacent to the binder to the nurse.
- Remove the binder at prescribed intervals.

Equipment

Gloves if wound drainage is present; abdominal binder; correct size cloth/elastic straight binder; safety pins (unless Velcro closure or metal fasteners are attached): six to eight safety pins are usually adequate for abdominal binders

Steps

1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.
2. Observe patient with need for support of abdomen. Observe ability to breathe deeply and cough effectively.
3. Review medical record if medical order for binder is required and reasons for application.
4. Inspect skin for actual or potential alterations in integrity. Observe for irritation, abrasion, skin surfaces that rub against one another, or allergic response to adhesive tape used to secure dressing.
5. Inspect any surgical dressing.
6. Assess patient's comfort level, using analog scale of 0 to 10 and noting any objective signs and symptoms.
7. Explain procedure to patient and family.
8. Perform hand hygiene and apply gloves (if likely to contact wound drainage).
9. Apply abdominal binder.
   a. Position patient in supine position with head slightly elevated and knees slightly flexed.
   b. Fanfold far side of binder toward midline of binder.

c. Instruct and help patient to roll onto side away from you and toward raised side rail while firmly supporting abdominal incision and dressing with hands.
d. Place fan-folded ends of binder under patient.
e. Instruct or help patient to roll back over folded ends.
f. Unfold and stretch ends out smoothly on far side of bed.
g. Instruct patient to roll back into supine position.
h. Adjust binder so supine patient is centered over it, using symphysis pubis and costal margins as lower and upper landmarks.
i. Close binder. Pull one end of binder over center of patient's abdomen. While maintaining tension on that end of binder, pull opposite end over center and secure with Velcro closure tabs, metal fasteners, or horizontally placed safety pins.
j. Adjust binder as necessary.

10. ***Apply mastectomy sports bra:***
    a. Protect surgical incision with prescribed dressing.
    b. Slip arms in bra strap openings (same as putting on a blouse) opening to the front.
    c. Fasten bra.
    d. If using a bra with additional support straps or binder, follow manufacturer instructions in application.

CLINICAL DECISION: Assess patient's ability to breathe deeply and cough effectively.

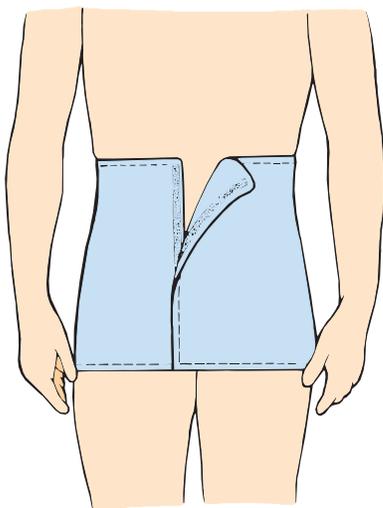
11. Remove and dispose of gloves and perform hand hygiene.
12. Observe site for skin integrity, circulation, and characteristics of wound. (Periodically remove binder and surgical dressing to assess wound characteristics.)
13. Evaluate comfort level of patient, using analog scale of 0 to 10 and noting any objective signs and symptoms.
14. Evaluate patient's ability to ventilate properly, including deep breathing and coughing.
15. Use ***Teach Back*** to determine if the patient understands about binder application. State, "I want to be sure that you understand how to correctly apply the binder. Can you demonstrate how to apply the binder?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to correctly demonstrate bandage application.


FIGURE 48-29 Securing abdominal binder with Velcro.
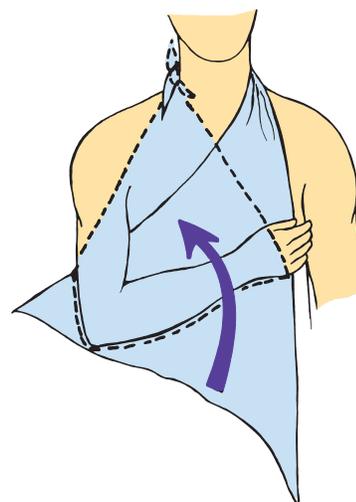

FIGURE 48-30 Application of sling.

appendix to rupture. If a patient has cardiovascular problems, it is unwise to apply heat to large parts of the body because the resulting massive vasodilation disrupts blood supply to vital organs.

Cold is contraindicated if the site of injury is already edematous. It further retards circulation to the area and prevents absorption of the interstitial fluid. If a patient has impaired circulation (e.g., arteriosclerosis), it further reduces blood supply to the affected area. Cold therapy is also contraindicated in the presence of neuropathy, because the patient is unable to perceive temperature change and damage resulting from temperature extremes. One other contraindication for cold therapy is shivering. Cold applications sometimes intensify shivering and dangerously increase body temperature.

If a patient has peripheral vascular disease, pay particular attention to the integrity of extremities. For example, if the health care provider's order is to apply a cold compress to a lower extremity, assess circulation to the leg by assessing for capillary refill; observing skin color; and palpating skin temperatures, distal pulses, and edematous areas. If signs of circulatory inadequacy are present, it is important for you to question the order.

When applying heat or cold pads, check electrical equipment for cracked cords, frayed wires, damaged insulation, and exposed heating components. Make sure that equipment containing circulating fluids does not have leaks. Check equipment for evenness of temperature distribution.

Local application of heat and cold to an injured body part is sometimes therapeutic. You are legally responsible to perform necessary assessments for safe administration of heat and cold applications.

Bodily Responses to Heat and Cold. Exposure to heat and cold causes systemic and local responses. Systemic responses occur through heat-loss mechanisms (sweating and vasodilation) or mechanisms promoting heat conservation (vasoconstriction and piloerection) and heat production (shivering) (see Chapter 30). Local responses to heat and cold occur through stimulation of temperature-sensitive nerve endings within the skin. This stimulation sends impulses from the periphery to the hypothalamus, which becomes aware of local temperature sensations and triggers adaptive responses for maintenance of normal body temperature. If alterations occur along temperature sensation pathways, the reception and eventual perception of stimuli are altered.

The body is able to tolerate wide variations in temperature. The normal temperature of the surface of the skin is 34°C (93.2°F), but temperature receptors usually adapt quickly to local temperatures between 15° and 45°C (59° and 113°F). Pain develops when local temperatures exceed this range. Excessive heat causes a burning sensation. Cold produces a numbing sensation before pain.

The adaptive ability of the body creates the major problem in protecting patients from injury resulting from temperature extremes. A person initially feels an extreme change in temperature but within a short time hardly notices it. This is dangerous because a person insensitive to heat and cold extremes can suffer serious tissue injury. You need to recognize patients most at risk for injuries from heat and cold applications (Table 48-9).

Local Effects of Heat and Cold. Heat and cold stimuli create different physiological responses. The choice of heat or cold therapy depends on local responses desired for wound healing (Table 48-10).

Effects of Heat Application. Generally heat is quite therapeutic, improving blood flow to an injured part. However, if it is applied for 1 hour or more, the body reduces blood flow by a reflex vasoconstriction to control heat loss from the area. Periodic removal and reapplication of local heat restores vasodilation. Continuous exposure to heat damages epithelial cells, causing redness, localized tenderness, and even blistering.

TABLE 48-9	Conditions That Increase Risk of Injury from Heat and Cold Application
Condition	**Risk Factors**
Very young or older patients	Thinner skin layers in children increase risk of burns. Older patients have reduced sensitivity to pain and may not perceive any pain associated with heat or cold applications.
Open wounds, broken skin, stomas	Subcutaneous and visceral tissues are more sensitive to temperature variations. They also contain no temperature and fewer pain receptors.
Areas of edema or scar formation	Reduced sensation to temperature stimuli occurs because of thickening of skin layers from fluid buildup or scar formation.
Peripheral vascular disease (e.g., diabetes, arteriosclerosis)	As a result of decreased peripheral circulation, extremities are less sensitive to temperature and pain stimuli because of circulatory impairment and local tissue injury. Cold application further compromises blood flow.
Confusion or unconsciousness	Perception of sensory or painful stimuli is reduced.
Spinal cord injury	Alterations in nerve pathways prevent reception of sensory or painful stimuli.
Abscessed tooth or appendix	Infection is highly localized. Application of heat causes rupture, with spread of microorganisms systemically.

Effects of Cold Application. The application of cold initially diminishes swelling and pain. Prolonged exposure of the skin to cold results in a reflex vasodilation. The inability of the cells to receive adequate blood flow and nutrients results in tissue ischemia. The skin initially takes on a reddened appearance, followed by a bluish-purple mottling, with numbness and a burning type of pain. Skin tissues freeze from exposure to extreme cold.

Factors Influencing Heat and Cold Tolerance. The response of the body to heat and cold therapies depends on the following factors:

- A person is better able to tolerate short exposure to temperature extremes than prolonged exposure.
- Exposed skin layers and certain areas of the skin (e.g., the neck, inner aspect of the wrist and forearm, and perineal region) are more sensitive to temperature variations. The foot and palm of the hand are less sensitive.
- The body responds best to minor temperature adjustments. If a body part is cool and a hot stimulus touches the skin, the response is greater than if the skin were already warm.
- A person has less tolerance to temperature changes to which a large area of the body is exposed.
- Tolerance to temperature variations changes with age. Patients who are very young or old are most sensitive to heat and cold.
- If a patient's physical condition reduces the reception or perception of sensory stimuli, tolerance to temperature extremes is high, but the risk of injury is also high.
- Uneven temperature distribution suggests that the equipment is functioning improperly.

Application of Heat and Cold Therapies. A prerequisite to using any heat or cold application is a health care provider's order, which includes the body site to be treated and the type, frequency, and duration of application. Safety guidelines for the use of heat and cold are

TABLE 48-10 Therapeutic Effects of Heat and Cold Applications

Physiological Response	Therapeutic Benefit	Examples of Conditions Treated
Heat		
Vasodilation	Improves blood flow to injured body part; promotes delivery of nutrients and removal of wastes; lessens venous congestion in injured tissues (Ebbinghaus and Kobayashi, 2010)	Open wounds, rectal surgery, episiotomy, painful hemorrhoids, muscle tension, vaginal inflammation, wound debridement
Reduced blood viscosity	Improves delivery of leukocytes and antibiotics to wound site	
Reduced muscle tension	Promotes muscle relaxation and reduces pain from spasm or stiffness (Bleakley and Costello, 2013)	
Increased tissue metabolism	Increases blood flow; provides local warmth	
Increased capillary permeability	Promotes movement of waste products and nutrients	
Cold		
Vasoconstriction	Reduces blood flow to injured body part, preventing edema formation; reduces inflammation	Direct trauma (sprains, strains, fractures, muscle spasms), superficial laceration or puncture wound, minor burn, suspected malignancy in area of injury or pain, injections, arthritis, and joint trauma
Local anesthesia	Reduces localized pain (Maxwell and Sterling, 2013)	
Reduced cell metabolism	Reduces oxygen needs of tissues	
Increased blood viscosity	Promotes blood coagulation at injury site	
Decreased muscle tension	Relieves pain	

summarized in Box 48-13. Consult agency procedure manual for correct temperatures to use.

You can administer heat and cold applications in dry or moist forms. The type of wound or injury, the location of the body part, and the presence of drainage or inflammation are factors to consider in selecting dry or moist applications. Box 48-14 summarizes advantages and disadvantages of both.

Warm, Moist Compresses. Warm, moist compresses improve circulation, relieve edema, and promote consolidation of purulent drainage. A compress is a piece of gauze dressing moistened in a prescribed warmed solution. A pack is a larger cloth or dressing applied to a larger body area.

Heat from warm compresses dissipates quickly. To maintain a constant temperature, you need to change the compress often. You can use a layer of plastic wrap or a dry towel to insulate the compress and retain heat. Moist heat promotes vasodilation and evaporation of heat from the surface of the skin. For this reason a patient can feel chilly. Always try to control drafts within the room and keep the patient covered with a blanket or robe.

Warm Soaks. Immersion of a body part in a warmed solution promotes circulation, lessens edema, increases muscle relaxation, and provides a means to apply medicated solution. Sometimes a soak is also accompanied by wrapping the body part in dressings and saturating them with the warmed solution.

Position the patient comfortably, place waterproof pads under the area to be treated, and heat the solution to about 40.5° to 43°C (105°

to 110°F). After immersing the body part, cover the container and extremity with a towel to reduce heat loss. It is usually necessary to remove the cooled solution and add heated solution after about 10 minutes. The challenge is to keep the solution at a constant temperature. Never add a hotter solution while the body part remains immersed. After any soak dry the body part thoroughly to prevent maceration.

Sitz Baths. A patient who has had rectal surgery, an episiotomy during childbirth, painful hemorrhoids, or vaginal inflammation benefits from a sitz bath, a bath in which only the pelvic area is immersed in warm or, in some situations, cool fluid. The patient sits in a special tub or chair or a basin that fits on the toilet seat so the legs and feet remain out of the water. Immersing the entire body causes widespread vasodilation and nullifies the effect of local heat application to the pelvic area.

The desired temperature for a sitz bath depends on whether the purpose is to promote relaxation or to clean a wound. It is often necessary to add warm or cool water during the procedure, which normally lasts 20 minutes, to maintain a constant temperature. Agency procedure manuals recommend safe water temperatures. A disposable sitz basin contains an attachment resembling an enema bag that allows gradual introduction of additional water.

Prevent overexposure of patients by draping bath blankets around their shoulders and thighs and controlling drafts. A patient should be able to sit in the basin or tub with feet flat on the floor and without pressure on the sacrum or thighs. Because exposure of a large part of the body to heat causes extensive vasodilation, assess the pulse and facial color and ask whether the patient feels light-headed or nauseated.

Commercial Hot and Cold Packs. Commercially prepared disposable hot packs apply warm, dry heat to an injured area. The chemicals mix and release heat when you strike, knead, or squeeze the pack. Package directions recommend the time for heat application.

Commercially prepared cold packs that are similar to the disposable hot packs for dry applications are available. They come in various shapes and sizes to fit different body parts. When using cold compresses, observe for adverse reactions such as burning or numbness, mottling of the skin, redness, extreme paleness, and a bluish skin discoloration.

Cold, Moist, and Dry Compresses. The procedure for applying cold, moist compresses is the same as that for warm compresses. Apply cold compresses for 20 minutes at a temperature of 15°C (59°F) to relieve inflammation and swelling. You can use clean or sterile compresses.

Cold Soaks. The procedure for preparing cold soaks and immersing a body part is the same as for warm soaks. The desired temperature for a 20-minute cold soak is 15°C (59°F). Control drafts and use outer coverings to protect the patient from chilling. It is often necessary to add cold water during the procedure to maintain a constant temperature.

Ice Bags or Collars. For a patient who has a muscle sprain, localized hemorrhage, or hematoma or who has undergone dental surgery, an ice bag is ideal to prevent edema formation, control bleeding, and anesthetize the body part. Proper use of the bag requires the following steps:

1. Fill the bag with water, secure the cap, invert to check for leaks, and pour out the water.
2. Fill the bag two-thirds full with crushed ice so you are able to easily mold it over a body part.
3. Release any air from the bag by squeezing its sides before securing the cap because excess air interferes with conduction of cold.
4. Wipe off excess moisture.
5. Cover the bag with a flannel cover, towel, or pillowcase.

6. Apply the bag to the injury site for 30 minutes; you can reapply the bag in an hour.

◆ Evaluation

You evaluate nursing interventions for reducing and treating pressure ulcers by determining the patient's response to nursing therapies and whether he or she achieved each goal. To evaluate outcomes and responses to care, you measure the effectiveness of interventions. The optimal outcomes are to prevent injury to the skin, to reduce injury to the skin and underlying tissues, and possible wound healing with restoration of skin integrity.

Through the Patient's Eyes. It is important to include the patient and family caregiver in the evaluation process. Review whether their expectations of care were met. For example, is the patient satisfied with the level of comfort achieved during wound care? Chronic wounds such as pressure ulcers take time to heal, so home care is likely. Does the patient feel comfortable or confident in being able to perform wound care at home? Does the family caregiver feel she or he has the information needed to know when to report a problem with a wound? If patient and family caregiver expectations are unmet, revise your plan of care to select the best ways to support and re-educate.

Patient Outcomes. The outcomes selected for a patient in the plan of care are the milestones you hope to achieve in order to meet goals of care. Each patient will have unique outcomes depending on whether he or she has an actual wound or is at risk to develop a wound. You evaluate nursing interventions for reducing and treating pressure ulcers by determining the patient's response to nursing therapies and whether he or she achieved each goal (Figure 48-31).

Knowledge
- Characteristics of normal wound healing
- Role of support surfaces and wound management treatment in promoting skin integrity

Experience
- Previous patient response to planned nursing therapies for improving skin integrity and wound healing (what worked and what did not work)

EVALUATION
- Reassess skin for signs and symptoms associated with impaired skin integrity and wound healing
- Obtain the patient's perception of skin integrity and intervention
- Ask if patient's expectations are being met

Standards
- Use established expected outcomes to evaluate the patient's response to care (e.g., wound will decrease in size)
- Apply standards of practice outlining expected outcomes

Attitudes
- Display fairness when identifying interventions that were not successful
- Act independently when redesigning new interventions

FIGURE 48-31 Critical thinking model for skin integrity and wound-care evaluation.

You will evaluate patients with impaired skin integrity on an ongoing basis for factors that contribute to skin breakdown and wound status. For example, during direct patient contact, if a patient continues to be diaphoretic or incontinent, apply wound assessment skills to note the condition of the skin and decide if additional therapies are needed. Your evaluation will include elements of a comprehensive skin reassessment. Use a validated wound assessment tool when appropriate. Evaluation provides information regarding the patient's progress toward wound healing or maintenance of skin integrity.

If the identified outcomes are not met for a patient with impaired skin integrity, questions to ask include the following:

- Was the etiology of the skin impairment addressed? Were the pressure, friction, shear, and moisture components identified;

and did the plan of care decrease the contribution of each of these components?

- Was wound healing supported by providing the wound base with a moist protected environment?
- Were issues such as nutrition assessed and a plan of care developed that provided the patient with the calories to support healing?

Finally evaluate the need for additional referrals to other experts in wound care and pressure ulcers such as nurses certified in wound care. Care of patients with a pressure ulcer or wound requires a multidisciplinary team approach.

SAFETY GUIDELINES FOR NURSING SKILLS

Ensuring patient safety is an essential role of the professional nurse. To ensure patient safety, communicate clearly with all members of the health care team, assess and incorporate a patient's priorities of care and preferences, and use the best evidence when making decisions about care. When performing the skills in this chapter, remember the following points to ensure safe, individualized patient-centered care:

- When changing wound dressings, follow proper aseptic technique. Keep a plastic bag within reach to discard dressings and prevent cross-

contamination. Keep extra gloves within reach to allow a change of gloves if the gloves become soiled.

- If irrigating a wound, use goggles and other personal protective equipment when the risk for splash exists.
- When applying an elastic bandage, check the extremity where the bandage is applied for temperature or sensation changes.

SKILL 48-1   ASSESSMENT FOR PRESSURE ULCER DEVELOPMENT

DELEGATION CONSIDERATIONS

The skill of assessing patients for risk of pressure ulcers cannot be delegated to nursing assistive personnel (NAP). Instruct the NAP to:

- Report any changes to patient's skin such as redness, blistering, abrasion, or cuts to nurse for further nursing assessment.
- Keep patient's skin dry and provide hygiene following fecal or urinary incontinence or exposure to other body fluids.
- Reposition patient according to frequency established on nursing care plan or agency policy.
- Avoid trauma to patient's skin from tape, pressure, friction, or shear.

EQUIPMENT

- Risk assessment tool, Braden Scale
- Documentation record
- Clean gloves when open wound is present

STEP	RATIONALE
ASSESSMENT	
1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
2. Inspect skin during the patient admission process and at least each shift for at-risk individuals needing prevention and for specific factors placing them at risk.	Determines factors that increase patient's risk for developing pressure ulcers (Bryant and Nix, 2016).
a. Use validated risk assessment tool such as Braden Scale. Assess patient and obtain risk score on admission to acute care, critical care rehabilitation hospitals, nursing homes, home care programs, and other health care facilities.	Pressure ulcer assessment scale provides objective baseline assessment. It should be used for all patients with one of more risk factors for pressure ulcer development: restricted mobility, moisture, impaired sensation, impaired nutrition, and medical devices such as casts or drainage tubes (Bryant and Nix, 2016).
3. Assess patient's level of consciousness and ability to respond meaningfully (e.g., move away) to pressure-related discomfort (sensory perception).	Patient with complete or partial limited ability to respond to pressure-related discomfort cannot communicate discomfort, has a limitation in ability to feel pain, and thus is at risk for developing pressure ulcers.
4. Perform hand hygiene. Apply clean gloves and conduct a systematic skin assessment from head to toe with special attention to the areas over bony prominences.	Bony prominences are at high risk of skin breakdown because of high pressures exerted on the area. If a patient has restricted mobility or other risk factor, risk for skin breakdown over bony prominences increases (Bryant and Nix, 2016).
a. Observe at-risk areas, including back of head, shoulders, ribs, hips, sacral region, ischium, inner and outer knees, inner and outer ankles, heels, and feet (see Figure 48-9).	The presence of redness or impairment in skin integrity necessitates planning appropriate interventions.

SKILL 48-1   **ASSESSMENT FOR PRESSURE ULCER DEVELOPMENT—cont'd**

STEP	RATIONALE
5. Assess the following potential sites for skin breakdown related to medical devices:	Pressure from medical devices or how the device is secured increases a patient's risk for tissue injury and skin breakdown under and around the device (Fletcher, 2012; McNichol et al., 2013).
a. Ears and nares	Cartilage that nasal cannulas or tubing compresses develops pressure necrosis.
b. Lips	Oral airway and endotracheal tubes exert pressure if left in place for prolonged time periods.
c. Tube sites (e.g., gastrostomy or nasogastric tubes, Foley catheters, Jackson-Pratt drains)	Tubes exert pressure if taped snugly against skin or if there is stress at insertion site (Black et al., 2015). If moisture is present around tube insertion sites, leakage of bodily fluids compromises skin integrity.
d. Orthopedic and positioning devices (e.g., casts, braces, cervical collar)	Improperly fitted or applied devices have potential to cause pressure on adjacent skin and underlying tissue (Black et al., 2010, 2015).
6. Assess all skin surfaces for the following:	
a. Absence of superficial skin layers	Damage of superficial skin layers indicates injury from friction or moisture. The area is moist and sore to the touch.
b. Blisters	Suggests skin damage from friction and/or inappropriate tape removal (McNichol et al., 2013). Blisters occur when top layer of skin is pulled or rubbed, separating epidermis from dermis.
c. Any loss of epidermis and dermis	Indicates damage to skin. Determine cause of this damage in order to select interventions to prevent further damage.
7. Assess degree to which patient's skin is exposed to moisture. If necessary, remove gloves to palpate skin surface. Then dispose of gloves and perform hand hygiene.	Exposure to excessive moisture increases risk for maceration and skin breakdown (Bryant, 2016; Colwell et al., 2011).
8. Assess patient's activity level.	Patient who is bedfast or chairfast or only walks occasionally is at risk for developing pressure areas because of the degree of physical inactivity (WOCN, 2010).
a. Determine patient's ability to change and control body position (mobility).	Potential for friction and shear increases when patient is completely dependent on others for position change.
b. Determine patient's preferred positions.	Weight of body is on certain bony prominences, and patient resists repositioning off these areas.
9. Assess patient's usual food intake pattern (nutrition).	Patient who rarely or never eats a complete meal is at risk for pressure ulcer formation.
a. Review recent weight pattern over last month, daily calorie intake, and nutritional laboratory values.	Decreased nutrition status is linked with pressure ulcer formation and poor wound healing (WOCN, 2010).
b. Complete fluid intake assessment.	Fluid imbalance, either dehydration or edema, increases patient's risk for pressure ulcers (Stotts, 2016a).
10. Assess presence of friction and/or shear.	Patient who has a problem moving, requires maximum assistance in moving, or slides against sheets when moved is at an increased risk of skin damage (Bryant, 2016).

PLANNING

1. Explain procedures for reducing pressure ulcer risk patient.	Promotes patient cooperation and reduces anxiety.

IMPLEMENTATION

1. Note score on Braden risk assessment scale.	Documentation provides a baseline for comparison of increased or decreased risk for development of pressure ulcers and allows planning of interventions.
a. As Braden Scale scores become lower, predicted risk becomes higher.	*Scores:*
	15 to 18, at risk general population, 13 at risk ICU patients
	13 to 14, moderate risk
	10 to 12, high risk
	9 or below, very high risk
b. Link risk assessment to preventive protocols. Perform hand hygiene and apply gloves.	Protocols target the problem areas to help prevent skin breakdown.
(1) Institute at-risk interventions (score of 15 to 18). Consider instituting frequent turning, protecting patient's heels, using a pressure-redistribution surface, and managing moisture.	Decreases risk of skin breakdown.
(2) Institute moderate-risk interventions (score of 13 to 14). Consider protocol of frequent turning; protecting patient's heels; providing pressure-redistribution surface; providing foam wedges for 30-degree lateral positioning; and managing moisture, shear, and friction.	Decreases pressure on bony prominences and reduces increased risk of skin breakdown.

STEP	RATIONALE
(3) Institute high-risk interventions (score of 10 to 12). Consider protocol that increases frequency of turning; supplements turning with small shifts in position; facilitates maximal remobilization; protects patient's heels; provides pressure-redistribution surface; provides foam wedges for 30-degree lateral positioning; and manages moisture, friction, and shear. If needed, institute nutritional interventions to reduce risk of pressure ulcer development.	Addresses factors that contribute to skin breakdown and plans for interventions to address causative factors (Bryant, 2016). Nutrition therapy promotes skin healing (Stotts, 2016a).
(4) Institute very high–risk interventions (score of 9 or below). Consider protocol that incorporates points for high-risk patients and uses pressure-redistribution surface if patient has intractable pain or severe pain exacerbated by turning.	Plans interventions to decrease effects of immobility, decreased sensory perception, moisture, friction, shear, decreased activity, and nutritional issues in high-risk individual.
2. When you note a reddened area, check for the following:	
a. Skin discoloration (e.g., redness in light-tone skin; purplish or bluish in darkly pigmented skin) (see Box 48-3)	May indicate that tissue was under pressure.
b. Blanchable erythema	Blanchable erythema is an early indication of pressure and usually resolves without tissue loss if pressure is eliminated. Blanching erythema is an area of erythema that turns white (blanches) under application of pressure (Pieper, 2016).
c. Nonblanchable erythema	Indicates potential damage to blood vessels and tissue damage. Once blood vessels are damaged, red area will not lighten in color because tissue and blood vessels are inflamed. Color of skin can be intense bright red to dark red or purple (Pieper, 2016). Position patient off area.
d. Pallor or mottling	Persistent hypoxia in tissues alters circulation, and pallor or mottling may occur.
3. Remove gloves and perform hand hygiene. Reposition patient in 30-degree lateral position (see Figure 48-15).	Reduces transmission of infection. Positions patient off bony prominences.
4. Educate patient and family regarding specific pressure ulcer risk factors and prevention.	Helps patients and family understand and adhere to interventions designed to reduce pressure ulcer risk (Berlowitz, 2014a).

EVALUATION

1. Observe condition of patient's skin each shift, especially areas at risk (check agency policy).	Determines over time patient's response to risk-redistribution interventions.
2. Observe tolerance of patient for positioning.	Frequent change in position further reduces patient's risk for pressure ulcer development.
3. Compare current risk assessment with previous scores.	Documents effectiveness of interventions and helps provide individualized plan of care.
4. Evaluate food intake and nutrition laboratory values.	Determines success of nutritional supplements in improving nutritional status.
5. Use **Teach Back** to determine patient's and family's understanding about pressure ulcer risk and prevention. State, "I want to be sure I explained the reasons why you are at risk to get a pressure ulcer. Can you explain to me the pressure ulcer risk factors that affect you?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient and family are able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Skin does not blanch when firmly pressed, has purple discoloration, or has significant color change.
- Reassess frequency of turning schedule.
- Implement agency skin-care protocols.
- Consider use of pressure-redistribution surface to reduce pressure ulcer risk.

RECORDING AND REPORTING

- Record patient's risk score and appearance of skin under pressure in progress notes in EHR or chart.
- Record position, turning intervals, pressure-redistribution devices, and other prevention strategies used and patient response in EHR or chart.
- Report any need for additional consultations for the high-risk patient.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- Instruct family caregiver in use of the 30-degree lateral position and how to assist patient into the position. This position prolongs the time between position changes, resulting in fewer sleep interruptions for patient and caregiver.
- Individualize pressure-redistribution maneuvers for patient needs and home environment.
- Provide family with community resources for hospital equipment.

SKILL 48-2	TREATING PRESSURE ULCERS	◉

DELEGATION CONSIDERATIONS

The skill of treating pressure ulcers cannot be delegated to nursing assistive personnel (NAP). In some practice settings you can delegate *nonsterile* dressing application for chronic, established wounds when a nurse has evaluated and designated a protocol. The nurse is responsible for *assessment* of the wound, even if the dressing change is delegated. Instruct the NAP to:

- Report changes in skin integrity to the nurse immediately.
- Report pain, fever, or wound drainage to the nurse immediately.
- Report any potential contamination to existing dressing (e.g., patient incontinence or other bodily fluids; dressing becomes dislodged).

EQUIPMENT

- Clean gloves
  - Sterile gloves (check agency policy)
- Goggles and personal protective equipment if splash risk is present
- Plastic bag for dressing disposal
- Measuring device
- Cotton-tipped applicators
- Topical cleaning agent
- Dressing of choice (see Table 48-8)
- Hypoallergenic tape (if needed)
- Documentation record
- Scale for assessing wound healing

STEP	RATIONALE

ASSESSMENT

1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.

   Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).

2. Assess patient's level of comfort using a scale of 0 to 10 and determine need for pain medication.

   Patients tolerate dressing change procedure better if pain is controlled. Some dressings may also contain a foam preparation of an analgesic such as ibuprofen to help in patient comfort (Berlowitz, 2014b).

3. Determine if patient has allergies to topical agents.

   Topical agents cause localized skin reactions.

4. Review order for topical agent or dressing and location.

   Ensures that you administer proper medication and treatment.

5. Close room door or bedside curtains. Describe to patient what will be done. Position patient to allow for access to ulcer and dressing removal.

   Provides privacy and ensures that area is accessible for dressing change.
   Decreases patient's anxiety.

6. Perform hand hygiene and apply clean gloves. Remove dressing and place in plastic bag. If glove is soiled with drainage, remove, perform hand hygiene, and then reglove.

   Reduces transmission of microorganisms and prevents accidental exposure to body fluids.

7. Assess pressure ulcer(s).

   Consistent assessment provides basis for evaluating wound progress (Nix, 2016).

   a. Note color, type, and percentage of tissue type present in wound base.

   Tissue type helps in choice of dressing.

   b. Measure width and length of ulcer(s). Determine width by measuring from left to right and length from top to bottom using a measuring device (see illustration).

   Ulcer size changes as healing progresses; therefore the longest and widest areas of the wound change over time. Measuring width and length by measuring consistent areas provides a consistent measurement (Nix, 2016).

   c. Measure depth of pressure ulcer with sterile cotton-tipped applicator or other device that allows measurement of wound depth.

   Depth measure is important for determining wound volume. Although surface area adequately represents tissue loss in stage II ulcers, volume more adequately represents tissue loss in stage III and IV wounds.

   d. Measure depth of undermining by using a cotton-tipped applicator and gently probing under skin edges.

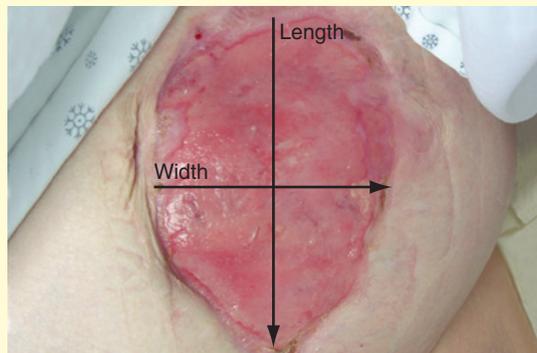
   Undermining represents the loss of underlying tissue (subcutaneous and muscle). It indicates progressive tissue loss and needs to be accommodated with an appropriate dressing.

8. Assess periwound skin; check for maceration, redness, denuded area.

9. Remove and discard gloves. Perform hand hygiene. Assist patient to comfortable position.

   Reduces transmission of microorganisms.

10. Review medical record to assess for significant weight loss (>5% change in 30 days or > 10% in 180 days).

    Patients who are underweight or losing weight need increased caloric and protein supplements (Berlowitz, 2014b; WOCN, 2010).


STEP 7b Measuring wound width, length, and undermining. (From Bryant RA, Nix DP, editors: *Acute and chronic wounds: current management concepts,* ed 5, St Louis, 2016, Elsevier.)

STEP	RATIONALE

PLANNING

1. Explain procedure to patient and family.

Preparatory explanations relieve anxiety, correct any misconceptions about ulcer and its treatment, and offer opportunity for patient and family education.

2. Prepare the following necessary equipment and supplies:
   a. Washbasin, warm water, soap, washcloth, and bath towel
   b. Normal saline or other wound-cleaning agent in sterile-solution container

Ulcer surface must be cleaned before application of topical agents and new dressing.

CLINICAL DECISION: *Use only noncytotoxic agents such as normal saline or commercially available wound cleansers to clean ulcers.*

---

   c. Prescribed topical agent (e.g., enzymatic agents, topical antibiotic). Follow manufacturer instruction on package insert carefully.

Enzymes debride dead tissue to clean ulcer surface. Topical antibiotics are used to decrease bioburden of wound and should be considered for use if no healing is noted after 2 to 4 weeks of optimal care (WOCN, 2010).

CLINICAL DECISION: *If using enzymatic debriding agent, do not use wound-cleaning agents with metals.*

---

   d. Select appropriate dressing and tape on the basis of pressure ulcer characteristics, purpose for which dressing is intended, and patient care setting (see Table 48-8).

Dressing should maintain moist environment for wound while keeping surrounding skin dry.

3. Position patient to allow dressing removal and position plastic bag for dressing disposal.

Area should be accessible for dressing change. Proper disposal of old dressing promotes proper handling of contaminated waste.

IMPLEMENTATION

1. Perform hand hygiene. Open sterile packages and topical solution containers as necessary.

Reduces transmission of microorganisms. Provides organized access to supplies.

2. Remove bed linen and patient's gown as necessary to expose ulcer and surrounding skin. Keep remaining parts covered and apply clean gloves.

Prevents unnecessary exposure of body parts.
Reduces transmission of microorganisms.

3. Clean ulcer thoroughly with normal saline or cleaning agent. Clean with irrigating syringe for deep ulcers.

Removes wound debris.

4. Remove gloves, perform hand hygiene, and apply clean or sterile gloves.

Aseptic technique must be maintained during cleaning and all phases of pressure ulcer treatment. Check agency policy regarding use of clean or sterile gloves.

5. Apply topical agents as prescribed:
   a. Debriding enzymes
      (1) Apply thin, even layer of ointment over necrotic areas of ulcer only. Do not apply enzyme to surrounding skin. Check manufacturer directions for frequency of application.

Thin layer absorbs and acts more effectively than thick layer. Excess medication irritates surrounding skin (Rolstad et al., 2016). Some enzymes cause burning, paresthesia, and dermatitis to surrounding skin.

      (2) Apply gauze dressing directly over ulcer.

Protects wound and keeps enzymes in place. Prevents bacteria from entering wound.

      (3) Tape securely in place.

Keeps dressing in place.

   b. Hydrogel
      (1) Cover surface of ulcer with hydrogel using applicator or gloved hand.

Hydrogel dressings are designed to hydrate and donate moisture to wound, thus facilitating moist wound healing (Rolstad et al., 2016).

      (2) Apply dry gauze, hydrocolloid, or transparent film dressing over wound and adhere to intact skin.

Covers wound base, maintaining hydrogel wound interface.

   c. Calcium alginate

Alginate dressings absorb serous fluid or exudate, forming a nonadhesive hydrophilic gel, which conforms to the shape of the wound (Rolstad et al., 2016).

      (1) Pack wound with alginate using applicator or gloved hand.

Provides maintenance of wound moisture while absorbing excess drainage.

      (2) Apply dry gauze or foam over alginate. Tape in place.

Holds alginate against wound surface.

6. Reposition patient comfortably off pressure area and other pressure points.

Reduces pressure on existing wound and decreases pressure on at-risk areas.

7. Remove gloves and dispose of soiled supplies. Perform hand hygiene.

Reduces transmission of microorganisms.

EVALUATION

1. Evaluate condition of pressure ulcer at each dressing change or sooner if wound or patient's condition deteriorates (Nix, 2016). Use agency tool for wound assessment.

Not all patients with wounds demonstrate quick wound healing because of other health care issues. Wound evaluation provides a report of wound-healing progress or lack of it.

2. Compare wound findings (e.g., type and amount of drainage, wound size, appearance of tissue) to previous findings.

Evaluates progress of wound healing.

CLINICAL DECISION: *A clean pressure ulcer should show evidence of some healing within 2 to 4 weeks. Do not use the pressure ulcer staging system to measure healing. System measures depth of wound, not healing (WOCN, 2010).*

SKILL 48-2	TREATING PRESSURE ULCERS—cont'd

STEP	RATIONALE
3. Use **Teach Back** to determine patient's and family's understanding about pressure ulcer treatment. State, "I want to be sure I explained how to pack the pressure ulcer wound. Can you show me how you will use the applicator to pack your wound?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient and family are able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Skin surrounding ulcer becomes macerated.
  - Reduce exposure of surrounding skin to topical agents and moisture.
  - Consider the use of a liquid skin barrier on periwound skin.
2. Ulcer becomes deeper with increased or foul-smelling drainage and pain.
  - Notify health care provider about possible change in pressure ulcer status.
  - Obtain necessary wound cultures.
  - Consult with health care provider about possible change in analgesic.
  - Obtain additional consults (e.g., wound-care specialist).

RECORDING AND REPORTING

  - Complete wound documentation required for the wound-assessment instrument per agency protocol.
  - Record assessment of ulcer; describe type of topical agent, dressing applied, and patient response.
  - Report any deterioration in ulcer assessment to nurse in charge or health care provider.
  - Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

  - Patients need to dispose of contaminated dressings in the home in a manner consistent with local regulations for contaminated waste.
  - Educate patient and family caregiver about signs of wound infection.
  - Discuss need for home pressure-redistribution surface or bed and whether it will fit in a room within the home.

SKILL 48-3	APPLYING DRY AND MOIST DRESSINGS

DELEGATION CONSIDERATIONS

The skill of applying dry and moist dressings to a new acute wound cannot be delegated to nursing assistive personnel (NAP). In some settings aspects of wound care such as changing dressings using *clean* technique for chronic wounds are delegated. The nurse's responsibility is *assessment* of the wound, even if the dressing change is delegated. Direct the NAP to:
  - Report pain, fever, bleeding, or wound drainage to the nurse immediately.
  - Report any potential contamination to existing dressing (e.g., patient incontinence or other bodily fluids, dressing becomes dislodged).
  - Adapt the skill (e.g., need for special tape or devices to secure dressing.

EQUIPMENT
  - Sterile gloves
  - Variety of gauze dressings and pads
  - Irrigation kit
  - Cleaning solution
  - Sterile solution: water, normal saline, sodium hypochlorite (Dakin's solution).
  - Clean, disposable gloves
  - Tape, ties, or bandage as needed
  - Waterproof pad and bag
  - Extra gauze dressings, or topper dressing (ABD pads)
  - Montgomery ties; elastic net
  - Mask, goggles, or gown for risk of splashing

STEP	RATIONALE

ASSESSMENT

1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
2. Review medical record for information about size and location of wound.	Provides baseline to compare your findings. Helps to plan for proper type and amount of supplies needed. Alerts you when help is needed to hold dressings in place.
3. Assess patient's level of comfort using a scale of 0 to 10.	Removal of dry dressing is painful; some patients require pain medication. Superficial wounds with multiple exposed nerves may be intensely painful, whereas deeper wounds with destruction of nerves should be less painful (Krazner, 2016).
4. Review orders for dressing change procedure.	Indicates type of dressing or applications to use.
5. Assess patient for allergies to wound cleansing agents or tape.	Prevents adverse reactions.
6. Assess patient's and family's knowledge of purpose and steps of dressing change.	Determine specific areas for patient and family teaching.

STEP	RATIONALE
7. Assess for risk of delayed or poor wound healing (e.g., age, obesity, diabetes, peripheral vascular diseases, poor nutritional status, steroid medications, stress, immunosuppression medications, and radiation therapy).	Physiological changes and effects of disease and treatment conditions can affect wound healing (Doughty and Sparks-DeFriese, 2016).

PLANNING

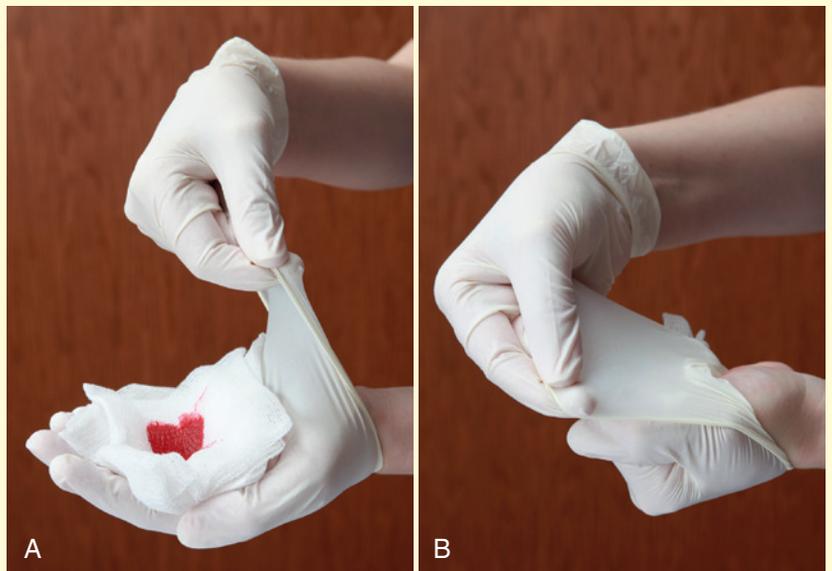
1. Explain procedure to patient and instruct him or her not to touch wound area or sterile supplies.	Decreases anxiety. Sudden, unexpected movement on patient's part results in contamination of wound and supplies.
2. Position patient comfortably and drape with bath blanket to expose only wound site.	Provides access to wound yet minimizes unnecessary exposure.
3. Plan dressing change 30 to 60 minutes following administration of analgesia.	Allows for peak action of medication so patient has optimal level of comfort during dressing change. Patients tolerate dressing changes when their pain is controlled.

IMPLEMENTATION

1. Close room door or pull bedside curtains. Perform hand hygiene and apply gloves.	Provides privacy and reduces transmission of microorganisms.
2. Position patient comfortably and drape only to expose wound site.	Draping provides access to wound while minimizing unnecessary exposure.
3. Place disposable bag within reach of work area. Fold top of bag to make cuff (see illustration).	Ensures easy disposal of soiled dressings. Prevents soiling of outer surface of bag.
4. *Remove tape:* Gently push skin away from tape while pulling adhesive from skin.	Push-pull technique releases tape from skin, reducing chance of skin damage.
5. With gloved hand carefully remove gauze dressings one layer at a time, taking care not to dislodge drains or tubes.	Removal of one layer at a time reduces chance of accidental removal of underlying drains.
a. If dressing sticks on dry dressing, moisten with saline and then remove.	Prevents damage to wound tissue.

CLINICAL DECISION: *Never use a moist-to-dry dressing in a clean granulating wound. Use only for debridement. For highly colonized wounds, use sodium hypochlorite (Dakin's solution) instead of water or normal saline (Ramundo, 2016).*

6. Observe wound for color, edema, drains, and exudates and amount of drainage on dressing.	Provides estimate of drainage amount and assessment of condition of wound.
7. Fold dressings with drainage contained inside and remove gloves inside out. With small dressings remove gloves inside out over dressing (see illustration). Dispose of gloves and soiled dressings in disposable bag. Perform hand hygiene.	Reduces transmission of microorganisms. Prevents contact of hands with material on gloves.

STEP 3 Disposable waterproof bag placed near dressing site.


STEP 7 Removing disposable gloves over contaminated dressing.

SKILL 48-3	APPLYING DRY AND MOIST DRESSINGS—cont'd

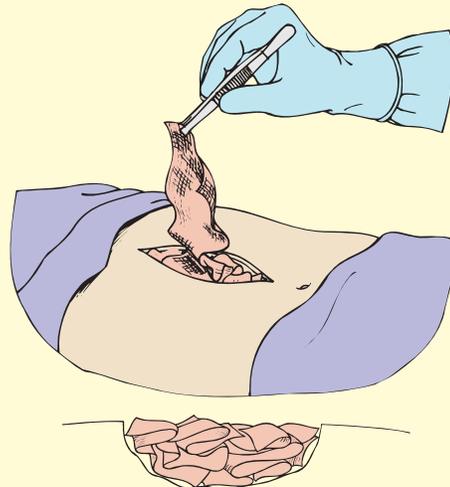
STEP	RATIONALE
8. Open sterile dressing tray or individually wrapped sterile supplies. Place on bedside table and apply clean gloves.	Sterile dressings remain sterile while on or within sterile surface. Preparation of supplies prevents break in technique during dressing change.
9. Clean wound with solution. Using gauze or antiseptic swab, clean from least-contaminated area, which is the incision or center of wound, to most-contaminated area, which is outside of incision and surrounding skin (see Chapter 29). Dry area. Remove and dispose of gloves and perform hand hygiene.	Prevents contamination of previously cleaned area. Reduces transmission of infection.
10. If ordered irrigate wound:	Removes drainage containing microorganisms.
a. Pour ordered solution into sterile irrigation container.	
b. Apply clean gloves, protective eyewear, mask, and protective gown if needed. Place waterproof pad under patient. Using syringe, gently allow solution to flow over wound. (Some commercial cleaners come in a spray bottle. Spray wound to loosen debris.)	Protects you from splash and reduces transmission of microorganisms.
c. Continue until irrigation creates a clear flow of solution.	Indicates debris is removed.
d. Dry surrounding skin with gauze pads.	
e. Measure wound (see Skill 48-1). Then remove and dispose of gloves. Perform hand hygiene.	Measurement of wound size with each dressing change provides data about progression of wound healing. Reduces transmission of microorganisms.
11. Apply dressing:	
a. Dry dressing	
(1) Apply clean or sterile gloves. Check agency policy.	Some agencies or condition of wound requires sterile gloves. Allows handling of sterile supplies without contamination.
(2) Inspect wound for appearance, drains, drainage, and integrity.	Once wound is clean you are able to better inspect wound condition. Indicates status of wound healing.
(3) Apply sterile, loose woven gauze (4 × 4, 2 × 2) dry dressing, covering wound. Apply additional gauze as needed.	Protects wound from external environment.

CLINICAL DECISION: *When a drain is present, use a precut, split gauze. Never cut gauze to fit around a drain because the cut edges will fray and enter the wound or irritate the periwound tissue.*

STEP	RATIONALE
(4) Apply topper dressing (e.g., ABD) if indicated.	Topper dressing is a thicker dressing that prevents strike-through of wound drainage and provides a surface to tape the dressing in place.
b. Moist to dry dressing	
(1) Apply sterile gloves (see agency policy).	Allows handling of sterile supplies without contamination.
(2) Assess appearance of surrounding skin (see illustration). Look for maceration.	Surrounding skin assessment provides evaluation of wound management.
(3) Moisten gauze with prescribed solution. Gently wring out excess solution. Unfold.	Gauze needs to be moist to allow for absorption of wound debris.

STEP 11b(2) Exposure of wound facilitates assessment of wound and surrounding skin.

STEP	RATIONALE
(4) Apply gauze as single layer directly onto wound surface (see illustration). If wound is deep, gently pack dressing into wound base by hand until all wound surfaces are in contact with gauze. If tunneling is present, use cotton-tipped applicator to place gauze into tunneled area. Be sure that gauze does not touch surrounding skin.	Inner gauze needs to be moist, not dripping wet, to absorb drainage and adhere to debris. Excessively moist dressings result in moisture-associated skin damage (maceration) in periwound skin (Gray et al., 2011). Wound needs to be packed loosely to facilitate wicking of drainage into absorbent outer layer of dressing.
(5) Cover with sterile dry gauze and topper dressing.	Dry dressing wicks drainage out of moist gauze. Topper dressing is thicker; it prevents strike-through of wound drainage and provides surface to tape dressing in place.
12. Secure dressing.	Goal for securing a dressing is to keep dressing in place and intact without causing damage to underlying and surrounding skin.
a. *Tape:* Apply tape 2.5-5 cm (1 to 2 inches) beyond dressing. Use nonallergenic tape to secure dressing in place.	Secures dressing. Reduces sensitivity reaction to tape.
b. Montgomery ties (see Figure 48-21)	Ties allow for repeated dressing changes without the need for tape removal and subsequent skin and tissue damage.
(1) Open by exposing adhesive surface of tape on end of each tie.	
(2) Place ties on opposite sides of dressing.	
(3) Place adhesive directly on skin or apply a solid skin barrier to skin and secure end of tape on skin barrier.	Solid skin barrier protects intact skin from stretch and tension of adhesive tape.
(4) Secure dressing by lacing ties across it.	
c. For dressings on an extremity, secure dressing with rolled gauze or elastic net (see illustration).	Prevents slipping of dressing.

STEP 11b(4) Packing wound with single layer of gauze.


STEP 12c Elastic net securing lower-extremity dressing.

SKILL 48-3	APPLYING DRY AND MOIST DRESSINGS—cont'd

STEP	RATIONALE
13. Remove gloves and dispose of them in bag. Remove any mask, eyewear, or gown.	Reduces transmission of infection.
14. Write date and time dressing applied in ink on tape securing dressing (not marker).	Provides guide for when to perform next dressing change.
15. Help patient to comfortable position.	Improves patient comfort.
16. Dispose of supplies and perform hand hygiene.	Reduces transmission of infection.

EVALUATION

1. Inspect condition of wound and any drainage.	Determines rate of healing.
2. Ask patient to rate level of pain during and after procedure.	Pain is early indicator of wound complications or result of dressing material pulling underlying tissue.
3. Inspect condition of dressing and note any observable drainage every shift.	Determines status of wound drainage.
4. Use **Teach Back** to determine patient's and family's understanding of dressing change procedure. State, "We talked about how to apply a gauze dressing at home. Can you show me now how to apply the dressing?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient and family are able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Wound appears inflamed, tender, with or without drainage.
   - Monitor patient for signs of infection (e.g., increased temperature, white blood cell count).
   - Obtain wound culture per order.
   - Notify health care provider.
2. Wound drainage increases.
   - Increase frequency of dressing changes.
   - Notify health care provider, who may consider drain placement to facilitate wound drainage.
3. Wound bleeds during dressing change.
   - Observe color. If drainage is bright red and excessive, you need to apply pressure.
   - Inspect along dressing and underneath patient to determine amount of bleeding.
   - Obtain vital signs as needed.
   - Notify health care provider.
4. Patient reports a sensation that "something has given way under the dressing."
   - Observe wound for increased drainage or separation of sutures.
   - Protect wound. If underlying organs protruding, cover with sterile moist dressing.
   - Instruct patient to lie still and place on NPO status.
   - Notify health care provider.

RECORDING AND REPORTING

- Report brisk, bright red bleeding or evidence of wound dehiscence or evisceration to health care provider immediately.
- Record condition of wound and periwound tissue appearance, color, tissue type, presence and characteristics of exudate, type and amount of dressings used, and tolerance of patient to procedure in EHR or chart.
- Record patient's level of comfort and response to analgesic.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- More expensive specialty dressings are sometimes used because they decrease the frequency of dressing changes.
- Clean dressings may also be used in the home setting.
- Patients need to dispose of contaminated dressings in the home in a manner consistent with local regulations.
- Be sure patient has a family caregiver able to assist and/or apply dressing, and instruct caregiver on dressing procedure.
- Be sure patient and family caregiver know signs of infection and when to notify physician.

SKILL 48-4	IMPLEMENTATION OF NEGATIVE-PRESSURE WOUND THERAPY

DELEGATION CONSIDERATIONS

The skill of negative-pressure wound therapy (NPWT) cannot be delegated to nursing assistive personnel (NAP). Instruct the NAP to:

- Use caution in positioning and turning patient to avoid tubing displacement.
- Report to the nurse any change in patient's temperature, level of comfort.
- Report change in pressure in NPWT unit.
- Report any change in the integrity of the dressing.

EQUIPMENT

- NPWT unit (For this skill the vacuum-assisted closure (V.A.C.) unit is used for illustration; several other systems are available, and their application may be slightly different; refer to manufacturer directions; requires health care provider order.)
- NPWT dressing (gauze or foam dressing and transparent dressing) (check manufacturer instructions)
- NPWT suction device
- Tubing for connection between NPWT unit and dressing
- Gloves, clean and sterile
- Sterile scissors
- Skin preparation/skin barrier
- Moist washcloth
- Waterproof, disposable biohazard bag
- Linen bag
- Protective gown, mask, goggles if risk of splashing wound drainage

STEP	RATIONALE

ASSESSMENT

1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.

   Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).

2. Review medical record for signs and symptoms related to condition of patient's wound.

   Provides you a baseline to compare with your findings, which will reflect if progress is occurring.

3. Assess location, appearance, and size of wound to be dressed (see Skill 48-2).

   Allows you to gather information regarding status of wound healing, presence of complications, and type of supplies and help needed to apply NPWT dressing.

4. Review health care provider's orders for frequency of dressing change, type of foam to use, and amount of negative pressure to be used.

   Health care provider orders frequency of dressing changes and special instructions.

5. Assess patient's level of comfort using a scale of 0 to 10.

   Patient who is comfortable during procedure is less likely to move suddenly, causing wound or supply contamination.

6. Assess patient's and family member's knowledge of purpose of dressing.

   Identifies patient's learning needs. Prepares patient and family if dressing needs to be changed at home.

PLANNING

1. Explain to patient what dressing change involves, including sensations to be felt.

   Provides patient with rationale for dressing change and reduces fears. Maintaining patient comfort helps to complete skill smoothly.

2. Administer ordered analgesic 30 minutes before dressing change.

   Pain has been reported with NPWT removal and application; pain medication given before dressing change can reduce procedural pain (Upton and Andrews, 2015).

3. Perform hand hygiene. Assemble supplies.

   Reduces transmission of microorganisms. Organizes procedure.

IMPLEMENTATION

1. Close room door or cubicle curtains.

   Provides privacy.

2. Position patient comfortably and drape to expose only wound site. Instruct patient not to touch wound or sterile supplies.

   Draping provides access to wound while minimizing unnecessary exposure.

3. Place disposable waterproof bag within reach of work area with top folded to make a cuff.

   Facilitates safe disposal of soiled dressings.

4. Apply clean gloves. If there is risk for splash or spray, apply protective gown, goggles, and mask.

   Reduces exposure to infectious microorganisms.

5. Keep system in "de vac" mode for 30 to 60 minutes before changing dressing.

   Loosens foam dressing for easier, less painful removal.

6. When NPWT is in place, push therapy on/off button (follow manufacturer directions).

   a. Keeping tube connectors with NPWT unit, raise tubing connectors above level of NPWT unit; disconnect tubes from one another to drain fluids into canister.

   Deactivates therapy and allows for proper drainage of fluid in drainage tubing.

   b. Before lowering, tighten clamp on canister tube and disconnect canister and dressing tubing at connection points.

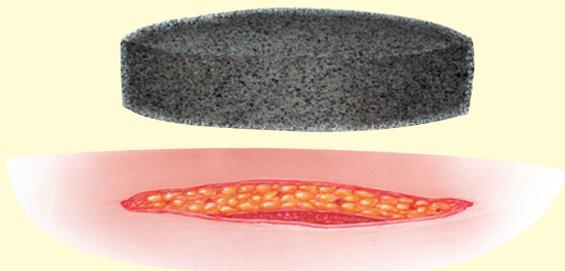
7. Remove transparent film by gently stretching transparent film horizontally and slowly pull away from skin.

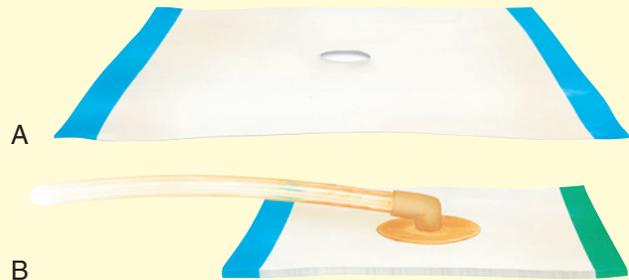
   Prevents skin breakdown from adhesive.

8. Remove old dressing, observing drainage on dressing. Use caution to avoid tension on any drains that are present. Discard dressing and remove gloves. Perform hand hygiene.

   Determines dressings needed for replacement. Avoids accidental removal of drains because they are sometimes sutured in place.

SKILL 48-4	**IMPLEMENTATION OF NEGATIVE-PRESSURE WOUND THERAPY—cont'd**

STEP	**RATIONALE**
	CLINICAL DECISION: *Verify that all prior dressing foam is removed. Infections from retained pieces of foam filler can result in further surgery, antibiotic use, and resistant wound infections (Netsch, 2016).*
9. Apply sterile or clean gloves (see agency policy). Irrigate wound with normal saline or other solution ordered by health care provider (see Skill 48-3). Blot dry with gauze.	Irrigation removes wound debris.
	CLINICAL DECISION: *When drainage looks purulent, amount or color changes, or it has a foul odor, obtain wound cultures even when they are not ordered for that particular dressing change (Netsch, 2016; Stotts 2016b).*
10. Measure wound as ordered: at baseline, first dressing change, weekly; discharge from therapy. Remove and discard gloves. Perform hand hygiene.	Objectively documents wound-healing process in response to NPWT (Nix, 2016).
11. Depending on type of wound, apply new sterile or clean gloves.	Fresh sterile wounds require sterile gloves. Chronic wounds may require clean technique. Never wear same gloves worn to remove old dressing or irrigate wound because cross-contamination may occur.
12. Prepare periwound skin by applying skin protectant/barrier film to protect and enhance adherence of adhesive drape.	Maintains air-tight seal needed for NPWT and protects periwound skin from maceration.
13. Prepare foam dressing.	
a. Select appropriate foam (follow manufacturer directions).	Black, polyurethane (PU) foam has larger pores and is most effective in stimulating granulation tissue and wound contraction. White, polyvinyl alcohol (PVA) soft foam is denser with smaller pores and is used when growth of granulation tissue needs to be restricted (Netsch, 2016).
	CLINICAL DECISION: *The brand of NPWT or specific wound filler dressing may need to be adjusted on the basis of undermining, tunneling, or sinus tracts (Netsch, 2016).*
b. Using sterile scissors, cut foam to exact wound size with foam height extending 1-2 cm ($\frac{1}{2}$ inch) above skin surface. Dressing must fit size and shape of wound, including tunnels and undermined areas.	Foam will contract to level of skin.
	CLINICAL DECISION: *Some patients experience more pain with the black foam because of excessive wound contraction. If this occurs, change wound filler to one that causes less contraction and is less likely to allow granulation growth into the dressing (Netsch, 2016).*
14. Gently place foam in wound; be sure that foam is in contact with entire wound base, margins, and tunneled and undermined areas (see illustration).	Achieves even distribution of negative pressure to entire wound.
15. Apply wrinkle-free transparent dressing over foam and to 3-5 cm (1.2-2 inches) of surrounding healthy skin. Secure tubing to unit (see illustration).	Ensures that wound is properly covered and helps achieve negative-pressure seal (see Box 48-12). Connects negative pressure from NPWT unit to wound foam.
16. Secure tubing to transparent film, aligning drainage holes to ensure occlusive seal. Do not apply tension to drape and tubing.	Excessive tension compresses foam dressing and impedes wound healing. Tension also produces shear force on periwound area (KCI, 2007).
17. Secure tubing several centimeters away from dressing, avoiding pressure points.	Drainage tubes over bony prominences can cause pressure ulcers (Netsch, 2016).
	CLINICAL DECISION: *Prevent medical device–related pressure ulcers (MD PUs) by avoiding placement of drainage tubing and suction device over bony prominences and other areas at risk for pressure ulcer development (Black et al., 2015; Netsch, 2016).*


STEP 14 Dressing application. Properly sized foam to cover wound.


STEP 15 A, Wrinkle-free transparent dressing applied over foam. **B,** Secure tubing to foam and transparent dressing. (Courtesy Kinetic Concepts, Inc [KCI], San Antonio, Tex.)

STEP	RATIONALE
18. Once you have completely covered the wound (see illustration), connect tubing from dressing to tubing from canister and NPWT unit.	Intermittent or continuous negative pressure can be administered at 50 to 175 mm Hg, according to health care provider's order and patient comfort. Continuous therapy is most routinely used. Average is 125 mm Hg (Netsch, 2016).
a. Remove canister from sterile packaging and push into unit until you hear a click. NOTE: An alarm sounds if canister is not engaged properly.	
b. Connect dressing tubing to canister tubing. Make sure that both clamps are open.	
c. Place unit on level surface or hang from foot of bed. NOTE: Unit alarms and deactivates therapy if it is tilted beyond 45 degrees.	
d. Press in green-lit power button and set pressure as ordered.	
19. Discard old dressing materials; remove gloves, discard, and perform hand hygiene.	Reduces transmission of microorganisms.
20. Inspect NPWT system to verify that negative pressure is achieved.	Negative pressure is achieved when there is an airtight seal.
a. Verify that display screen reads THERAPY ON.	
b. Be sure that clamps are open and tubing is patent.	
c. Listen for air leaks.	
d. If leak is present, use strips of transparent film to patch areas around edges of wound.	

EVALUATION

1. Inspect condition of wound on ongoing basis; note drainage and odor.	Determines status of wound healing.
2. Ask patient to rate pain using a scale of 0 to 10.	Determines patient's level of comfort following procedure.
3. Compare wound size and condition with baseline wound assessment.	Provides objective documentation of wound healing.
4. Verify airtight dressing seal and proper negative pressure.	To achieve prescribed vacuum level, wound must be covered with airtight seal. This airtight seal and negative pressure promote wound drainage, circulation, and healing.
5. Measure wound drainage in canister on regular basis per agency policy.	Monitors fluid balance and wound drainage.
6. Use **Teach Back** to determine patient's and family's understanding about **negative pressure wound therapy**. State, "I want to be sure I explained why you have this suction device attached to your dressing. Can you tell me what this suction does to help heal your wound?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient and family are able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Wound appears inflamed and tender, drainage has increased, and an odor is present.
- Notify health care provider.
- Obtain wound culture per order.
- Increase frequency of dressing changes.

2. Patient reports increase in pain.
- If using black foam, switch to the PVA foam product.
- Patient sometimes needs more analgesic support when NPWT is initiated.
- Reduce suction.

3. Negative pressure seal has broken.
- *Take preventive measures:* Shave hair around wound, avoid wrinkles in transparent dressing, and avoid use of adhesive remover because it leaves residue that hinders film adherence.
- Reinforce with transparent dressing strips.

STEP 18 Foam, transparent dressing, and tubing secured over existing wound. (Courtesy Kinetic Concepts, Inc [KCI], San Antonio, Tex.)

SKILL 48-4	IMPLEMENTATION OF NEGATIVE-PRESSURE WOUND THERAPY—cont'd

RECORDING AND REPORTING

- Record appearance of wound, size, color, characteristics of any drainage, presence of wound healing, and patient's response to dressing change in progress notes in EHR or chart.
- Record pressure setting of NPWT.
- Record date and time of dressing change.
- Report brisk, bright bleeding; evidence of poor wound healing; and possible wound infection to health care provider.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- Patients can use NPWT in the home safely. Some patients need clinic or home care nursing visits to change and monitor wound healing.
- Provide resources to patient for supplies for NPWT.
- Instruct family and family caregiver regarding proper disposal of contaminated product.

SKILL 48-5	PERFORMING WOUND IRRIGATION

DELEGATION CONSIDERATIONS

The skill of wound irrigation cannot be delegated to nursing assistive personnel. Direct the NAP to:

- Report any change in wound appearance or increased wound drainage to the nurse.
- Report patient pain.

EQUIPMENT

- Irrigant/cleaning solution (volume 1.2 to 2 times the estimated wound volume)
- Irrigation delivery system, depending on amount of pressure desired:
- Sterile irrigation 35-mL syringe with sterile soft 19-gauge angiocatheter (Rolstad et al., 2016)
- Clean gloves and sterile gloves (check agency policy)
- Waterproof under pad, if needed
- Gauze dressing supplies
- Disposable waterproof bag
- Gown, goggles, or mask, if risk of spray

STEP	RATIONALE

ASSESSMENT

STEP	RATIONALE
1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
2. Assess patient's level of pain.	Provides baseline to measure patient's response to therapy. Discomfort is related directly to wound or indirectly to muscle tension or immobility.
3. Review medical record for health care provider's prescription for irrigation of open wound and type of solution to be used.	Open-wound irrigation requires medical order, including type of solution to use.
4. Review medical record for signs and symptoms related to patient's open wound.	Data provide baseline to indicate change in condition of wound (Nix, 2016).
a. Extent of impairment of skin integrity, including size of wound (Measure length, width, and depth in centimeters in the following order: length, width, and depth.)	Assesses volume of irrigation solution needed. Data also used as baseline to indicate change in condition of wound.
b. Verify number and types of drains present.	Awareness of drain placement facilitates safe dressing removal and identifies type and quantity of new dressings needed.
c. Drainage from wound (amount and color) (Amount can be measured by part of dressing saturated or in terms of quantity [e.g., scant, moderate, copious].)	Expect amount to decrease as healing takes place. Serous drainage is clear like plasma; sanguineous or bright red drainage indicates fresh bleeding; serosanguineous drainage is pink; purulent drainage is thick and yellow, pale green, or white.
d. Odor (must state whether or not there is odor)	Strong odor indicates infectious process.
e. Wound tissue color	Color represents balance between necrotic tissue and new scar tissue. Proper selection of wound products on the basis of color of wound facilitates removal of necrotic tissue and promotes new tissue growth (Nix, 2016).
f. Consistency of drainage	Type and color of drainage depend on moisture of wound and type of organisms present.
g. Culture reports	Chronic wounds heal by secondary intention, and they are often colonized with bacteria.
h. Condition of dressing: dry and clean; evidence of bleeding, profuse drainage	Provides initial assessment of present wound drainage.

PLANNING

STEP	RATIONALE
1. Explain procedure of wound irrigation and cleaning and how you will prepare patient.	Information reduces patient's anxiety.

STEP	RATIONALE
2. Administer prescribed analgesic 30 to 60 minutes before starting wound irrigation procedure.	Promotes pain control and permits patient to move more easily and be positioned to facilitate wound irrigation.
3. Position patient to access wound for easy irrigation.	
a. Position comfortably so wound is vertical to collection basin, which permits gravitational flow of irrigating solution through wound and into collection receptacle.	Directing solution from top to bottom of wound and from clean to contaminated area reduces spread of infection. Position patient, keeping in mind bed surfaces needed for later preparation of equipment.
b. Place container of irrigant/cleaning solution in basin of hot water to warm solution to body temperature.	Warmed solution increases comfort and reduces vascular constriction response in tissues.
c. Place padding or extra towel in bed.	Protects bedding.

IMPLEMENTATION

STEP	RATIONALE
1. Perform hand hygiene.	Reduces transmission of microorganisms.
2. Form cuff on waterproof bag and place it near bed.	Cuffing helps to maintain large opening, thereby permitting placement of contaminated dressing without touching refuse bag itself.
3. Close room door or bed curtains.	Maintains privacy.
4. Apply gown, mask, or goggles if needed.	Protects nurse from splashes or sprays of blood and body fluids.
5. Apply clean gloves and remove soiled dressing and discard in waterproof bag. Discard gloves and perform hand hygiene.	Reduces transmission of microorganisms.
6. Prepare equipment; open sterile supplies.	
7. Put on clean or sterile gloves (check agency policy).	Reduces transmission of microorganisms.
8. To irrigate wound with wide opening:	
a. Fill 35-mL syringe with irrigation solution.	Flushing wound helps remove debris and facilitates healing by secondary intention.
b. Attach soft 19-gauge angiocatheter (see Figure 48-17).	Provides ideal pressure for cleaning and removing debris (Ramundo, 2016).
c. Hold syringe tip 2.5 cm (1 inch) above upper end of wound and over area being cleaned.	Prevents syringe contamination. Careful placement of syringe prevents unsafe pressure of flowing solution.
d. Using continuous pressure, flush wound; repeat Steps 8a, b, and c until solution draining into basin is clear.	Clear solution indicates that you have removed all debris.
9. To irrigate deep wound with very small opening:	
a. Attach soft 19-gauge angiocatheter to filled irrigating syringe.	Catheter permits direct flow of irrigant into wound. Expect wound to take longer to empty when opening is small.
b. Gently insert tip of catheter into wound and pull out about 1 cm ($\frac{1}{2}$ inch).	Removes tip from fragile inner wall of wound.
c. Using slow, continuous pressure, flush wound. *CAUTION:* Splashing sometimes occurs during this step.	Cleans all wound surfaces.
d. Pinch off catheter just below syringe while keeping catheter in place.	Avoids contamination of sterile solution.
e. Remove and refill syringe. Reconnect to catheter and repeat until solution draining into basin is clear.	Indicates wound clear of debris.

CLINICAL DECISION: *Pulsatile high-pressure lavage may be the irrigation of choice for necrotic wounds. The amount of irrigant depends on the size of the wound. Pressure settings on the device should remain between 8 and 15 psi. Do not use pulsatile high-pressure lavage on exposed blood vessels, muscle, tendon, and bone. This type of irrigation should not be used with graft sites and should be used with caution in patients receiving anticoagulant therapy (Ramundo, 2016).*

STEP	RATIONALE
10. Obtain cultures, if ordered, after cleaning with nonbacteriostatic saline.	Type of wound culture obtained depends on resources available in facility. The three most common types of wound specimens are tissue biopsy, needle aspirated wound fluid, and swab technique (Stotts, 2016b).

CLINICAL DECISION: *Consider culturing a wound if it has a foul, purulent odor; inflammation surrounds the wound; a nondraining wound begins to drain; or patient is febrile.*

STEP	RATIONALE
11. Assess type of tissue in wound bed and periwound skin.	Identifies wound-healing progress and determines if wound has increased in size.
12. Dry wound edges with gauze.	Prevents maceration of surrounding tissue caused by excess moisture.
13. Apply appropriate dressing (see Skills 48-2 and 48-3).	Maintains protective barrier and healing environment for wound.
14. Remove gloves and, if worn, mask, goggles, and gown.	Prevents transfer of microorganisms.
15. Dispose of equipment and soiled supplies. Perform hand hygiene.	Reduces transmission of microorganisms.
16. Help patient to comfortable position.	

EVALUATION

STEP	RATIONALE
1. Inspect dressing periodically.	Determines patient's response to wound irrigation and need to modify plan of care.
2. Determine patient's level of pain.	Patient's pain should not increase as result of wound irrigation.
3. Observe for presence of retained irrigant.	Retained irrigant is medium for bacterial growth and subsequent infection.

SKILL 48-5	PERFORMING WOUND IRRIGATION—cont'd

STEP	RATIONALE
4. Use **Teach Back** to determine patient's and family's understanding about the need for the wound to be irrigated. State, "I want to be sure I explained why we irrigate your abdominal wound. Can you tell me why irrigation is important?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient and family are able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Wound does not appear to heal.
  - Obtain wound culture per order.
  - Notify health care provider, who may change dressing and/or irrigation frequency.
2. Wound drainage increases.
  - Apply more absorbent gauze; consider more observant dressing such as an alginate.
  - Increase the frequency of irrigation.

RECORDING AND REPORTING

- Record wound irrigation, patient response, and appearance of wound in progress notes in EHR or chart.
- Immediately report any evidence of fresh bleeding, sharp increase in pain, retention of irrigant, or signs of shock to attending health care provider.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- Teach patient and family caregiver how to make normal saline, especially if cost is an issue. You make normal saline by using 8 tsp of salt in 1 gallon of distilled water.
- Instruct family caregiver on irrigation technique and have caregiver demonstrate.
- Be sure patient and family know signs of infection and when to notify health care provider.

SKILL 48-6	APPLYING AN ELASTIC BANDAGE

DELEGATION CONSIDERATIONS

The skill of applying an elastic bandage can be delegated to nursing assistive personnel (NAP). The nurse is responsible for assessing the wound and the adequacy of circulation to the extremity distal to the bandage. Direct the NAP to:
  - Report any restrictions that patient has (e.g., unable to independently raise leg or roll over).
  - Report any change in skin color of patient's injured extremity.
  - Report any increases in patient's pain.

EQUIPMENT
- Correct width and number of bandages
- Safety pins, clips, or adhesive tape
- Clean gloves if wound drainage is present

STEP	RATIONALE
ASSESSMENT	
1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
2. Review medical record for specific orders related to application of elastic bandage. Note area to be covered, type of bandage required, frequency of change, and previous response to treatment.	Specific orders sometimes direct procedure, including factors such as extent of application (e.g., toe to knee, toe to groin) and duration of treatment.
3. Perform hand hygiene and apply gloves if needed. Inspect skin for alterations in integrity as indicated by abrasions, discoloration, chafing, or edema. (Look carefully at bony prominences.)	Altered skin integrity contraindicates use of elastic bandages.
4. Inspect surgical dressing if present. Remove gloves and perform hand hygiene.	Surgical dressing replacement or reinforcement precedes application of any bandage. Reduces transmission of microorganisms.
5. Observe adequacy of circulation (distal to bandage) by noting surface temperature, skin color, and sensation in body parts to be wrapped.	Comparison of area before and after application of bandage is necessary to ensure continued adequate circulation. Impairment of circulation can result in coolness to touch when compared with opposite side of body, cyanosis, pallor of skin, diminished or absent pulses, edema or localized pooling, and numbness or tingling of part.
PLANNING	
1. Explain each step of procedure to patient.	Increased knowledge promotes cooperation and reduces anxiety.
2. Demonstrate skill to patient and family caregiver during bandage application.	Helps to ensure continuity of care after discharge.

CLINICAL DECISION: *Apply bandages to lower extremities before patient sits or stands. Elevate dependent extremities for 20 minutes before bandage application to enhance venous return.*

STEP	RATIONALE
IMPLEMENTATION	
1. Close room door or curtains.	Maintains patient's comfort and dignity.
2. Help patient assume comfortable, anatomically correct position.	Maintains alignment. Prevents musculoskeletal deformity.
3. Perform hand hygiene and apply gloves if drainage is present.	Reduces transmission of microorganisms.
4. Hold roll of elastic bandage in dominant hand and use other hand to lightly hold beginning of bandage at distal body part. Continue transferring roll to dominant hand as bandage is wrapped.	Maintains appropriate and consistent bandage tension.

<div align="center">CLINICAL DECISION: Toes or fingertips need to be visible for follow-up circulatory assessment.</div>

STEP	RATIONALE
5. Apply bandage from distal point toward proximal boundary using variety of turns to cover various shapes of body parts.	Bandage is applied in manner that conforms evenly to body part and promotes venous return.
a. Spiral dressing is often used to cover cylindrical body parts such as wrist or upper arms. To apply bandage in an ascending motion, overlap previous bandage by one-half to two-thirds width of bandage.	
b. Use figure-eight dressing to cover joint because snug fit provides excellent immobilization. *To apply:* Overlap turns, alternately ascending and descending over bandaged part; each turn crossing previous one to form figure eight.	
6. Unroll and very slightly stretch bandage.	Maintains uniform bandage tension.
7. Overlap turns by one-half to two-thirds width of bandage roll.	Prevents uneven bandage tension and circulatory impairment.
8. Secure first bandage with clip or tape before applying additional rolls.	
9. Apply additional rolls without leaving any skin surface uncovered. Secure last bandage applied.	Prevents wrinkling or loose ends.
10. Remove gloves if worn and perform hand hygiene.	Reduces transmission of microorganisms.
EVALUATION	
1. Assess distal circulation when bandage application is complete and at least twice during 8-hour period.	Early detection and management of circulatory impairment ensures healthy neurovascular status.
a. Observe skin color for pallor or cyanosis.	
b. Palpate skin for warmth.	
c. Palpate pulses and compare bilaterally.	
d. Ask if patient is aware of pain, numbness, tingling, or other discomfort.	Neurovascular changes indicate impaired venous return.
e. Observe mobility of extremity.	Determines if bandage is too tight, which restricts movement, or if joint immobility is attained.
2. Use **Teach Back** to determine patient's and family's understanding about bandage application. State, "I want to be sure that you can correctly apply the bandage. Can you demonstrate how to apply the elastic bandage for me now?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient and family are able to demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Impaired circulation distal to elastic bandage
   - Release bandage.
   - Palpate extremity and assess pulse, temperature, and capillary refill.
   - Reapply dressing with less pressure.
2. Break in skin under elastic bandage
   - Remove bandage.
   - Reapply bandage over different area of skin with less pressure.
3. Patient unable to perform dressing change
   - Reinstruct patient or family caregiver on bandage application.
   - Observe patient or family caregiver apply bandage.

RECORDING AND REPORTING

- Document condition of wound, integrity of dressing, application of bandage, circulation, and patient's comfort level in progress notes in EHR or chart.
- Report any changes in neurological or circulatory status to nurse in charge or health care provider.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- Instruct patient or caregiver not to make bandages too tight, which interferes with circulation.
- Elastic bandages that reduce swelling are best applied to the feet and ankles in the morning, before getting out of bed.
- Always remove an elastic bandage daily and inspect skin beneath it.
- Be sure patient has two sets of bandages to alternate; making it easy to clean one set while other is in place.

KEY POINTS

- Pressure ulcers contribute to patient discomfort and decreased functional status, increased length of stay in acute and extended care settings, and increased cost of care.
- Wound assessment determines progress toward pressure ulcer healing; do not use the staging system for this purpose.
- Assess all patients on an ongoing basis for risk factors that contribute to development of any type of impaired skin integrity such as blistering or burning sensation.
- Alterations in mobility, sensory perception, level of consciousness, and nutrition and the presence of moisture increase the risk for pressure ulcer development.
- Pressure, shearing force, and friction are contributing factors to the development of pressure ulcers.
- Meticulous ongoing assessment of the skin and identification of risk factors are important in decreasing the opportunity for pressure ulcer development.
- Preventive skin care is aimed at controlling external pressure on bony prominences and keeping the skin clean, well lubricated and hydrated, and free of excess moisture.
- Proper positioning reduces the effects of pressure and guards against the shearing force.
- Therapeutic beds and mattresses redistribute the effects of pressure; however, base selection on assessment data to identify the best support surface for individual needs.
- Cleaning and topical agents used to treat pressure ulcers vary according to the stage of the pressure ulcer and condition of the wound bed. Assessment of the ulcer enables the nurse to select proper skin-care agents.
- Direct nutritional interventions at improving wound healing through increasing protein and calorie levels.
- Wound assessment requires a description of the appearance of the wound base, size, presence of exudate, and periwound skin condition.
- The chances of wound infection are greater when a wound contains dead or necrotic tissue, when foreign bodies lie on or near the wound, and when the blood supply is reduced.
- The principles of wound first aid include control of bleeding, cleaning, and protection.
- A moist environment supports wound healing.
- An acute sprain, closed fracture, or bruise responds best to cold applications.
- The selection of the type of dressing is determined by the type and condition of a wound.
- Use medical versus surgical asepsis when applying dressings on a clean chronic wound versus a new surgical wound.

CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

1. Because of the foul-smelling tan-colored drainage from Mrs. Stein's hip incision, the staples were removed by the health care provider, and an order was written for moist saline gauze dressing to the area 3 times a day. When the dressing is removed, which factors are critical to assess?
2. A head-to-toe skin assessment is done per institutional policy each shift or on a daily basis. At the most recent assessment of Mrs. Stein's skin, blistering was noted over the sacral area; on direct examination it was a small area of denuded tissue with redness around the blistered area. The area was found to have minimal

depth and a red, moist base. How would you describe the impairment in skin integrity in your charting?
3. What will you include in your plan of care for Mrs. Stein to address the impairment in skin integrity in the sacral area?

ⓔ *Answers to Clinical Application Questions can be found on the Evolve website.*

REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. When repositioning an immobile patient, the nurse notices redness over the hip bone. What is indicated when a reddened area blanches on fingertip touch?
   1. A local skin infection requiring antibiotics
   2. Sensitive skin that requires special bed linen
   3. A stage III pressure ulcer needing the appropriate dressing
   4. Blanching hyperemia, indicating the attempt by the body to overcome the ischemic episode
2. Match the pressure ulcer categories/stages with the correct definition.
   1. Category/stage I
   2. Category/stage II
   3. Category/stage III
   4. Category/stage IV

   a. Nonblanchable redness of intact skin. Discoloration, warmth, edema, or pain may also be present.
   b. Full-thickness skin loss; subcutaneous fat may be visible. May include undermining.
   c. Full thickness tissue loss; muscle and bone visible. May include undermining.
   d. Partial-thickness skin loss or intact blister with serosanguinous fluid.
3. When obtaining a wound culture to determine the presence of a wound infection, from where should the specimen be taken?
   1. Necrotic tissue
   2. Wound drainage
   3. Wound circumference
   4. Cleansed wound
4. After surgery the patient with a closed abdominal wound reports a sudden "pop" after coughing. When the nurse examines the surgical wound site, the sutures are open, and pieces of small bowel are noted at the bottom of the now-opened wound. Which are the priority nursing interventions? (Select all that apply.)
   1. Notify the surgeon.
   2. Allow the area to be exposed to air until all drainage has stopped.
   3. Place several cold packs over the area, protecting the skin around the wound
   4. Cover the area with sterile, saline-soaked towels immediately.
   5. Cover the area with sterile gauze and apply an abdominal binder.
5. What is the correct sequence of steps when performing wound irrigation to a large open wound?
   1. Use slow, continuous pressure to irrigate wound.
   2. Attach 19-gauge angiocatheter to syringe.
   3. Fill syringe with irrigation fluid.
   4. Place waterproof bag near bed.
   5. Position angiocatheter over wound.
6. For a patient who has a muscle sprain, localized hemorrhage, or hematoma, which wound-care product helps prevent edema formation, control bleeding, and anesthetize the body part?

1. Binder
2. Ice bag
3. Elastic bandage
4. Absorptive dressing

7. Which skin-care measures are used to manage a patient who is experiencing fecal and/or urinary incontinence? (Select all that apply.)
   1. Frequent position changes
   2. Keeping the buttocks exposed to air at all times
   3. Using a large absorbent diaper, changing when saturated
   4. Using an incontinence cleaner
   5. Frequent cleaning, applying an ointment, and covering the areas with a thick absorbent towel
   6. Applying a moisture barrier ointment

8. Which of the following describes a hydrocolloid dressing?
   1. A seaweed derivative that is highly absorptive
   2. Premoistened gauze placed over a granulating wound
   3. A debriding enzyme that is used to remove necrotic tissue
   4. A dressing that forms a gel that interacts with the wound surface

9. Which of the following is an indication for a binder to be placed around a surgical patient with a new abdominal wound? (Select all that apply.)
   1. Collection of wound drainage
   2. Providing support to abdominal tissues when coughing or walking
   3. Reduction of abdominal swelling
   4. Reduction of stress on the abdominal incision
   5. Stimulation of peristalsis (return of bowel function) from direct pressure

10. When is an application of a warm compress to an ankle muscle sprain indicated? (Select all that apply.)
    1. To relieve edema
    2. To reduce shivering
    3. To improve blood flow to an injured part
    4. To protect bony prominences from pressure ulcers
    5. To immobilize area

11. What is the removal of devitalized tissue from a wound called?
    1. Debridement
    2. Pressure reduction
    3. Negative pressure wound therapy
    4. Sanitization

12. Name the three important dimensions to consistently measure to determine wound healing.

13. What does the Braden Scale evaluate?
    1. Skin integrity at bony prominences, including any wounds
    2. Risk factors that place the patient at risk for skin breakdown
    3. The amount of repositioning that the patient can tolerate
    4. The factors that place the patient at risk for poor healing

14. On assessing your patient's sacral pressure ulcer, you note that the tissue over the sacrum is dark, hard, and adherent to the wound edge. What is the correct category/stage for this patient's pressure ulcer?
    1. Category/stage II
    2. Category/stage IV
    3. Unstageable
    4. Suspected deep-tissue damage

15. Which of the following are measures to reduce tissue damage from shear? (Select all that apply.)
    1. Use a transfer device (e.g., transfer board)
    2. Have head of bed elevated when transferring patient
    3. Have head of bed flat when repositioning patient
    4. Raise head of bed 60 degrees when patient positioned supine
    5. Raise head of bed 30 degrees when patient positioned supine

Answers: 1. 4; **2.** 1a, 2d, 3b, 4c; **3.** 4; **4.** 1, 4; **5.** 4, 3, 2, 5, 1; **6.** 2; **7.** 1, 4, 6; **8.** 4; **9.** 2, 4; **10.** 1, 3; **11.** 1; **12.** Width, length, and depth; **13.** 2; **14.** 3; **15.** 1, 3, 5.

Sensory Alterations

OBJECTIVES

- Differentiate among the processes of reception, perception, and reaction to sensory stimuli.
- Discuss the relationship of sensory function to an individual's level of wellness.
- Discuss common causes and effects of sensory alterations.
- Discuss common sensory changes that normally occur with aging.
- Assess a patient's sensory status.
- Identify nursing diagnoses relevant to patients with sensory alterations.

- Develop a plan of care for patients with sensory deficits.
- List interventions for preventing sensory deprivation and controlling sensory overload.
- Describe conditions in a health care agency or patient's home that you can modify to promote meaningful sensory stimulation.
- Discuss ways to maintain a safe environment for patients with sensory deficits.

Imagine the world without sight, hearing, the ability to feel objects, or the ability to sense aromas around you. People rely on a variety of sensory stimuli to give meaning and order to events occurring in their environment. The senses form the perceptual base of our world. Stimulation comes from many sources in and outside the body, particularly through the senses of sight (visual), hearing (**auditory**), touch (**tactile**), smell (**olfactory**), and taste (**gustatory**). The body also has a **kinesthetic** sense that enables a person to be aware of the position and movement of body parts without seeing them. **Stereognosis** is a sense that allows a person to recognize the size, shape, and texture of an object. The ability to speak is not a sense, but it is similar in that some patients lose the ability to interact meaningfully with other human beings. Meaningful stimuli allow a person to learn about the environment and are necessary for healthy functioning and normal development. When sensory function is altered, a person's ability to relate to and function within the environment changes drastically.

Many patients seeking health care have preexisting sensory alterations. Others develop them as a result of medical treatment (e.g., hearing loss from antibiotic use or hearing or visual loss from brain tumor removal) or hospitalization. The health care environment is a place of unfamiliar sights, sounds, and smells and minimal contact with family and friends. If patients feel depersonalized and are unable to receive meaningful stimuli, serious sensory alterations sometimes develop.

As a nurse you meet the needs of patients with existing sensory alterations and recognize those most at risk for developing sensory problems. You also help patients who have partial or complete loss of a major sense to find alternate ways to function safely within their environment.

SCIENTIFIC KNOWLEDGE BASE

Normal Sensation

The nervous system continually receives thousands of bits of information from sensory nerve organs, relays the information through appropriate neurological channels, and integrates the information into a meaningful response. Sensory stimuli reach the sensory organs to elicit an immediate reaction or store information in the brain for future use. The nervous system must be intact for sensory stimuli to reach appropriate brain centers and for an individual to perceive the sensation. After interpreting the significance of a sensation, the person is

TABLE 49-1	Normal Hearing and Vision
Function	**Anatomy and Physiology**
Ear	
Transmits to brain a pattern of all sounds received from the environment, the relative intensity of these sounds, and the direction from which they originate	Two ears provide stereophonic hearing to judge sound direction. The external ear canal shelters the eardrum and maintains relatively constant temperature and humidity to maintain elasticity. The middle ear is an air-containing space between the eardrum and oval window. It contains three small bones (ossicles). The eardrum and ossicles transfer sound to the fluid-filled inner ear. Movement of the stapes in the oval window creates vibrations in the fluid that bathes the membranous labyrinth, which contains the end organs of hearing and balance. The union of the vestibular (balance) and cochlear (hearing) parts of the labyrinth explains the combination of hearing and balance symptoms that occur with inner ear disorders. Vibration of the eardrum transmits through the bony ossicles. Vibrations at the oval window transmit in perilymph within the inner ear to stimulate hair cells that send impulses along the eighth cranial nerve to the brain.
Eye	
Transmits a pattern of light to the brain that is reflected from solid objects in the environment and becomes transformed into color and hue	Light rays enter the convex cornea and begin to converge. An adjustment of light rays occurs as they pass through the pupil and lens. Change in the shape of the lens focuses light on the retina. The retina has a pigmented layer of cells to enhance visual acuity. The sensory retina contains the rods and cones (i.e., photoreceptor cells sensitive to stimulation from light). Photoreceptor cells send electrical potentials by way of the optic nerve to the brain.

then able to react to the stimulus. Table 49-1 summarizes normal hearing and vision.

Reception, perception, and reaction are the three components of any sensory experience. Reception begins with stimulation of a nerve cell called a *receptor,* which is usually for only one type of stimulus such as light, touch, taste, or sound. In the case of special senses, the receptors are grouped close together or located in specialized organs such as the taste buds of the tongue or the retina of the eye. When a nerve impulse is created, it travels along pathways to the spinal cord or directly to the brain. For example, sound waves stimulate hair cell receptors within the organ of Corti in the ear, which causes impulses to travel along the eighth cranial nerve to the acoustic area of the temporal lobe. Sensory nerve pathways usually cross over to send stimuli to opposite sides of the brain.

The actual perception or awareness of unique sensations depends on the receiving region of the cerebral cortex, where specialized neurons interpret the quality and nature of sensory stimuli. When a person becomes conscious of a stimulus and receives the information, perception takes place. Perception includes integration and interpretation of stimuli on the basis of the person's experiences. A person's level of consciousness influences perception and interpretation of stimuli. Any factors lowering consciousness impair sensory perception. If sensation is incomplete such as blurred vision or if past experience is inadequate for understanding stimuli such as pain, the person can react inappropriately to the sensory stimulus.

It is impossible to react to all stimuli entering the nervous system. The brain prevents sensory bombardment by discarding or storing sensory information. A person usually reacts to stimuli that are most meaningful or significant at the time. After continued reception of the same stimulus, a person stops responding, and the sensory experience goes unnoticed. For example, a person concentrating on reading a good book is not aware of background music. This adaptability phenomenon occurs with most sensory stimuli except for those of pain.

The balance between sensory stimuli entering the brain and those actually reaching a person's conscious awareness maintains a person's well-being. If an individual attempts to react to every stimulus within the environment or if the variety and quality of stimuli are insufficient, sensory alterations occur.

Sensory Alterations

The most common types of sensory alterations are sensory deficits, sensory deprivation, and sensory overload. When a patient suffers from more than one sensory alteration, the ability to function and relate effectively within the environment is seriously impaired.

Sensory Deficits. A deficit in the normal function of sensory reception and perception is a **sensory deficit**. When a person loses visual or hearing acuity, he or she withdraws by avoiding communication or socialization with others in an attempt to cope with the sensory loss. It becomes difficult for the person to interact safely with the environment until he or she learns new skills. When a deficit develops gradually or when considerable time has passed since the onset of an acute sensory loss, a person learns to rely on unaffected senses. Some senses may even become more acute to compensate for an alteration. For example, a blind patient develops an acute sense of hearing to compensate for visual loss.

Patients with sensory deficits often change behavior in adaptive or maladaptive ways. For example, a patient with a hearing impairment turns the unaffected ear toward the speaker to hear better, whereas another patient avoids people because he or she is embarrassed about not being able to understand what other people say. Box 49-1 summarizes common sensory deficits and their influence on those affected.

Sensory Deprivation. The reticular activating system in the brainstem mediates all sensory stimuli to the cerebral cortex; thus patients are able to receive stimuli even while sleeping deeply. Sensory stimulation must be of sufficient quality and quantity to maintain a person's awareness. Three types of **sensory deprivation** are reduced sensory input (sensory deficit from visual or hearing loss), the elimination of patterns or meaning from input (e.g., exposure to strange environments), and restrictive environments (e.g., bed rest) that produce monotony and boredom (Touhy and Jett, 2014).

BOX 49-1   Common Sensory Deficits

Visual Deficits

Presbyopia: A gradual decline in the ability of the lens to accommodate or focus on close objects. Individual is unable to see near objects clearly.

Cataract: Cloudy or opaque areas in part of the lens or the entire lens that interfere with passage of light through the lens, causing problems with glare and blurred vision. Cataracts usually develop gradually, without pain, redness, or tearing in the eye.

Dry eyes: Result when tear glands produce too few tears, resulting in itching, burning, or even reduced vision.

Glaucoma: A slowly progressive increase in intraocular pressure that, if left untreated, causes progressive pressure against the optic nerve, resulting in peripheral visual loss, decreased visual acuity with difficulty adapting to darkness, and a halo effect around lights.

Diabetic retinopathy: Pathological changes occur in the blood vessels of the retina, resulting in decreased vision or vision loss caused by hemorrhage and macular edema.

Macular degeneration: Condition in which the macula (specialized part of the retina responsible for central vision) loses its ability to function efficiently. First signs include blurring of reading matter, distortion or loss of central vision, and distortion of vertical lines.

Hearing Deficits

Presbycusis: A common progressive hearing disorder in older adults.

Cerumen accumulation: Buildup of earwax in the external auditory canal. Cerumen becomes hard and collects in the canal and causes conduction deafness.

Balance Deficit

Dizziness and disequilibrium: Common condition in older adulthood, usually resulting from vestibular dysfunction. Frequently a change in position of the head precipitates an episode of vertigo or disequilibrium.

Taste Deficit

Xerostomia: Decrease in salivary production that leads to thicker mucus and a dry mouth. Often interferes with the ability to eat and leads to appetite and nutritional problems.

Neurological Deficits

Peripheral neuropathy: Disorder of the peripheral nervous system, characterized by symptoms that include numbness and tingling of the affected area and stumbling gait.

Stroke: Cerebrovascular accident caused by clot, hemorrhage, or emboli disrupting blood flow to the brain. Creates altered proprioception with marked incoordination and imbalance. Loss of sensation and motor function in extremities controlled by the affected area of the brain also occurs. A stroke affecting the left hemisphere of the brain results in symptoms on the right side such as difficulty with speech. A stroke on the right hemisphere has symptoms on the left side, which includes visual spatial alterations such as loss of half of a visual field or inattention and neglect, especially to the left side.

BOX 49-2   Effects of Sensory Deprivation

Cognitive
- Reduced capacity to learn
- Inability to think or problem solve
- Poor task performance
- Disorientation/confusion
- Bizarre thinking
- Increased need for socialization, altered mechanisms of attention

Affective
- Boredom
- Restlessness
- Increased anxiety
- Emotional lability
- Panic
- Increased need for physical stimulation

Perceptual
- Changes in visual/motor coordination
- Reduced color perception
- Less tactile accuracy
- Changes in ability to perceive size and shape
- Changes in spatial and time judgment

prevents the brain from responding appropriately to or ignoring certain stimuli. Because of the multitude of stimuli leading to overload, a person no longer perceives the environment in a way that makes sense. Overload prevents meaningful response by the brain; the patient's thoughts race, attention scatters in many directions, and anxiety and restlessness occur. As a result, overload causes a state similar to that produced by sensory deprivation. However, in contrast to deprivation, overload is individualized. The amount of stimuli necessary for healthy function varies with each individual. People are often subject to environmental overload more at one time than another. A person's tolerance to sensory overload varies with level of fatigue, attitude, and emotional and physical well-being.

A patient who is acutely ill, especially one in a critical care unit, experiences sensory overload easily. A patient in constant pain or who undergoes frequent monitoring of vital signs is also at risk. Multiple stimuli combine to cause overload even if you offer a comforting word or provide a gentle backrub. Some patients do not benefit from nursing intervention because their attention and energy are focused on more stressful stimuli. In a critical care unit where the activity is constant, the lights are frequently on. Patients can hear sounds from monitoring equipment, staff conversations, equipment alarms, and the activities of people entering the unit.

It is easy to confuse the behavioral changes associated with sensory overload with mood swings or simple disorientation. Look for symptoms such as racing thoughts, scattered attention, restlessness, and anxiety. Patients in intensive care units (ICUs) sometimes constantly play with tubes and dressings. Constant reorientation and control of excessive stimuli become an important part of a patient's care.

NURSING KNOWLEDGE BASE

Factors Influencing Sensory Function

Many factors influence the capacity to receive or perceive stimuli. You manage all of these conditions or situations when delivering patient care.

Age.   Infants and children are at risk for visual and hearing impairment because of a number of genetic, prenatal, and postnatal conditions. A concern with high-risk neonates is that early intense visual and auditory stimulation can adversely affect visual and auditory pathways and alter the developmental course of other sensory organs (Hockenberry and Wilson, 2015). Visual changes during adulthood include presbyopia and the need for glasses for reading. These changes

There are many effects of sensory deprivation (Box 49-2). In adults the symptoms are similar to those of psychological illness, confusion, symptoms of severe electrolyte imbalance, or the influence of psychotropic drugs. Therefore always be aware of a patient's existing sensory function and the quality of stimuli within the environment.

Sensory Overload.   When a person receives multiple sensory stimuli and cannot perceptually disregard or selectively ignore some stimuli, **sensory overload** occurs. Excessive sensory stimulation

usually occur from ages 40 to 50. In addition, the cornea, which assists with light refraction to the retina, becomes flatter and thicker, which often leads to astigmatism. Pigment is lost from the iris; and collagen fibers build up in the anterior chamber, which increases the risk of glaucoma by decreasing the resorption of intraocular fluid. Other normal visual changes associated with aging include reduced visual fields, increased glare sensitivity, impaired night vision, reduced depth perception, and reduced color discrimination.

Hearing changes begin at the age of 30. Changes associated with aging include decreased hearing acuity, speech intelligibility, and pitch discrimination. Low-pitched sounds are easiest to hear, but it is difficult to hear conversation over background noise. It is also difficult to discriminate the consonants *(z, t, f, g)* and high-frequency sounds *(s, sh, ph, k)*. Vowels that have a low pitch are easiest to hear. Speech sounds are distorted, and there is a delayed reception and reaction to speech. A concern with normal age-related sensory changes is that older adults with a deficit are sometimes inappropriately diagnosed with dementia (Touhy and Jett, 2014).

Gustatory and olfactory changes begin around age 50 and include a decrease in the number of taste buds and sensory cells in the nasal lining. Reduced taste discrimination and sensitivity to odors are common.

Proprioceptive changes common after age 60 include increased difficulty with balance, spatial orientation, and coordination. The person cannot avoid obstacles as quickly, and the automatic response to protect and brace oneself when falling is slower. There are also tactile changes, including declining sensitivity to pain, pressure, and temperature secondary to peripheral vascular disease and neuropathies.

Meaningful Stimuli. Meaningful stimuli reduce the incidence of sensory deprivation. In the home meaningful stimuli include pets, music, television, pictures of family members, and a calendar and clock. The same stimuli need to be present in health care settings. Note whether patients have roommates or visitors. The presence of others offers positive stimulation. However, a roommate who constantly watches television, persistently tries to talk, or continuously keeps lights on contributes to sensory overload. The presence or absence of meaningful stimuli influences alertness and the ability to participate in care.

Amount of Stimuli. Excessive stimuli in an environment causes sensory overload. The frequency of observations and procedures performed in an acute health care setting are often stressful. If a patient is in pain or restricted by a cast or traction, overstimulation frequently is a problem. In addition, a room that is near repetitive or loud noises (e.g., an elevator, stairwell, or nurses' station) contributes to sensory overload.

Social Interaction. The amount and quality of social contact with supportive family members and significant others influence sensory function. The absence of visitors during hospitalization or residency in an extended care facility influences the degree of isolation a patient feels. This is a common problem in hospital intensive care settings, where visitation is often restricted. The ability to discuss concerns with loved ones is an important coping mechanism for most people. Therefore the absence of meaningful conversation results in feelings of isolation, loneliness, anxiety, and depression for a patient. Often this is not apparent until behavioral changes occur.

Environmental Factors. A person's occupation places him or her at risk for hearing, visual, and peripheral nerve alterations. Individuals who have occupations involving exposure to high noise levels (e.g.,

factory or airport workers) are at risk for noise-induced hearing loss and need to be screened for hearing impairments. Hazardous noise is common in work settings and recreational activities. Noisy recreational activities that weaken hearing ability include target shooting and hunting, woodworking, and listening to loud music. Individuals who have occupations involving risk of exposure to chemicals or flying objects (e.g., welders) are at risk for eye injuries and need to be screened for visual impairments. Sports activities and consumer fireworks also place individuals at risk for visual alterations. Occupations that involve repetitive wrist or finger movements (e.g., heavy assembly line work, long periods of computer use) cause pressure on the median nerve, resulting in carpal tunnel syndrome. Carpal tunnel syndrome alters tactile sensation and is one of the most common industrial or work-related injuries. Patients at risk for carpal tunnel need to be carefully assessed for numbness, tingling, weakness, and pain.

A patient who is hospitalized is sometimes at risk for sensory alterations as a result of exposure to environmental stimuli or a change in sensory input. Patients who are immobilized by bed rest or who have a chronic disability are unable to experience all of the normal sensations of free movement. Another group at risk includes patients isolated in a health care setting or at home because of conditions such as active tuberculosis (see Chapter 29). These patients stay in private rooms and are often unable to enjoy normal interactions with visitors.

Cultural Factors. Certain sensory alterations occur more commonly in select cultural groups. Analysis of data from the National Health and Nutrition Examination Survey (NHANES) and the National Health Interview Survey (NHIS) showed that non-Hispanic whites had a higher prevalence of age-related macular degeneration than non-Hispanic African-Americans but a lower prevalence of diabetic retinopathy and glaucoma (Zhang et al., 2012). Cultural disparities in vision impairment are significant, in part because vision loss has a significant impact on activities of daily living, symptoms of depression, and feelings of anxiety (Box 49-3) (Kempen et al., 2012). Changes in hearing and visual acuity also impact a person's health literacy and his or her ability to understand medications, procedures, and restorative and home care interventions, which are further complicated when English is a second language.

CRITICAL THINKING

Successful critical thinking requires a synthesis of knowledge and information gathered from patients, experience, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require you to anticipate the information necessary, analyze the data, and make decisions regarding patient care. Patients' conditions are always changing. During assessment (Figure 49-1) consider all critical thinking elements that help you make appropriate nursing diagnoses. In the case of sensory alterations, integrate knowledge of the pathophysiology of sensory deficits, factors that affect sensory function, and therapeutic communication principles. This knowledge enables you to conduct appropriate assessments, anticipate what to recognize when a patient describes a sensory problem, and make judgments of abnormalities. For example, knowing the typical symptoms caused by a cataract helps you recognize the pattern of visual changes that a patient with cataracts reports.

Previous experiences in caring for patients with sensory deficits help you recognize limitations in a patient's functioning and how these limitations affect the ability to carry out daily activities. For example, after caring for one patient with a hearing impairment, you are able to conduct a more effective assessment of the next patient by using

⊕ BOX 49-3   CULTURAL ASPECTS OF CARE

Disparities in Eye Care Practices

The early diagnosis and treatment of visual impairments in people from other cultures could improve their quality of life (Wang et al., 2014). However, some individuals, especially older adults, do not always volunteer information about impairments or seek professional advice because of cultural reasons or language difficulties (Higginbottom et al., 2014). A lack of awareness of existing services also contributes to disparities in using eye care resources. Findings from the Behavioral Risk Factor Surveillance System data revealed state-level disparities in eye care use by culture, annual income, and education level (Chou et al., 2012). In some states Hispanics and non-Hispanic African-Americans were less likely to have visited an eye doctor in the previous year than non-Hispanic whites. In nearly all states a lack of awareness regarding vision health was greater among people at lower income and education levels (Chou et al., 2012).

Implications for Patient-Centered Care
- Encourage patients to discuss changes in visual acuity or other eye or vision issues by asking a few focused questions.
- Enhance your knowledge of the eye care services available to patients.
- Facilitate access to services to promote the early detection and treatment of visual impairments.
- When English is a second language, identify the patient's preferred method of communication; use an interpreter service if needed.
- Ensure that written eye care information is available in the appropriate language and format (e.g., large print).

Knowledge
- Pathophysiology of specific sensory deficit
- Factors that potentially may alter sensory function
- Effects of sensory deprivation/overload
- Communication principles used to interact with patients having sensory deficits

Experience
- Caring for patients with sudden and long-term sensory alterations
- Personal experience with temporary or permanent sensory deficit

ASSESSMENT
- Patient's health promotion practices
- Nursing history regarding extent of risks for and existing sensory deficits
- Review of factors that affect the patient's sensory function
- Extent of lifestyle and self-care alterations
- Patient's expectations regarding sensory alterations

Standards
- Apply intellectual standards of clarity, precision, accuracy, and depth when assessing the patient's sensory function
- Standards of care from:
  - American Academy of Ophthalmology
  - American Speech-Language-Hearing Association

Attitudes
- Show confidence in your ability to provide a safe level of care
- Use curiosity to clarify and explore the nature of signs and symptoms to rule out causes other than sensory change

FIGURE 49-1 Critical thinking model for sensory alterations assessment.

previously successful approaches that promote the patient's ability to hear your questions.

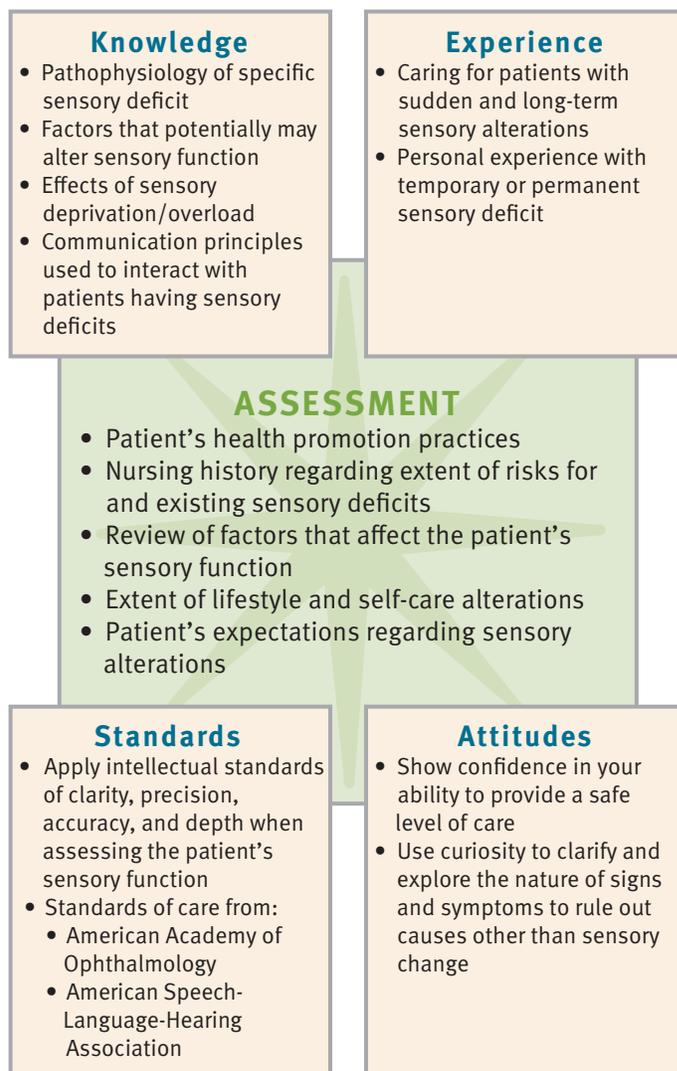
When critical thinking attitudes and standards are applied during assessment, they ensure a thorough and accurate database from which to make decisions. For example, perseverance is necessary to learn details about how visual changes influence a patient's ability to socialize. Evidence-based standards of care and practice such as those from the American Academy of Ophthalmology and the American Speech-Language-Hearing Association provide criteria for screening sensory problems and establishing standards for competent, safe, effective care and practice. Use critical thinking to conduct a thorough assessment and then plan, implement, and evaluate care that enables a patient to function safely and effectively (Box 49-4).

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care for your patients.

◆ Assessment

During the assessment process, thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care.

Through the Patient's Eyes. When conducting an assessment, value the patient as a full partner in planning, implementing, and evaluating care. Patients are often hesitant to admit sensory losses. Therefore start gathering information by establishing a therapeutic rapport with the patient. Elicit his or her values, preferences, and expectations with regard to his or her sensory impairment. Many patients have a definite plan as to how they want their care delivered.


Some patients expect caregivers to recognize and appropriately manage and adjust their environment to meet their sensory needs. This includes helping the family and patient learn and adapt to a changed lifestyle on the basis of the specific sensory impairment. Determine from the patient which interventions were helpful in the past in the management of limitations. Assess the patient's expertise with his or her own health and symptoms. Always remember that patients with sensory alterations have strengthened their other senses and expect caregivers to anticipate their needs (e.g., for safety and security).

When assessing a patient with or at risk for sensory alteration, first consider the pathophysiology of existing deficits and the factors influencing sensory function to anticipate how to approach his or her assessment. For example, if a patient has a hearing disorder, adjust your communication style and focus the assessment on relevant criteria related to hearing deficits. Collect a history that also assesses the patient's current sensory status and the degree to which a sensory deficit affects the patient's lifestyle, psychosocial adjustment, developmental status, self-care ability, health promotion habits, and safety. Also focus the assessment on the quality and quantity of stimuli within the patient's environment.

People at Risk. Older adults are a high-risk group because of normal physiological changes involving sensory organs. However, be

BOX 49-4 EVIDENCE-BASED PRACTICE

Visual Impairment and Quality of Life

PICO Question: Are older adults who have an age-related eye disease at an increased risk for a lower health-related quality of life?

Evidence Summary

According to the National Health Interview Survey, only 11.2% of people with visual impairment used assistive and adaptive devices in 2008. The survey also found that vision rehabilitation services were underused among adults who are blind or have low vision (USDHHS, 2015b). These findings are significant since targeted treatments for low vision could help improve patients' quality of life. Research shows that older adults with visual impairments are more likely than those without visual impairment to have poorer levels of functioning in activities of daily (Kempen et al., 2012). Recent studies have also found that visual impairment is associated with higher levels of depression and feelings of anxiety (Kempen et al., 2012), particularly among individuals with low coping skills (Stone et al., 2012)

Application to Nursing Practice

- Inform patients of vision rehabilitation services available in the community.
- Give patients as much time as needed to discuss the personal impact of low vision (Kempen et al., 2012).
- Encourage patients to access support from others with visual impairments.
- Actively listen and provide opportunity for questions.
- Identify positive and negative coping mechanisms (Stone et al., 2012).
- Teach patients adaptive daily living skills.

BOX 49-5 Nursing Assessment Questions

Nature of the Problem
- Which type of problem are you having with your vision/hearing?
- What have you tried to correct the vision/hearing difficulty?
- Do you use any devices to improve your vision/hearing?
- How effective are your glasses or hearing aids?

Signs and Symptoms
- Ask a patient with visual alterations: Do you require books with large print or on audiotape? Are you able to prepare a meal or write a check? Do you notice any eye irritation or drainage?
- Ask a patient with hearing alterations: Which types of sounds or tones do you have difficulty hearing? Do people tell you that they have to "shout" for you to hear them? Do people ask you not to talk so loud? Do you have a ringing, crackling, or buzzing in your ears? Is there pain: sharp, dull, burning, itching? Have you noticed any redness, swelling, or drainage? Any signs of infection?

Onset and Duration
- When did you notice the problem? How long has it lasted?
- Does it come and go, or is it constant?
- What makes the problem better or worse?

Predisposing Factors
- Do you work or participate in any activities that have the potential for vision/hearing injury? If so, how do you protect your hearing and vision?
- Do you have a family history of cataracts, glaucoma, macular degeneration, or hearing loss?
- When was your last vision/hearing examination?

Effect on Patient
- What effect has your vision/hearing problem had on your work, family, or social life?
- Have changes in your vision/hearing affected your feelings of independence?
- How does your vision/hearing problem make you feel about yourself?
- Do you have problems with routine care of glasses, contact lenses, or hearing aids?

careful not to automatically assume that a patient's sensory problem is related to advancing age. For example, adult sensorineural hearing loss is often caused by exposure to excess and prolonged noise or metabolic, vascular, and other systemic alterations. Some patients benefit from a referral to an audiologist or **otolaryngologist** when serious hearing problems are identified during assessment.

Other individuals at risk for sensory alterations include those living in a confined environment such as a nursing home. Although most quality nursing homes or centers offer meaningful stimulation through group activities, environmental design, and mealtime gatherings, there are exceptions. An individual who is confined to a wheelchair, suffers from poor hearing and/or vision, has decreased energy, and avoids contact with others is at significant risk for sensory deprivation.

Patients who are acutely ill are also at risk because of an unfamiliar and unresponsive environment. This does not mean that all hospitalized patients have sensory alterations. However, you need to carefully assess patients subjected to continued sensory stimulation (e.g., ICU settings, long-term hospitalization, or multiple therapies). Assess a patient's environment within both the health care setting and the home, looking for factors that pose risks or need adjustment to provide safety and more appropriate sensory stimulation.

Sensory Alterations History. The nursing history includes assessment of the nature and characteristics of sensory alterations or any problem related to an alteration (Box 49-5). When taking the history, consider the ethnic or cultural background of the patient because certain alterations are higher in some cultural groups.

During the history it is useful to have a patient self-rate his or her sensory deficit by asking, "Rate your hearing as excellent, good, fair, poor, or bad." Then, on the basis of the patient's self-rating, explore his or her perception of a sensory loss more fully. This provides an in-depth

look at how the sensory loss influences the patient's quality of life. In the case of hearing problems, a screening tool such as the Hearing Handicap Inventory for the Elderly (HHIE-S) effectively identifies patients needing audiological intervention (Tomioka et al., 2013). The HHIE-S is a 5-minute, 10-item questionnaire that assesses how the individual perceives the social and emotional effects of hearing loss. The higher the HHIE-S score, the greater the handicapping effect of a hearing impairment.

A nursing history also reveals any recent changes in a patient's behavior. Frequently friends or family are the best resources for this information. Ask the family the following questions:
- Has your family member shown any recent mood swings (e.g., outbursts of anger, nervousness, fear, or irritability)?
- Have you noticed the family member avoiding social activities?

Mental Status. Assessment of mental status is valuable when you suspect sensory deprivation or overload. Observation of a patient during history taking, during the physical examination (see Chapter 31), and while providing nursing care offers valuable data about a patient's behaviors and mental status. Observe the patient's physical appearance and behavior, measure cognitive ability, and assess his or her emotional status. The Mini-Mental State Examination (MMSE) is

TABLE 49-2 Assessment of Sensory Function

Assessment Activities	Behavior Indicating Deficit (Children)	Behavior Indicating Deficit (Adults)
Vision Ask patient to read newspaper, magazine, or lettering on menu. Ask patient to identify colors on color chart or crayons. Observe patients performing ADLs.	Self-stimulation, including eye rubbing, body rocking, sniffing or smelling, arm twirling; hitching (using legs to propel while in sitting position) instead of crawling	Poor coordination, squinting, underreaching or overreaching for objects, persistent repositioning of objects, impaired night vision, accidental falls
Hearing Assess patient's hearing acuity (see Chapter 31) using spoken word and tuning fork tests. Assess for history of tinnitus. Observe patient conversing with others. Inspect ear canal for hardened cerumen. Observe patient behaviors in a group.	Frightened when unfamiliar people approach, no reflex or purposeful response to sounds, failure to be awakened by loud noise, slow or absent development of speech, greater response to movement than to sound, avoidance of social interaction with other children	Blank looks, decreased attention span, lack of reaction to loud noises, increased volume of speech, positioning of head toward sound, smiling and nodding of head in approval when someone speaks, use of other means of communication such as lip-reading or writing, complaints of ringing in ears
Touch Check patient's ability to discriminate between sharp and dull stimuli. Assess whether patient is able to distinguish objects (coin or safety pin) in the hand with eyes closed. Ask whether patient feels unusual sensations.	Inability to perform developmental tasks related to grasping objects or drawing, repeated injury from handling of harmful objects (e.g., hot stove, sharp knife)	Clumsiness, overreaction or underreaction to painful stimulus, failure to respond when touched, avoidance of touch, sensation of pins and needles, numbness Unable to identify object placed in hand
Smell Have patient close eyes and identify several nonirritating odors (e.g., coffee, vanilla).	Difficult to assess until child is 6 or 7 years old, difficulty discriminating noxious odors	Failure to react to noxious or strong odor, increased body odor, decreased sensitivity to odors
Taste Ask patient to sample and distinguish different tastes (e.g., lemon, sugar, salt). (Have patient drink or sip water and wait 1 minute between each taste.)	Inability to tell whether food is salty or sweet, possible ingestion of strange-tasting things	Change in appetite, excessive use of seasoning and sugar, complaints about taste of food, weight change

ADLs, Activities of daily living.

a tool you can use to measure disorientation, change in problem-solving abilities, and altered conceptualization and abstract thinking (see Chapter 31). For example, a patient with severe sensory deprivation is not always able to carry on a conversation, remain attentive, or display recent or past memory. An important step toward preventing cognition-related disability is education by nurses about disease process, available services, and assistive devices.

Physical Assessment. To identify sensory deficits and their severity, use physical assessment techniques to assess vision; hearing; olfaction; taste; and the ability to discriminate light touch, temperature, pain, and position (see Chapter 31). Table 49-2 summarizes specific assessment techniques for identifying sensory deficits. You gather more accurate data when the examination room is private, quiet, and comfortable for the patient. In addition, rely on personal observation to detect sensory alterations. Patients with a hearing impairment may seem inattentive to others, respond with inappropriate anger when spoken to, believe people are talking about them, answer questions inappropriately, have trouble following clear directions, and have monotonous voice quality and speak unusually loud or soft.

Ability to Perform Self-Care. Assess patients' functional abilities in their home environment or health care setting, including the ability to perform feeding, dressing, grooming, and toileting activities. For example, assess whether a patient with altered vision is able to find

items on a meal tray and read directions on a prescription. Also determine a patient's ability to perform instrumental activities of daily living (IADLs) such as reading bills and writing checks, differentiating money denominations, and driving a vehicle at night. If a patient seems to have a sensory deficit, does he or she show concern for grooming? Does a patient's loss of balance prevent rising from a toilet seat safely? Can a patient recovering from a stroke manipulate buttons or zippers for dressing? If a sensory alteration impairs a patient's functional ability, providing resources within the home is a necessary part of discharge planning. Your findings may indicate the need for an occupational therapy consultation.

Health Promotion Habits. Assess the daily routines that patients follow to maintain sensory function. Which type of eye and ear care is a part of a patient's daily hygiene? For individuals who participate in sports (e.g., racquetball) or recreational activities (e.g., motorcycle riding) or who work in a setting in which ear or eye injury is a possibility (e.g., chemical exposure, welding, glass or stone polishing, or constant exposure to loud noise), determine if they wear safety glasses or hearing-protective devices (HPDs). Do patients who use assistive devices such as eyeglasses, contact lenses, or hearing aids know how to provide daily care (see Chapter 40)? Do patients use the devices, and are they in proper working order?

It is also important to assess a patient's adherence with routine health screening. When was the last time the patient had an eye

examination or hearing evaluation? For adults routine screening of visual and hearing function is imperative to detect problems early. This is especially true in the case of glaucoma, which, if undetected, leads to permanent visual loss. Recommended screening guidelines usually occur on the basis of age. When a patient begins to show a hearing deficit, incorporate routine screening in regular examinations.

Environmental Hazards. Patients with sensory alterations are at risk for injury if their living environments are unsafe. For example, a patient with reduced vision cannot see potential hazards clearly. A patient with proprioceptive problems loses balance easily. A patient with reduced sensation cannot perceive hot-versus-cold temperatures. The condition of the home, the rooms, and the front and back entrances is often problematic to the patient with sensory alterations. Assess his or her home for common hazards, including the following:

- Uneven, cracked walkways leading to front/back door
- Extension and phone cords in the main route of walking traffic
- Loose area rugs and runners placed over carpeting
- Bathrooms without shower or tub grab bars
- Water faucets unmarked to designate hot and cold
- Unlit stairways, lack of handrails
- Poor lighting in stairways, halls, and entrance doors

In the hospital environment caregivers often forget to rearrange furniture and equipment to keep pathways from the bed and chair to the bathroom and entrance clear. It is helpful to walk into a patient's room and look for safety hazards:

- Is the call light within easy, safe reach?
- Are intravenous (IV) poles on wheels and easy to move?
- Are suction machines, IV pumps, or drainage bags positioned so a patient can rise from a bed or chair easily?
- Are bedside tables and areas clutter free?

An additional problem faced by patients who are visually impaired is the inability to read medication labels and syringe markings. Ask the patient to read a label to determine if he or she is able to read the dosage and frequency. If a patient has a hearing impairment, check to see whether the sounds of a doorbell, telephone, smoke alarm, and alarm clock are easy to discriminate.

Communication Methods. To understand the nature of a communication problem, you need to know whether a patient has trouble speaking, understanding, naming, reading, or writing. Patients with existing sensory deficits often develop alternate ways of communicating. To interact with a patient and promote interaction with others, understand his or her method of communication (Figure 49-2). Vision becomes almost a primary sense for people with hearing impairments. As a result, face-to-face communication is essential.

Patients with visual impairments are unable to observe facial expressions and other nonverbal behaviors to clarify the content of spoken communication. Instead they rely on voice tones and inflections to detect the emotional tone of communication. Some patients with visual deficits learn to read Braille. Patients with **aphasia** have varied degrees of inability to speak, interpret, or understand language. **Expressive aphasia,** a motor type of aphasia, is the inability to name common objects or express simple ideas in words or writing. For example, a patient understands a question but is unable to express an answer. Sensory or **receptive aphasia** is the inability to understand written or spoken language. A patient is able to express words but is unable to understand questions or comments of others. Global aphasia is the inability to understand language or communicate orally.

The temporary or permanent loss of the ability to speak is extremely traumatic to an individual. Assess for alternate communication methods and whether they cause anxiety. Patients who have undergone

FIGURE 49-2 Nurse sits at eye level so patient with hearing impairment can communicate.

laryngectomies often write notes, use communication boards or laptop computers, speak with mechanical vibrators, or use esophageal speech. Patients with endotracheal or tracheostomy tubes have a temporary loss of speech. Most use a notepad to write their questions and requests. However, some patients become incapacitated and unable to write messages. Determine whether the patient has developed a sign-language system or symbols to communicate needs.

Social Support. Determine if a patient lives alone and whether family or friends visit frequently. Assess the patient's social skills and level of satisfaction with the support given by family and friends. Is the patient satisfied with the support available? Is he or she able to solve problems with family members? Is there a family caregiver who offers support when the patient requires assistance as a result of a sensory loss? The long-term effects of sensory alterations influence family dynamics and a patient's willingness to remain active in society.

Use of Assistive Devices. Assess the use of assistive devices (e.g., use of a hearing aid or glasses). Assess if the patient thinks that these devices are beneficial. This includes learning how often the patient uses the devices daily, the patient's or family caregiver's method of caring for and cleaning the devices, and the patient's knowledge of what to do when a problem develops. When you identify that a patient has an assistive device, remember that, just because the individual has the device, it does not mean that it works or that the patient uses it or benefits from it.

Other Factors Affecting Perception. Factors other than sensory deprivation or overload cause impaired perception (e.g., medications or pain). Assess the patient's medication history, which includes prescribed and over-the-counter medications and herbal products. Also gather information regarding the frequency, dose, method of administration, and last time these medications were taken. Some antibiotics (e.g., streptomycin, gentamicin, and tobramycin) are **ototoxic** and permanently damage the auditory nerve, whereas chloramphenicol sometimes irritates the optic nerve. Opioid analgesics, sedatives, and antidepressant medications often alter the perception of stimuli. Conduct a thorough pain assessment (see Chapter 44) when you suspect that pain is causing perceptual problems.

◆ Nursing Diagnosis

After assessment review all available data and look critically for patterns and trends suggestive of a health problem relating to sensory alterations (e.g., visual problems [Box 49-6]). Validate findings to

ensure accuracy of the diagnosis. Determine the factor that likely causes a patient's health problem. The etiology or related factor of a nursing diagnosis is a condition that nursing interventions can affect. The etiology needs to be accurate; otherwise nursing therapies are ineffective.

Some patients have health care problems for which sensory alteration is the etiology such as with the diagnosis of *Risk for Injury.* You select nursing diagnoses by recognizing the way that sensory alterations affect a patient's ability to function (e.g., *Self-Care Deficit*). In addition, most patients present themselves to health care professionals with multiple diagnoses (Figure 49-3). In the concept map example, a patient with a cataract has the nursing diagnoses of *Risk for Injury, Anxiety, Fear,* and *Risk for Falls.* The sensory alteration caused by the cataract is an etiology for both risk for injury and risk for falls. Furthermore, fear occurs as a response to a perceived risk of falling. You need to recognize patterns of data that reveal health problems created by a patient's sensory alteration. Examples of nursing diagnoses that apply to patients with sensory alterations include the following:
- Risk-Prone Health Behavior
- Impaired Verbal Communication
- Risk for Injury
- Impaired Physical Mobility
- Bathing Self-Care Deficit
- Situational Low Self-Esteem
- Risk for Falls
- Social Isolation

BOX 49-6 Nursing Diagnostic Process

Risk for Injury

Assessment Activities	Defining Characteristics
Assess patient's visual acuity.	Has reduced ability to see objects clearly; needs brighter light to read; has trouble distinguishing edges of stairs
Visit home setting and inspect for hazards that pose risks to patient.	Lighting in rooms, hallways, and stairwells very dim; carpet in living room old, edges curled up; steps leading up to front entrance of home
Review medical record from clinic visit.	Bilateral cataracts

CONCEPT MAP

Nursing diagnosis: Risk for injury
- Blurred vision
- Difficulty reading
- Cataract in left eye

Interventions
- Teach methods to improve environmental safety (e.g., removing throw rugs)
- Encourage use of magnifying glass when reading
- Encourage Ms. Long to make appointment with ophthalmologist in next month
- Install brighter light bulbs

Nursing diagnosis: Risk for falls
- Cluttered home environment
- Dimly lit room
- Age over 65 years

Interventions
- Assess home for slip hazards
- Provide Ms. Long with an electronic device to summon help if she falls or injures herself
- Remove fall hazards from environment (e.g., throw rugs, frayed carpet)

Primary health problem: Cataracts in left eye that have not been surgically corrected
Priority assessments: Visual acuity, ability to perform ADLs, safety of home environment

Nursing diagnosis: Fear
- States, "I am afraid to go down my stairs at home"
- Verbalizing fear about what will happen if loses vision because of cataracts

Interventions
- Explore ways Ms. Long coped with fear in previous situations
- Provide consistency in caregivers
- Teach muscle-strengthening and balance exercises to reduce fear of falling

Nursing diagnosis: Anxiety
- Makes poor eye contact during conversations
- States is having difficulty concentrating

Interventions
- Assess for depression and suicidal ideation
- Teach Ms. Long methods to self-manage anxiety
- Teach son ways to provide support to mother

——— Link between medical diagnosis and nursing diagnosis   - - - - - Link between nursing diagnoses

FIGURE 49-3 Concept map for Ms. Long.

◆ Planning

During planning synthesize information from multiple resources (Figure 49-4). Reflect on knowledge gained from the assessment and knowledge of how sensory deficits affect normal functioning. In this way you are able to recognize the extent of a patient's deficit and know the type of interventions most likely to be helpful. Also consider the role that health professionals play in planning care and the available community resources that will be useful. Previous experience in caring for patients with sensory alterations is invaluable.

When applying critical thinking to planning care, professional standards are particularly useful. These standards recommend evidence-based interventions for the patient's condition. For example, patients who have visual deficits and are hospitalized are often placed on a fall-prevention protocol that incorporates research-based precautions to ensure patient safety.

Goals and Outcomes. During planning develop an individualized plan of care for each nursing diagnosis (see the Nursing Care Plan). Partner with your patient to develop a realistic plan that incorporates what you know about his or her sensory problems and the extent to which he or she can maintain or improve sensory function. Goals and outcomes need to be realistic and measurable. An example of a goal of care for a patient with an actual or potential sensory alteration is, "The patient will achieve improvement in hearing acuity within 2 weeks." Associated outcomes for this goal include the following:

- The patient and family report using communication techniques to send and receive messages within 2 days.
- The patient successfully demonstrates correct technique for cleaning a hearing aid within 1 week.
- The patient self-reports improved hearing acuity.

Setting Priorities. You consider the type and extent of sensory alteration affecting a patient when determining priorities of care. For example, a patient who enters the emergency department after experiencing eye trauma has priorities of reducing anxiety and preventing further injury to the eye. In contrast, a patient who is being discharged from an outpatient surgery department following cataract removal has the priority of learning about self-care restrictions. Safety is always a top priority. The patient also helps prioritize aspects of care. A patient wishes to learn ways to communicate more effectively or participate in favorite hobbies given his or her limitation.

Some sensory alterations are short term (e.g., a patient experiencing sensory overload in an ICU). Thus appropriate interventions are likely to be temporary (e.g., frequent reorientation or introduction of pleasant stimuli such as a backrub). Some sensory alterations such as permanent visual loss require long-term goals of care for patients to adapt. Patients who have sensory alterations at the time of entering a health care setting are usually most informed about how to adapt interventions to their lifestyles. For example, allow patients who are blind to control whichever parts of their care they can. Sometimes it becomes necessary for a patient to make major changes in self-care activities, communication, and socialization to ensure safe and effective nursing care.

> **QSEN** **QSEN: BUILDING COMPETENCY IN SAFETY** Ms. Long's church asks you to do a presentation on fall prevention to older adult members of the congregation. Many members also have impaired vision. How will you develop a program to educate this elderly population and communicate observations or concerns related to fall hazards to them?
>
> ⓔ *Answers to QSEN Activities can be found on the Evolve website.*

Knowledge
- Understanding of how a sensory deficit can affect the patient's functional status
- Knowledge of therapies that promote or restore sensory function
- Role other health professionals might provide for sensory function management
- Services of community resources
- Adult learning principles to apply when educating the patient and family

Experience
- Previous patient responses to planned nursing interventions to promote sensory function

PLANNING
- Select strategies to assist the patient in remaining functional in the home
- Adapt therapies depending on whether sensory deficit is short or long term
- Involve the family in helping the patient adjust to limitations
- Refer to appropriate health care professional and/or community agency

Standards
- Individualize therapies that allow the patient to adapt to sensory loss in any setting
- Apply standards of safety

Attitudes
- Use creativity to find interventions that help the patient adapt to the home environment

FIGURE 49-4 Critical thinking model for sensory alterations planning.

Teamwork and Collaboration. When developing a plan of care, consider all resources available to patients. The family plays a key role in providing meaningful stimulation and learning ways to help the patient adjust to any limitations. Engaging the family or designated surrogate is a fundamental skill of patient-centered care (Institute for Patient- and Family-Centered Care, 2015). You also frequently refer patients to other health care professionals. For example, if a patient has a major loss of sensory function and is also unable to manage medical needs such as medication self-administration or dressing changes, referral to home care is an option. Valuing interprofessional collaboration is an essential nurse competency that results in better patient health outcomes and greater patient and family satisfaction (Interprofessional Education Collaborative Expert Panel, 2011). Numerous community-based resources (e.g., local chapter of the Society for the Blind and Visually Impaired and the Area Agency on

◎ NURSING CARE PLAN

Risk for Injury

ASSESSMENT

Ms. Judy Long is a 70-year-old retired widow who resides in a ranch-style home with her son. The family and craft room is located in a walkout basement area. She tells the community health nurse that she is having increased difficulty with night driving and blurry vision. She enjoys reading and sewing; however, her reduced vision limits her ability to participate in these activities. Ms. Long reports that her vision is blurred even with glasses and she is afraid that she will fall. She visited an ophthalmologist 1 year ago but didn't follow up with the recommended treatment.

Assessment Activities	*Findings/Defining Characteristics**
Ask Ms. Long to describe her vision changes.	Ms. Long states, "My left eye seems to have a film over it that makes my **vision blurred.** I am having **difficulty reading.** I also have **difficulty with night driving."**
Ask Ms. Long to describe life changes that have occurred since the change in vision.	Ms. Long states, "I've lost my independence because I can no longer drive at night. **I'm afraid to use the stairs at home because I can't judge steps clearly**."
Assess Ms. Long's visual acuity.	Ms. Long states she can't read the Snellen chart with her left eye.
Ask Ms. Long the results of the visit to the ophthalmologist.	Ms. Long states, "I was told I had a **cataract of the left eye,** and surgery was recommended."
Conduct a home hazard assessment.	There is **clutter in the home, dim lighting,** and stairs with **poor lighting and a broken handrail.**

****Defining characteristics** are shown in bold type.

NURSING DIAGNOSIS: Risk for injury

PLANNING

Goal	*Expected Outcomes (NOC)†*
	Safe Home Environment
Ms. Long will maintain independence in a safe home environment.	Ms. Long and her son make recommended changes in lighting, handrail, and clutter in the home environment within 4 weeks.
	Ms. Long reports an increased sense of home safety and independence within 4 weeks.

†Outcome classification labels from Moorhead S et al: *Nursing outcomes classification (NOC),* ed 5, St Louis, 2013, Mosby.

INTERVENTIONS (NIC)‡

Environmental Management

INTERVENTIONS	RATIONALE
Teach Ms. Long and her son methods to improve environmental safety such as installing handrails along stairs, securing carpeting, removing throw rugs, and painting stairs.	Home environmental and health-related factors place a patient at risk for falls. Environmental safety modifications reduce the risk of falls and injury (Lim and Sung, 2012).
Teach Ms. Long to use a light over the shoulder for reading and sewing.	Adequate lighting with an adjustable lamp helps reduce eye strain and increase enjoyment (Perlmutter et al., 2013).
Explain use of a pocket magnifier and offer list of locations where Ms. Long can purchase one.	Magnifier enlarges visual images when reading or doing close work (Touhy and Jett, 2014).
Have Ms. Long make appointment with ophthalmologist within the next 4 weeks.	Older adults need a routine eye examination annually or as recommended (Touhy and Jett, 2014).
Emotional Support	
Encourage Ms. Long to discuss with family and friends how a loss of vision affects her independence and lifestyle.	Visual impairment may lead to depression, social isolation, and some functional disabilities, which can have adverse effects on a person's quality of life (Higginbottom et al., 2014).

‡Intervention classification labels from Bulechek GM et al: *Nursing interventions classification (NIC),* ed 6, St Louis, 2013, Mosby.

EVALUATION

Nursing Actions	*Patient Response/Finding*	*Achievement of Outcome*
Ask Ms. Long to describe the changes made in the home to reduce environmental hazards.	Ms. Long responds that she removed the clutter and placed handrails at the entryway. She also placed lighting behind her chair, and there are 100-watt lights in the living room. She has a specific craft light that provides additional "over-the-shoulder" lighting.	Ms. Long reports feeling safer walking the stairs and moving about in her home. She reduced the home hazards. She is now able to enjoy her craft activities.
Ask Ms. Long to read a medication label using her magnifier.	Ms. Long is able to read name of medication and dosage correctly.	Visual acuity has not been further compromised.
Ask Ms. Long if she is able to maintain a degree of independence with the environmental and lifestyle modifications.	Ms. Long states, "I'm more independent at home, and until surgery I don't mind having someone drive for me."	Ms. Long has attained some degree of independence.

Aging) are also available. Try to arrange for a volunteer to visit a patient or have printed materials made available that describe ways to cope with sensory problems.

◆ **Implementation**

Nursing interventions involve a patient and family so the patient is able to maintain a safe, pleasant, and stimulating sensory environment. The most effective interventions enable a patient with sensory alterations to function safely with existing deficits and continue a normal lifestyle. Patients can learn to adjust to sensory impairments at any age with the proper support and resources. Use measures to maintain a patient's sensory function at the highest level possible.

Health Promotion.   Good sensory function begins with prevention. When a patient seeks health care, provide education about interventions that reduce the risk for sensory losses. Also recommend relevant visual and hearing guidelines. Remember to assess a patient's capacity to process and understand the health information to ensure that the patient makes appropriate decisions regarding his or her health.

Screening.   An estimated 285 million people in the world are visually impaired (WHO, 2010). Preventable blindness is a worldwide health issue that begins with children and requires appropriate screening. Four recommended interventions are: (1) screening for rubella, syphilis, chlamydia, and gonorrhea in women who are considering pregnancy; (2) advocating adequate prenatal care to prevent premature birth (with the danger of exposure of the infant to excessive oxygen); (3) administering eye prophylaxis in the form of erythromycin ointment approximately 1 hour after an infant's birth; and (4) periodic screening of all children, especially newborns through preschoolers, for congenital blindness and visual impairment caused by refractive errors and **strabismus** (Hockenberry and Wilson, 2015).

Visual impairments are common during childhood. The most common visual problem is a **refractive error** such as nearsightedness. The nurse's role is one of detection, education, and referral. Parents need to know the signs of visual impairment (e.g., failure to react to light and reduced eye contact from the infant). Instruct parents to report these signs to their health care provider immediately. Vision screening of school-age children and adolescents helps detect problems early (USDHHS, 2015b). School nurses are usually responsible for vision testing.

In the United States glaucoma is the second leading cause of blindness in the general population and the primary cause of blindness in African-Americans. If left undetected and untreated, it leads to permanent visual loss. The American Optometric Association (2014) recommends a regular medical eye examination annually for those over 60 years old. Screening every 1 or 2 years is also recommended for individuals between 18 and 60 years of age who are at risk for developing eye and vision problems. Individuals at risk include the following: those with diabetes, hypertension, or a family history of ocular disease; working in occupations that are highly demanding visually or eye hazardous; taking prescription or nonprescription drugs with ocular side effects; or wearing contact lenses. Individuals who have had eye surgery or who have other health concerns or conditions are also at risk for the development of vision problems.

Hearing impairment is one of the most common disabilities in the United States. The prevalence of hearing loss is nearly 50% in those older than 75 years of age (NIDCD, 2014). Deafness or hearing impairment affects not only older adults but also children. Children at risk include those with a family history of childhood hearing impairment, perinatal infection (rubella, herpes, or cytomegalovirus), low birth weight, chronic ear infection, and Down syndrome. Advise pregnant women of the importance of early prenatal care, avoidance of ototoxic drugs, and testing for syphilis or rubella.

Children with chronic middle ear infections, a common cause of impaired hearing, need to receive periodic auditory testing. Warn parents of the risks and to seek medical care when a child has symptoms of earache or respiratory infection.

Because aging is associated with degenerative changes in the ear, patients need to have hearing screenings at least every decade through age 50 and every 3 years thereafter (American Speech-Language-Hearing Association, 2014). Once a patient reports a hearing loss, regular testing also becomes necessary. In addition, a patient who works or lives in a high–noise level environment requires annual screening. Occupational health nurses play a key role in the assessment of the auditory system and the initiation of prompt referrals. The early identification and treatment of problems help older adults be more active and healthy.

Preventive Measures.   Trauma is a common cause of blindness in children. Penetrating injury from propulsive objects such as firecrackers or slingshots or from penetrating wounds from sticks, scissors, or toy weapons are just a few examples. Parents and children require counseling on ways to avoid eye trauma such as avoiding use of toys with long, pointed projections and instructing children not to walk or run while carrying pointed objects. Instruct patients that they can find safety equipment in most sports shops and large department stores.

Adults are at risk for eye injury while playing sports and working in jobs involving exposure to chemicals or flying objects. The Occupational Safety and Health Administration (OSHA, n.d.) has guidelines for workplace safety. Employers are required to have eyewash stations and to have employees wear eye goggles and/or use equipment such as HPDs to reduce the risk of injury. *Healthy People 2020* (USDHHS, 2015a) identifies goals that include reducing new cases of work-related, noise-induced hearing loss. Occupational health nurses reinforce the use of protective devices. In addition, nurses need to routinely assess patients for noise exposure and participate in providing hearing conservation classes for teachers, students, and patients.

Another means of prevention involves regular immunization of children against diseases capable of causing hearing loss (e.g., rubella, mumps, and measles). Nurses who work in health care providers' offices, schools, and community clinics instruct patients about the importance of early and timely immunization. Use caution when administering ototoxic drugs in all populations.

Use of Assistive Devices.   Patients who wear corrective contact lenses, eyeglasses, or hearing aids need to make sure that they are clean, accessible, and functional (see Chapter 40). It is helpful to have a family member or friend who also knows how to care for and clean an assistive aid. A contact lens wearer must clean lenses frequently (see Chapter 40) and use the appropriate solutions for cleaning and disinfection. Contact lens wearers are subject to serious eye infections caused by infrequent lens disinfection, contamination of lens storage cases or contact lens solutions, and use of homemade saline. Swimming while wearing lenses also creates a serious risk of infection. Reinforce proper lens care in any health maintenance discussion.

Older adults are often reluctant to use hearing aids. Reasons cited most often include cost, appearance, insufficient knowledge about hearing aids, amplification of competing noise, and unrealistic expectations. Neuromuscular changes in the older adult such as stiff fingers, enlarged joints, and decreased sensory perception also make the handling and care of a hearing aid difficult. Fortunately today there are a wide variety of aids that not only enhance a person's hearing but also are cosmetically acceptable and useful for people with manual dexterity issues. Chapter 40 summarizes the types of hearing aids available and tips for proper care and use.

BOX 49-7   PATIENT TEACHING

Effective Use of a Hearing Aid

Objective
- Patient and family member will describe how to use a hearing aid correctly.

Teaching Strategies
- Show patient and family member locations on hearing aid device where damage (e.g., cracks, fraying) is likely to occur: earmold or case, earphone, dials, cord, and connection plugs.
- Instruct patient and family how to assess integrity of aid each day.
- Demonstrate battery replacement: Have extra set of unused batteries available.
- Instruct patient to store batteries in a dry, secure place away from pets and children.
- Instruct patient to clean ear canal daily.
- Instruct patient not to use hair spray and other hair products when hearing aid is in place
- Review method to check volume: Turn dial to maximum gain and check. Is voice clear?
- Review factors to report to hearing aid laboratory: static, distortion of sound, poor volume quality.

Evaluation
- Have patient and family demonstrate how to assess for hearing aid damage.
- Have patient and family demonstrate battery removal and cleaning.
- Have patient describe where to safely store battery.

Acknowledging a need to improve hearing is a person's first step. Give patients useful information on the benefits of hearing aid use. A person who understands the need for good hearing will likely be influenced to wear hearing aids. It is also important to have a significant other available to assist with hearing aid adjustment (Box 49-7). Federal regulations require prospective hearing aid users to either have a medical examination or sign a waiver saying they do not want it. The purpose of the examination is to rule out a medical reason for the hearing loss before hearing aids are purchased (U.S. Food and Drug Administration, 2014). Hearing aid dispensers should have prospective users consult their health care provider or an otolaryngologist for the following conditions: visible congenital or traumatic deformity of the ear, active drainage in the last 90 days, sudden or progressive hearing loss within the last 90 days, acute or chronic dizziness, unilateral sudden hearing loss within the last 90 days, visible cerumen accumulation or a foreign body in the ear canal, pain or discomfort in the ear, or an audiometric air-bone gap of 15 decibels or greater (U.S. Food and Drug Administration, 2015).

Promoting Meaningful Stimulation. Life becomes more enriching and satisfying when meaningful and pleasant stimuli exist within the environment. You can help patients adjust to their environment in many ways so it becomes more stimulating. You do this best by considering the normal physiological changes that accompany sensory deficits.

Vision. The pupil's ability to adjust to light diminishes as a result of the normal changes of aging; thus older adults are often very sensitive to glare. Suggest the use of yellow or amber lenses and shades or blinds on windows to minimize glare. Wearing sunglasses outside obviously reduces the glare of direct sunlight. Other interventions to enhance vision for patients with visual impairment include warm incandescent lighting and colors with sharp contrast and intensity.

The ability to read is important. Therefore allow patients to use their glasses whenever possible (e.g., during procedures and instruction). Some patients with reduced visual acuity need more than corrective lenses. A pocket magnifier helps a patient read most printed material. Telescopic-lens eyeglasses are smaller, easier to focus, and have a greater range. Books and other publications are also available in larger print. If a patient has a legal or another important document that he or she wishes to read, standard copying machines have enlarging capabilities. Software is also available that converts text into artificial voice output (Touhy and Jett, 2014).

With aging a person experiences a change in color perception. Perception of the colors blue, violet, and green usually declines. Brighter colors such as red, orange, and yellow are easier to see. Offer suggestions of ways to decorate a room and paint hallways or stairwells so the patient is able to differentiate surfaces and objects in a room.

Hearing. To maximize residual hearing function, work closely with a patient to suggest ways to modify the environment. Patients can amplify the sound of telephones and televisions. An innovative way to enrich the lives of patients with hearing impairments is recorded music. Some patients with severe hearing loss are able to hear music recorded in the low-frequency sound cycles.

One way to help an individual with a hearing loss is to ensure that the problem is not impacted cerumen. With aging cerumen thickens and builds up in the ear canal. Excessive cerumen occluding the ear canal causes **conductive hearing loss**. Instilling a softening agent such as 0.5 to 1 mL of warm mineral oil into the ear canal followed by irrigation of a solution of 3% hydrogen peroxide in a quart of warmed water removes cerumen and significantly improves a patient's hearing ability (Touhy and Jett, 2014).

Taste and Smell. Promote the sense of taste by using measures to enhance remaining taste perception. Good oral hygiene keeps the taste buds well hydrated. Well-seasoned, differently textured food eaten separately heightens taste perception. Flavored vinegar or lemon juice adds tartness to food. Always ask a patient which foods are most appealing. Improving taste perception improves food intake and appetite as well.

Stimulation of the sense of smell with aromas such as brewed coffee, cooked garlic, and baked bread heightens taste sensation. Patients need to avoid blending or mixing foods because these actions make it difficult to identify tastes. Older people need to chew food thoroughly to allow more food to contact remaining taste buds.

Improve smell by strengthening pleasant olfactory stimulation. Make a patient's environment more pleasant with smells such as cologne, mild room deodorizers, fragrant flowers, and sachets. Consult with patients to find out which scents they can tolerate. The removal of unpleasant odors (e.g., bedpans or soiled dressings) also improves the quality of a patient's environment.

Touch. Patients with reduced tactile sensation usually have the impairment over a limited part of their bodies. Providing touch therapy stimulates existing function. If a patient is willing to be touched, hair brushing and combing, a backrub, and touching the arms or shoulders are ways of increasing tactile contact. When sensation is reduced, a firm pressure is often necessary for a patient to feel a nurse's hand. Turning and repositioning also improves the quality of tactile sensation.

If a patient is overly sensitive to tactile stimuli (**hyperesthesia**), minimize irritating stimuli. Keeping bed linens loose to minimize direct contact with a patient and protecting the skin from exposure to

irritants are helpful measures. Physical therapists can recommend special wrist splints for patients to wear to dorsiflex their wrists and relieve nerve pressure when they have numbness and tingling or pain in the hands, as with carpal tunnel syndrome. For patients who use computers, special keyboards and wrist pads are available to decrease the pressure on the median nerve, aid in pain relief, and promote healing.

Establishing Safe Environments. When sensory function becomes impaired, individuals become less secure within their home and workplace. Security is necessary for a person to feel independent. Make recommendations for improving safety within a patient's living environment without restricting independence. During a home visit or while completing an examination in the clinic, offer several useful suggestions for home safety. The nature of the actual or potential sensory loss determines the safety precautions you take.

Adaptations for Visual Loss. When a patient experiences a decrease in visual acuity, peripheral vision, adaptation to the dark, or depth perception, safety is a concern. With reduced peripheral vision a patient cannot see panoramically because the outer visual field is less discrete. With reduced depth perception a person is unable to judge how far away objects are located. This is a special danger when he or she walks down stairs or over uneven surfaces.

Driving is a particular safety hazard for older adults with visual alterations. Reduced peripheral vision prevents a driver from seeing a car in an adjacent lane. A sensitivity to glare creates a problem for driving at night with headlights. Vision is a primary consideration for safety, but there are other factors as well. In the case of older adults, decreased reaction time, reduced hearing, and decreased strength in the legs and arms further compromise driving skills. Some safety tips to share with those who continue to drive include the following: drive in familiar areas, do not drive during rush hour, avoid interstate highways for local drives, drive defensively, use rear-view and side-view mirrors when changing lanes, avoid driving at dusk or night, go slow but not too slow, keep the car in good working condition, and carry a preprogrammed cellular phone.

The presence of visual alterations makes it difficult for a person to conduct normal activities of living within the home. Because of reduced depth perception, patients can trip on throw rugs, runners, or the edge of stairs. Teach patients and family members to keep all flooring in good condition, and advise them to use low-pile carpeting. Thresholds between rooms need to be level with the floor. Recommend the removal of clutter to ensure clear pathways for walking and arrangement of furniture so a patient can move about easily without fear of tripping or running into objects. Suggest that stairwells have a securely fastened banister or handrail extending the full length of the stairs.

Front and back entrances to the home, work areas, and stairwells need to be lighted properly. Light fixtures need high-wattage bulbs with wider illumination. There needs to be a light switch at the top and bottom of stairwells. It is also important to be sure that lighting on the stairs does not cast shadows. Have a family member paint the edge of steps so the patient can see each step, especially the first and last, clearly. When possible have patients replace steps inside and outside the home with ramps.

An added consideration is to administer eye medications safely (see Chapter 32). Patients need to closely adhere to regular medication schedules for conditions such as glaucoma. Labels on medication containers need to be in large print. Make sure that a friend or spouse is familiar with dosage schedules in case a patient is unable to self-administer a medication. Patients with visual impairments often have difficulty manipulating eyedroppers.

Adaptations for Reduced Hearing. Patients hear important environmental sounds (e.g., doorbells and alarm clocks) best if they are amplified or changed to a lower-pitched, buzzer-like sound. Lamps designed to turn on in response to sounds such as doorbells, burglar alarms, smoke detectors, and babies crying are also available. Family members and anyone who calls the patient regularly need to learn to let the phone ring for a longer period. Amplified receivers for telephones and telephone communication devices (TCDs) are available that use a computer and printer to transfer words over the telephone for the hearing impaired. Both sender and receiver need to have the special device to complete a call.

Adaptations for Reduced Olfaction. The patient with a reduced sensitivity to odors is often unable to smell leaking gas, a smoldering cigarette, fire, or spoiled food. Advise patients to use smoke detectors and take precautions such as checking ashtrays or placing cigarette butts in water. In addition, teach patients to check food package dates, inspect the appearance of food, and keep leftovers in labeled containers with the preparation date. Pilot gas flames need to be checked visually.

Adaptations for Reduced Tactile Sensation. When patients have reduced sensation in their extremities, they are at risk for impaired skin integrity and injury from exposure to temperature extremes. Always caution these patients about the use of heating and cooling devices (see Chapter 48). The temperature setting on the home water heater should be no higher than 48.8° C (120° F). If a patient also has a visual impairment, it is important to be sure that water faucets are clearly marked "hot" and "cold" or use color codes (i.e., red for hot and blue for cold). Discourage the use of heating pads in this population.

Communication. A sensory deficit often causes a person to feel isolated because of an inability to communicate with others. It is important for individuals to be able to interact with people around them. The nature of the sensory loss influences the methods and styles of communication that nurses use during interactions with patients (Box 49-8). You also teach communication methods to family members and significant others. For patients with visual deficits or blindness, speak normally, not from a distance, and be sure to have sufficient lighting.

The patient with a hearing impairment is often able to speak normally. To more clearly hear what a person communicates, family and friends need to learn to move away from background noise, rephrase rather than repeat sentences, be positive, and have patience. In a group setting it is better to form a semicircle in front of the patient so he or she can see who is speaking next; this helps foster group involvement. On the other hand, some patients who are deaf have serious speech alterations. Some use sign language or lip reading, wear special hearing aids, write with a pad and pencil, or learn to use a computer for communication. Special communication boards that contain common terms (e.g., *pain, bathroom, dizzy*, or *walk*) help patients express their needs.

Patient education is one aspect of communication. Teaching booklets are available in large print for patients with visual loss. The patient who is blind often requires more frequent and detailed verbal descriptions of information. This is particularly true if there are no instructional booklets written in Braille. Patients with visual impairments can also learn by listening to audiotapes or the sound part of a televised teaching session. Patients with hearing impairments often benefit from written instructional materials and visual teaching aids (e.g., posters and graphs). Demonstrations by the nurse are very useful. Hospitals are required to make professional interpreters available to read sign language for patients who are deaf.

BOX 49-8 Communication Methods

Patients with Aphasia

- Listen to patient and provide sufficient time for him or her to communicate.
- Do not shout or speak loudly (hearing loss is not the problem).
- If patient has problems with comprehension, use simple, short questions and facial gestures to give additional clues.
- Speak of things familiar and of interest to patient.
- If patient has problems speaking, ask questions that require simple yes or no answers or blinking of the eyes. Offer pictures or a communication board so patient can point.
- Speak slowly and give patient time to understand; be calm and patient; do not pressure or tire him or her.
- Avoid patronizing and childish phrases.

Patients with an Artificial Airway

- Use pictures, objects, or word cards so patient can point.
- Offer a pad and pencil or Magic Slate for patient to write messages.
- Do not shout or speak loudly.
- Give patient time to write messages because patients tire easily.
- Provide an artificial voice box (vibrator) for patient with a laryngectomy to use to speak.

Patients with Hearing Impairment

- Get patient's attention. Do not startle him or her when entering the room. Do not approach patient from behind. Be sure that he or she knows that you want to speak.
- Face patient and stand or sit on the same level. Be sure that your face and lips are illuminated to promote lip reading. Keep hands away from mouth.
- Be sure that the environment is not noisy.
- Be sure that patients keep eyeglasses clean so they are able to see your gestures and face.
- If patient wears a hearing aid, make sure that it is in place and working.
- Speak slowly and articulate clearly. Sometimes people with hearing loss take longer to process verbal messages.
- Use a normal tone of voice and inflections of speech. Do not speak with something in your mouth.
- When you are not understood, rephrase rather than repeat the conversation.
- Use visible expressions. Speak with your hands, face, and eyes.
- Do not shout. Loud sounds are usually higher pitched and often impede hearing by accentuating vowel sounds and concealing consonants. If you need to raise your voice, speak in lower tones.
- Talk toward patient's best or normal ear.
- Use written information to enhance the spoken word.
- Do not restrict the hands of patient who is deaf. Never have intravenous lines in both of patient's hands if the preferred method of communication is sign language.
- Avoid eating, chewing, or smoking while speaking.
- Avoid speaking from another room or while walking away.

Acute Care. When patients enter acute care settings for therapeutic management of sensory deficits or as a result of traumatic injury, use different approaches to maximize sensory function existing at the time. Safety is an obvious priority until a patient's sensory status is either stabilized or improved. For example, patients with sensory deficits have a high risk for falls in the acute care environment. It is very important to know the extent of any existing sensory impairment before the acute episode of illness so you are able to reinforce what the patient already knows about self-care or plan for more instruction before and after discharge.

Orientation to the Environment. A patient with a sensory impairment requires a complete orientation to the immediate environment. Provide reorientation as needed to the institutional environment by ensuring that name tags on uniforms are visible, addressing the patient by name, explaining where the patient is (especially if patients are transported to different areas for treatment), and using conversational cues to time or location. Reduce the tendency for patients to become confused by offering short, simple, repeated explanations and reassurance. Encourage family members and visitors to help orient patients to the hospital surroundings.

Patients with serious visual impairment need to feel comfortable in knowing the boundaries of the immediate environment. Normally people see physical boundaries within a room. Patients who are blind or severely visually impaired often touch the boundaries or objects to gain a sense of their surroundings. The patient needs to walk through a room and feel the walls to establish a sense of direction. Help patients by explaining objects within the hospital room such as furniture or equipment. It takes time for a patient to absorb room arrangement. He or she often needs to reorient again as you explain the location of key items (e.g., call light, telephone, and chair). Remember to approach the patient from the front to avoid startling him or her.

It is important to keep all objects in the same position and place. After an object is moved even a short distance, it no longer exists for a person who is blind. Simply moving a chair creates a safety hazard. Ask the patient if any item needs to be rearranged to make ambulation easier. Clear traffic patterns to the bathroom. Give the patient extra time to perform tasks. He or she needs a detailed description of how to perform an activity and moves slowly to remain safe.

Patients confined to bed are at risk for sensory deprivation. Normally movement gives an awareness of self through vestibular and tactile stimulation. Movement patterns influence sensory perception. The limited movement of bed rest changes how a person interprets the environment; surroundings seem different, and objects seem to assume shapes different from normal. A person who is on bed rest requires routine stimulation through range-of-motion exercises, positioning, and participation in self-care activities (as appropriate). Comfort measures such as washing the face and hands and providing backrubs improve the quality of stimulation and lessen the chance of sensory deprivation. Planning time to talk with patients is also essential. Explain unfamiliar environmental noises and sensations. A calm, unhurried approach gives you quality time to help reorient and familiarize the patient with care activities. The patient who is well enough to read will benefit from a variety of reading material.

Communication. The most common language disorder following a stroke is aphasia. Depending on the type of aphasia, the inability to communicate is often frustrating and frightening (see Box 49-8). Initially you need to establish very basic communication and recognize that it does not indicate intellectual impairment or degeneration of personality. Explain situations and treatments that are pertinent to the patient because he or she is able to understand the speaker's words. Because a stroke often causes partial or complete paralysis of one side of a patient's body, the patient needs special assistive devices. A variety of communication boards for different levels of disability are available. Sensitive pressure switches activated by the touch of an ear, nose, or chin control electronic communication boards (Touhy and Jett, 2014). Make referrals to speech therapists to develop appropriate rehabilitation plans.

In acute care hospitals or long-term care facilities, nurses often care for patients with artificial airways (such as an endotracheal tube) (see Chapter 41). The placement of an endotracheal tube prevents a patient from speaking. In this case the nurse uses special communication methods to facilitate his or her ability to express needs. The patient is

sometimes completely alert and able to hear and see the nurse normally. Giving him or her time to convey any needs or requests is very important. Use creative communication techniques (e.g., a communication board or electronic tablet) to foster and strengthen a patient's interactions with health care personnel, family, and friends.

Controlling Sensory Stimuli. Patients need time for rest and freedom from stress caused by frequent monitoring and repeated tests. Reduce sensory overload by organizing the patient's plan of care. Combine activities such as dressing changes, bathing, and vital sign measurement in one visit to conserve a patient's energy and prevent fatigue. A patient also needs scheduled time for rest and quiet. Planning for rest periods often requires cooperation from family, visitors, and health care colleagues. Coordination with laboratory and radiology departments minimizes the number of interruptions for procedures. A creative solution to decrease excessive environmental stimuli that prevents restful, healing sleep is to institute "quiet time" in ICUs. Quiet time means dimming the lights throughout the unit, closing the shades, and shutting the doors. Data collected from one hospital that implemented 1 hour of quiet time daily found decreased staff and unit noise and improved patient satisfaction (Haupt, 2012).

When patients experience sensory overload or deprivation, their behavior is often difficult for family or friends to accept. Encourage the family not to argue with or contradict the patient but to calmly explain location, identity, and time of day. Engaging a patient in a normal discussion about familiar topics helps in reorientation. Anticipating patient needs such as voiding helps reduce uncomfortable stimuli.

Try to control extraneous noise in and around a patient's room. It is often necessary to ask a roommate to lower the volume on a television or to move the patient to a quieter room. Keep equipment noise to a minimum. Turn off bedside equipment not in use such as suction and oxygen equipment. Avoid making abrupt loud noises such as dropping objects or causing the over-bed table to suddenly adjust to the lowest level. Nursing staff also need to control laughter or conversation outside the patients' rooms. Allow patients to close their room doors.

When a patient leaves an acute care setting for the home environment, communicate with colleagues in the home care setting about the patient's existing sensory deficits and the interventions that helped the patient adapt to sensory problems. You achieve continuity of care when the patient has to make only minimal changes in the home setting.

Safety Measures. A patient with recent visual impairment often requires help with walking. The presence of an eye patch, frequently instilled eyedrops, and the swelling of eyelid structures following surgery are just a few factors that cause a patient to need more help than usual. A sighted guide gives confidence to patients with visual impairments and ensures safe mobility. The American Foundation for the Blind (2015) lists several suggestions for a sighted guide:

1. Ask the patient if he or she wants a "sighted guide." If assistance is accepted, offer your arm. Tap the back of your hand against his or her hand. The person will then grasp your arm directly above the elbow (Figure 49-5).
2. Relax and walk at a comfortable pace. Walk one step ahead of the person you are guiding, except at the top and bottom of stairs and streets. At these places pause and stand alongside the person. Be sure that the person has a strong grasp on your arm.
3. While walking with a patient, describe the surroundings and ensure that obstacles have been removed. Never leave a patient with a visual impairment standing alone in an unfamiliar area.
4. To guide a person to a seat, place his or her hand on the back of the seat. The person you are guiding will find the seat by following along your arm.

FIGURE 49-5 Nurse helps to ambulate patient with visual impairment. (From Sorrentino SA, Remmert LN: *Mosby's textbook for nursing assistants,* ed 8, St Louis, 2012, Mosby.)

It is important to teach family members techniques for helping with ambulation. Nursing staff also need to ensure that the patient knows where the call light is before leaving him or her alone. Place necessary objects in front of the patient to prevent falls caused by reaching over the bedside. Appropriate use of side rails is also an option.

Nurses often rely on patients in health care settings to report unusual sounds such as a suction apparatus running improperly or an IV pump alarm. However, a patient with a hearing loss does not always hear these sounds and thus requires more frequent visits by nurses. The patient also benefits from learning to use vision to discover sources of danger. It is wise to note on the intercom system at the nurse's station and in the medical record if the patient is deaf and/or blind. A patient lacking the ability to speak cannot call out for assistance. Patients need to have message boards and call lights close at hand.

Patients with reduced tactile sensation risk injury when their conditions confine them to bed because they are unable to sense pressure on bony prominences or the need to change position. These patients rely on nurses for timely repositioning, moving tubes or devices on which the patient is lying, and turning to avoid skin breakdown. When a patient is less able to sense temperature variations, use extra caution in applying heat and cold therapies (see Chapter 48) and preparing bath water. Check the condition of the patient's skin frequently.

Restorative and Continuing Care

Maintaining Healthy Lifestyles. After a patient has experienced a sensory loss, it becomes important to understand the implications of the loss and make adjustments needed to continue a normal lifestyle. Sensory impairments need not prevent a person from leading an active, rewarding life. Many of the interventions applicable to health promotion such as adapting the home environment are useful after a patient leaves an acute care setting.

Understanding Sensory Loss. Patients who have experienced a recent sensory loss need to understand how to adapt so their living environments are safe and appropriately stimulating. All family members need to understand how a patient's sensory impairment affects normal daily activities. Family and friends are more supportive when they understand sensory deficits and factors that worsen or

Principles for Reducing Loneliness in Patients with Sensory Impairments

- Spend time with a person in silence or conversation.
- When it is culturally appropriate, use physical contact (e.g., holding a hand, embracing a shoulder) to convey caring.
- Recommend alterations in living arrangements if physical isolation is a factor.
- Help patients keep contact with people important to them.
- Provide information about support groups or groups that provide assistive services.
- Arrange for security escort services as needed.
- Introduce the idea of bringing a companion such as a pet into the home when appropriate.
- Link a person with organizations attuned to the social needs of older adults.

FIGURE 49-6 Location of food using clock as frame of reference.

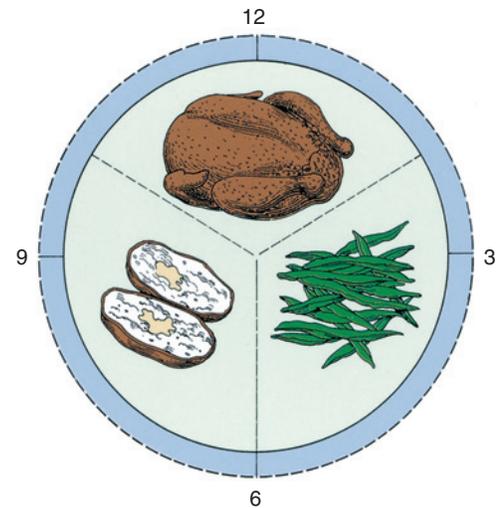
lessen sensory problems. For example, they need to learn how to communicate with someone who has a hearing loss. Community resources are available to provide information to help patients with personal management needs. The American Foundation for the Blind, American Red Cross, and National Association for Speech and Hearing offer resource materials and product information.

Socialization. The ability to communicate is gratifying. It tests a person's intellect, opens opportunities, and allows him or her to exchange the feelings that he or she has about others. When sensory alterations hinder interactions, a person feels ineffective and loses self-esteem. When patients feel socially unaccepted, they perceive sensory losses as seriously impairing their quality of life.

Interacting with others becomes a burden for many patients with sensory alterations. They lose the motivation to engage in social situations, resulting in a deep sense of loneliness. Use therapies to reduce loneliness, particularly in older adults (Box 49-9). These principles support the *Healthy People 2020* objective to increase the proportion of adults with disabilities reporting sufficient emotional support. In addition, family members need to learn to focus on a person's ability to interact rather than on his or her disability. For example, do not assume that a person who is hard of hearing does not want to speak. A person who is blind can still enjoy a walk through a park with a companion describing the sights around them.

Promoting Self-Care. The ability to perform self-care is essential for self-esteem. Frequently family members and nurses believe that people with sensory impairments require assistance, when in fact they are able to help themselves. To help with meals, arrange food on the plate and condiments, salad, or drinks according to numbers on the face of a clock (Figure 49-6). A patient can also use this method to place personal care items on the bedside or on the bathroom vanity. It is easy for a patient to become oriented to the items after a nurse or family member explains the location of each item.

Help patients reach toilet facilities safely. Safety bars need to be installed near the toilet. It is often helpful to have the bar a different color than the wall for easier visibility. Never place towels on a safety bar because they interfere with a person's grasp. Toilet paper needs to be within easy reach. Sharply contrasting colors within the room help the partially sighted and promote functional independence. General principles for promoting self-care in older adults also include using warm incandescent lighting and controlling glare by using shades and blinds (Touhy and Jett, 2014).

If the sense of touch is diminished, a patient can dress more easily with zippers or Velcro strips, pullover sweaters or blouses, and elasticized waists. If a patient has partial paralysis and reduced sensation, he or she dresses the affected side first. Encourage family members responsible for selecting clothing for patients with visual impairments to follow the patient's preferences. Any sensory impairment has a significant influence on body image, and it is important for the patient to feel well groomed and attractive. Some patients need assistance with basic grooming such as brushing, combing, and shampooing hair. Others need assistance with medication administration, clothing identification, and learning to manage routine procedures such as blood pressure and glucose monitoring. An assortment of low-vision devices is now available. It is important for you to make appropriate referrals to allow the patient to maintain a maximum degree of independence.


Patients with proprioceptive problems often lose their balance easily. Make sure that bathrooms have nonskid surfaces in the tub and shower. Install grab bars either vertically or horizontally in tubs and showers, depending on how a patient is able to grasp or hold onto the bar. Instruct family members to supervise ambulation and sitting, make frequent checks to prevent falls, and caution the patient against leaning forward.

◆ Evaluation

Through the Patient's Eyes. It is important to evaluate whether care measures maintain or improve a patient's ability to interact and function within the environment. The patient is the source for evaluating outcomes. He or she is the only one who knows if sensory abilities are improved and which specific interventions or therapies are most successful in facilitating a change in his or her performance (Figure 49-7). Collaborate with family members to determine if a patient's ability to function within the home has improved.

If you have developed a positive relationship with a patient successfully, notice that subtle behaviors often indicate the level of his or her satisfaction. You may notice that the patient responds appropriately such as by smiling. However, it is important for you to ask the patient if his or her sensory needs have been met. For example, ask, "Have we done all we can do to help improve your ability to hear?" If the patient's expectations have not been met, ask him or her, "How can the health care team better meet your needs?" Working closely with the patient and family enables you to redefine expectations that can be met realistically within the limits of the patient's condition and therapies. You have been effective when the patient's goals and expectations have been met.

Knowledge
- Characteristics of improved hearing, sight, touch, or taste
- The patient's ability to recognize sensory changes

Experience
- Previous patient responses to planned nursing interventions to promote sensory function

EVALUATION
- Reassess signs and symptoms of sensory alteration
- Determine the patient's ability to remain functional within the home or health care environment
- Ask the patient to demonstrate or explain newly learned self-care skill
- Ask the patient if expectations are being met

Standards
- Use established expected outcomes (e.g., improved sensory acuity, creation of a safe home environment) to evaluate the patient's response to care

Attitudes
- Think independently and consider the patient's views about whether the level of care has improved his or her sensory status
- Use creativity and observe the patient in the home to adequately evaluate sensory function

FIGURE 49-7 Critical thinking model for sensory alterations evaluation.

Patient Outcomes. To evaluate the effectiveness of specific nursing interventions, use critical thinking and make comparisons with baseline sensory assessment data to evaluate if sensory alterations have changed. It is your responsibility to determine if expected outcomes have been met. For example, use evaluative data to determine whether care measures improve or at least maintain a patient's ability to interact and function within the environment. The nature of a patient's sensory alterations influences how you evaluate the outcome of care. When caring for a patient with a hearing deficit, use proper communication techniques and then evaluate whether he or she has gained the ability to hear or interact more effectively. When expected outcomes have not been achieved, there is a need to change interventions or alter the patient's environment. If outcomes are not met, it is important to ask questions such as, "How are you feeling emotionally?" "Do you feel that you are at risk for injury?"

If you have directed nursing care at improving or maintaining sensory acuity, evaluate the integrity of the sensory organs and the patient's ability to perceive stimuli. Evaluate interventions designed to relieve problems associated with sensory alterations on the basis of a patient's ability to function normally without injury. When you directly or indirectly (through education) alter a patient's environment, evaluate by observing whether the patient makes environmental changes. When designing patient teaching to improve sensory function, it is important to determine whether the patient is following recommended

therapies and meeting mutually set goals. Asking a patient to explain or demonstrate self-care skills is an effective evaluative measure. It is often necessary to reinforce previous instruction if learning has not taken place. If outcomes are not met, these are examples of questions to ask:
- "How often do you wear your hearing aids/corrective lenses?"
- "Are you able to participate in a small group discussion?"
- "Are you able to read the newspaper without squinting?"

The results of your evaluation will determine whether to continue the existing plan of care, make modifications, or end the use of select interventions.

KEY POINTS

- Sensory reception involves the stimulation of sensory nerve fibers and the transmission of impulses to higher centers within the brain.
- Sensory deprivation results from an inadequate quality or quantity of sensory stimuli.
- Aging results in a gradual decline of acuity in all senses.
- Patients who are older, immobilized, or confined in isolated environments are at risk for sensory alterations.
- Assessment of a patient's health promotion habits reveals risks for sensory impairment.
- An assessment of hazards in the environment requires the nurse to tour living areas in the home and look for conditions that increase the chances of injury such as falls.
- The plan of care for patients with sensory alterations needs to include participation by family members. The extent of support from family members and significant others influences the quality of sensory experiences.
- Patients with sensory deficits often develop alternate ways of communicating that rely on other senses.
- Care of patients at risk for sensory deprivation includes introducing meaningful and pleasant stimuli for all senses.
- To prevent sensory overload, control stimuli and orient the patient to the environment.
- Patients with artificial airways are able to communicate effectively with communication boards, laptop computers, and written messages.

CRITICAL APPLICATION QUESTIONS

Preparing for Clinical Practice
Ms. Long made an informed decision to have cataract surgery 1 month ago. After surgery she reported improved vision and ability to participate in activities of daily living. Today the community health nurse visits, and Ms. Long reports shortness of breath with activity. After the nurse consults with Ms. Long's health care provider, Ms. Long is admitted from the emergency department to a telemetry heart monitoring unit with a diagnosis of heart failure.

1. Three days after being admitted, Ms. Long reports less shortness of breath; however, she is restless, tired, and irritable. She is on a cardiac monitor and continues to receive oxygen. The staff nurse reports that Ms. Long has slept very little since her admission. Her semiprivate room is directly across from a busy central nurses' station, and she frequently calls out for assistance. Identify the sensory alteration Ms. Long is experiencing and three strategies that will ensure that she gets enough sleep.

2. Ms. Long was released from the hospital in good health 1 week after admission. Following the recommendation of her health care provider, she regularly attends a heart-failure support group. She asks you to speak with the group regarding age-related visual changes

and signs and symptoms that may indicate problems. What information will you share with them to promote healthy vision?

3. Ms. Long is worried about how to communicate with her sister who had a stroke and developed aphasia. What would you teach her to help her communicate more effectively with her sister?

■ REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. A patient has been on contact isolation for 4 days because of a hospital-acquired infection. He has had few visitors and few opportunities to leave his room. His ambulation is also still limited. Which are the correct nursing interventions to reduce sensory deprivation? (Select all that apply.)
   1. Teaching how activities such as reading and using crossword puzzles provide stimulation
   2. Moving him to a room away from the nurse's station
   3. Turning on the lights and opening the room blinds
   4. Sitting down, speaking, touching, and listening to his feelings and perceptions
   5. Providing auditory stimulation for the patient by keeping the television on continuously

2. The home care nurse is instructing a nursing assistant about interventions to facilitate location of items for patients with vision impairment. Which are effective strategies for enhancing a patient's impaired vision? (Select all that apply.)
   1. Use of fluorescent lighting
   2. Use of warm, incandescent lighting
   3. Use of yellow or amber lenses to decrease glare
   4. Use of adjustable blinds, sheer curtains, or draperies
   5. Indirect lighting to reduce glare

3. An elderly patient with bilateral hearing loss wears a hearing aid in her left ear. Which of the following approaches best facilitates communication with her?
   1. Talk to the patient at a distance so he or she may read your lips.
   2. Keep your arms at your side; speak directly into the patient's left ear.
   3. Face the patient when speaking; demonstrate ideas you wish to convey.
   4. Position the patient so the light is on his or her face when speaking.

4. The nurse is caring for a patient with glaucoma. When developing a discharge plan, which priority intervention enables the patient to function safely with existing deficits and continue a normal lifestyle?
   1. Encourage the patient to rearrange her home furnishings regularly to keep active.
   2. Suggest to the patient that he or she consider either moving to a smaller home or long-term care facility.
   3. Say nothing because it is most appropriate that the patient identify personal interventions to compensate for a sensory alteration.
   4. Work closely with the patient and family to identify in-home modifications to create a comfortable and accessible environment.

5. A patient is returning to an assisted-living apartment following a diagnosis of declining, progressive visual loss. Although she is familiar with her apartment and residence, she reports feeling a little uncertain about walking alone. There is one step into her apartment. Her children are scheduling themselves to be available to their mom for the next 2 weeks. Which of the following approaches will you teach the children to assist ambulation? (Select all that apply.)
   1. Walk one-half step behind and slightly to her side.
   2. Have her grasp your arm just above the elbow and walk at a comfortable pace.
   3. Stand next to your mom at the top and bottom of stairs.
   4. Stand one step ahead of mom at the top of the stairs.
   5. Place yourself alongside your mom and hold onto her waist.

6. A new nurse is going to help a patient walk down the corridor and sit in a chair. The patient has an eye patch over the left eye and poor vision in the right eye. What is the correct order of steps to help the patient safely walk down the hall and sit in the chair?
   1. Tell patient when you are approaching the chair.
   2. Walk at a relaxed pace.
   3. Guide patient's hand to nurse's arm, resting just above the elbow.
   4. Position yourself one-half step in front of patient.
   5. Position patient's hand on back of chair.

7. Because hearing impairment is one of the most common disabilities among children, a health promotion intervention is to teach parents and children to:
   1. Avoid activities in which there may be crowds.
   2. Delay childhood immunizations until hearing can be verified.
   3. Take precautions when involved in activities associated with high-intensity noises.
   4. Prophylactically administer antibiotics to reduce the incidence of infections.

8. A nurse is conducting discharge teaching for a patient with diminished tactile sensation. Which of the following statements made by the patient indicates that additional teaching is needed?
   1. "I am at risk for injury from temperature extremes."
   2. "I may be able to dress more easily with zippers or pullover sweaters."
   3. "A home care nurse may help me figure out how to be more independent."
   4. "I have right-sided partial paralysis and reduced sensation; so I should dress the left side of my body first."

9. Which of the following is the best nursing intervention when communicating with a patient who has expressive aphasia?
   1. Ask open-ended questions
   2. Speak to the patient as if he or she is a child
   3. Use a dry-erase board or paper and pen for writing messages
   4. Avoid the use of gestures and other nonverbal forms of communication

10. A patient with progressive vision impairments had to surrender his driver's license 6 months ago. He comes to the medical clinic for a routine checkup. He is accompanied by his son. His wife died 2 years ago, and he admits to feeling lonely much of the time. Which of the following interventions reduce loneliness? (Select all that apply.)
    1. Sharing information about senior transportation services
    2. Reassuring the patient that loneliness is a normal part of aging
    3. Maintaining distance while talking to avoid overstimulating the patient
    4. Providing information about local social groups in the patient's neighborhood
    5. Recommending that the patient consider making living arrangements that will put him closer to family or friends

11. A nurse is performing an assessment on a patient admitted to the unit following treatment in the emergency department for severe bilateral eye trauma. During patient admission the nurse's priority interventions include which of the following? (Select all that apply.)
    1. Conducting a home-safety assessment and identifying hazards in the patient's living environment
    2. Reinforcing eye safety at work and in activities that place the patient at risk for eye injury
    3. Placing necessary objects such as the call light and water in front of the patient to prevent falls caused by reaching
    4. Orienting the patient to the environment to reduce anxiety and prevent further injury to the eye
    5. Placing signage on the patient's room door and over the bed to alert health care providers about patient's visual status

12. Which patient is most likely to experience sensory overload?
    1. A patient in the intensive care unit whose pain is not well controlled
    2. A patient with a protective patch on her right eye following cataract surgery
    3. A woman whose hearing aids were lost when she transferred to a long-term care facility
    4. A visually impaired resident of a nursing home who enjoys taking part in different hobbies and activities

13. An older adult is admitted from a skilled nursing home to a medical unit with pneumonia. A review of the medical record reveals that he had a stroke affecting the right hemisphere of the brain 6 months ago and was placed in the skilled nursing home because he was unable to care for himself. Which of these assessment findings does the nurse expect to find? (Select all that apply.)
    1. Slow, cautious behavioral style
    2. Inattention and neglect, especially to the left side
    3. Cloudy or opaque areas in part of the lens or the entire lens
    4. Visual spatial alterations such as loss of half of a visual field
    5. Loss of sensation and motor function on the right side of the body

14. A nurse is performing a home care assessment on a patient with a hearing impairment. The patient reports, "I think my hearing aid is broken. I can't hear anything." Which of the following teaching strategies does the nurse implement? (Select all that apply.)
    1. Demonstrate hearing aid battery replacement.
    2. Review method to check volume on hearing aid.
    3. Demonstrate how to wash the earmold and microphone with hot water.
    4. Discuss the importance of having wax buildup in the ear canal removed.
    5. Recommend a chemical cleaner to remove difficult buildup.

15. Identify the measures to ensure safety for a patient who has no sensation on one side of the body.

Care of Surgical Patients

OBJECTIVES

- Explain the concept of perioperative nursing care.
- Discuss common surgical risk factors and related nursing implications.
- Describe preoperative assessment data to collect for a surgical patient.
- Explain the elements of a typical preoperative teaching plan.
- Explain the components of an effective perioperative communication hand-off.
- Demonstrate postoperative exercises.

- Prepare a patient physically and psychologically for surgery.
- Discuss the benefits of preoperative warming.
- Explain the registered nurse's role in the operating room.
- Describe factors to assess in a patient during postoperative recovery.
- Describe the rationale for nursing interventions designed to prevent postoperative complications.
- Describe patients at risk for postoperative complications.

Perioperative nursing includes activities performed by a professional registered nurse (RN) before (preoperative), during (intraoperative) and after (postoperative) surgery. Nurses provide this care in many settings, including hospitals, surgical centers attached to hospitals, free-standing surgical centers, or health care providers' offices. Perioperative nursing is a fast-paced, changing, and challenging field. It is based on a nurse's understanding of several important principles, including:

- High-quality and patient safety–focused care, including a safe environment of care.
- Evidence-based practices and participation in generation of new knowledge through research.
- Multidisciplinary teamwork.
- Effective therapeutic communication and collaboration with a patient, the patient's family, and the surgical team.
- Effective and efficient assessment and intervention in all phases of surgery.

- Advocacy for a patient and the patient's family.
- Understanding of cost containment.

Perioperative nursing is a dynamic process guided by theoretical knowledge, ethical principles, ongoing research, specialized clinical skills, and caring practices (Operating Room Nurses Association of Canada (ORNAC, 2015). A nurse working within the perioperative setting responds to complex and changing clinical needs during a crucial period of a patient's surgical experience. When you work in any perioperative setting, you need to use critical thinking, practice competently using strict surgical asepsis, communicate effectively with members of the surgical team, and emphasize patient safety in all phases of care. Effective teaching and discharge planning involving patients and their family members prevent or minimize complications and ensure quality outcomes. The nursing process provides a basis for perioperative nursing, allowing you to individualize strategies throughout the perioperative period. A patient's smooth transition

from admission into the health care system through convalescence is the aim of quality perioperative care.

Care of a patient having surgery has shifted from a hospital- to home-based focus. Often convalescence occurs in the home or in rehabilitation sites within long-term care facilities. When care is in the home, responsibility shifts to the patient and/or family. As the length of hospital stay decreases, the educational needs of a patient undergoing a surgical procedure increase. Patients return home with complex medical/surgical conditions that require education and follow-up. Proper patient and family education is essential to ensuring positive surgical outcomes.

SCIENTIFIC KNOWLEDGE BASE

Classification of Surgery

The types of surgical procedures are classified according to seriousness, urgency, and purpose (Table 50-1). Some procedures fall into more than one classification. For example, surgical removal of a disfiguring scar is minor in seriousness, elective in urgency, and reconstructive in purpose. Frequently the classes overlap. An urgent procedure is also major in seriousness. Sometimes the same operation is performed for different reasons on different patients. For example, a gastrectomy may be performed as an emergency procedure to resect a bleeding ulcer or as an urgent procedure to remove a cancerous growth. Knowing the classifications helps you plan appropriate intraoperative care.

The surgical classification indicates the level of care a patient requires. The **American Society of Anesthesiologists (ASA)** assigns classification on the basis of a patient's physiological condition independent of the proposed surgical procedure (Table 50-2). Anesthesia always involves risks even in healthy patients, but certain patients are at higher risk, including those with metabolic and cardiac dysfunction.

Surgical Risk Factors

Numerous factors create risks for patients facing surgery. Risk factors can affect patients at any point in the perioperative experience. Knowledge of the physiology of the stress response (Chapter 38) and risk factors that affect patients' responses to surgery is necessary to anticipate patient needs and the type of preparation required.

Smoking. Cigarette smoking by surgical patients is associated with increased perioperative complications, particularly respiratory problems (e.g., pneumonia and atelectasis) and poor wound healing

TABLE 50-1	**Classification of Surgical Procedures**	
Classification Type	**Description**	**Example**
Seriousness		
Major	Involves extensive reconstruction or alteration in body parts; poses great risks to well-being	Coronary artery bypass, colon resection, removal of larynx, resection of lung lobe
Minor	Involves minimal alteration in body parts; often designed to correct deformities; involves minimal risks compared with major procedures	Cataract extraction, facial plastic surgery, tooth extraction
Urgency		
Elective	Performed on basis of patient's choice; is not essential and is not always necessary for health	Bunionectomy, facial plastic surgery; hernia repair; breast reconstruction
Urgent	Necessary for patient's health; often prevents development of additional problems (e.g., tissue destruction or impaired organ function); not necessarily emergency	Excision of cancerous tumor; removal of gallbladder for stones; vascular repair for obstructed artery (e.g., coronary artery bypass)
Emergency	Must be done immediately to save life or preserve function of body part	Repair of perforated appendix or traumatic amputation; control of internal hemorrhaging
Purpose		
Diagnostic	Surgical exploration that allows health care providers to confirm diagnosis; often involves removal of tissue for further diagnostic testing	Exploratory laparotomy (incision into peritoneal cavity to inspect abdominal organs); breast mass biopsy
Ablative	Excision or removal of diseased body part	Amputation; removal of appendix or an organ such as gallbladder (cholecystectomy)
Palliative	Relieves or reduces intensity of disease symptoms; does not produce cure	Colostomy; debridement of necrotic tissue; resection of nerve roots
Reconstructive/restorative	Restores function or appearance to traumatized or malfunctioning tissues	Internal fixation of fractures; scar revision
Procurement for transplant	Removal of organs and/or tissues from a person pronounced brain dead for transplantation into another person	Kidney, heart, or liver transplant
Constructive	Restores function lost or reduced as result of congenital anomalies	Repair of cleft palate; closure of atrial septal defect in heart
Cosmetic	Performed to improve personal appearance	Blepharoplasty for eyelid deformities; rhinoplasty to reshape nose

TABLE 50-2	ASA Physical Status (PS) Classification	
ASA PS Class	**Definition**	**Characteristics**
ASA I	A normal healthy patient	No physiological, biological, organic disturbance; healthy, nonsmoking; no or minimal alcohol use
ASA II	A patient with mild systemic disease	Mild diseases only without substantive functional changes (e.g., current smoker, social alcohol drinker, pregnancy, obesity [BMI 30-39], well-controlled DM/HTN, mild lung disease)
ASA III	A patient with severe systemic disease	Substantive functional changes with one or more moderate-to-severe diseases (e.g., poorly controlled DM or HTN, COPD, morbid obesity [BMI 40 or greater], active hepatitis, alcohol dependence or abuse, implanted pacemaker, or moderate reduction of cardiac ejection fraction)
ASA IV	A patient with severe systemic disease that is a constant threat to life	Examples include: recent (less than 3 months) MI, CVA, TIA, ongoing cardiac ischemia or severe valve dysfunction, sepsis, disseminated intravascular coagulation, end-stage renal disease not undergoing regularly scheduled dialysis
ASA V	A **moribund** patient who is not expected to survive without the operation	Examples include ruptured abdominal/thoracic aneurysm, massive trauma, intracranial bleed with mass effect, ischemic bowel with significant cardiac pathology
ASA VI	A patient declared brain dead whose organs are being removed for donor purpose	Wide variety of dysfunctions that are being managed to optimize blood flow to the heart and organs (e.g., aggressive fluid replacement and blood pressure medications)

Modified from American Society of Anesthesiologists: *ASA Physical Status Classification System,* October 15, 2014, http://www.asahq.org/resources/clinical-information/asa-physical-status-classification-system. Accessed May 17, 2015.
BMI, Body mass index; *CVA,* cardiovascular accident; *COPD,* chronic obstructive pulmonary disease; *DM,* diabetes mellitus; *HTN,* hypertension; *MI,* myocardial infarction; *TIA,* transient ischemic attack.

(Lee et al., 2013). Chronic smoking increases the amount and thickness of airway secretions. After surgery a patient who smokes has greater difficulty clearing the airways of mucus. When patients have elective surgery, encourage them to stop smoking as early as possible. There has been limited research showing that a simple perioperative smoking cessation intervention for a busy preadmission surgery clinic has success in reducing patients' smoking rates and intraoperative and immediate postoperative complications (Lee et al., 2013).

Age. Very young and older patients are at greater surgical risk as a result of an immature or a declining physiological status. These patients often present problems in temperature control during surgery. General anesthetics inhibit shivering and cause vasodilation, which results in heat loss. These anesthetic changes coupled with age-related physiological factors increase the risk for unintended hypothermia. Infants also have difficulty maintaining normal circulatory blood volume, causing a risk for dehydration and overhydration.

Older adults account for 55% of all those who undergo operative procedures (Kotthoff-Burrell et al., 2012). With advancing age patients have less physical capacity to adapt to the stress of surgery (Table 50-3). Thus the risk for surgical complications increases due to the physiological, cognitive/psychological, and sociological changes associated with aging (AORN, 2010; Nelson & Carrington, 2011).

Nutrition. Normal tissue repair and resistance to infection depend on adequate nutrition. Surgery increases the need for nutrients. Patients who are thin or obese are often deficient in protein and vitamins, putting them at greater risk for complications following surgery (Lewis et al., 2014). After surgery a patient requires at least 1500 kcal/day to maintain energy reserves. This intake is difficult to attain when a patient's food or fluid intake is limited after surgery or if a patient experiences postoperative nausea and vomiting (PONV). Traditionally patients gradually increase their dietary intake over 3 to 5 days after surgery until they can tolerate normal meals. Patients who enter surgery malnourished are more likely to have poor tolerance for anesthesia, negative nitrogen balance, delayed postoperative recovery, infection, and delayed wound healing. Current recommendations suggest replacing iron, vitamin B_{12}, and folate at least 28 days before scheduled elective surgery (Goodnough et al., 2011). Some studies show that recovery is enhanced in several ways: regulating the metabolic status of a patient before surgery (e.g., minimizing metabolic stress and insulin resistance by giving carbohydrate-based drinks and fluid loading) and after surgery (e.g., early oral feeding and giving prokinetic medications to enhance gastric motility, resulting in improved enteral feeding tolerance) (Awad and Lobo, 2011; Fearon and Luff, 2003).

Obesity. Patients who are morbidly obese typically live up to 20 years less than their average-weight counterparts (Dunham, 2013). According to the CDC (2015a), more than one third (34.9% or 78.6 million) of U.S. adults are obese, but the prevalence of morbid obesity isn't limited to adults. Approximately 17% (or 12.7 million) of children and adolescents ages 2 to 19 years are also obese (CDC, 2015b). As a patient's weight increases, his or her ventilatory and cardiac function reduces, increasing the risk for postoperative **atelectasis,** pneumonia, and death. Obstructive sleep apnea (OSA), hypertension, coronary artery disease, diabetes mellitus, and heart failure are **co-morbid** conditions in the **bariatric** (obese) population. Patients who are obese often have difficulty resuming normal physical activity after surgery because of the pain and fatigue caused by surgery in addition to preexisting impaired physical mobility. This combination of factors increases the risk of developing venous thromboembolism (VTE).

Excess weight placed on skin over bony prominences restricts blood flow and poses risks for pressure ulcers to form on the operating table. Obesity increases the risk of poor wound healing, wound infection, dehiscence, and evisceration because fatty tissue contains a poor blood supply, slowing the delivery of essential nutrients and antibodies needed for wound healing (see Chapter 48). In addition, surgeons

TABLE 50-3   Physiological Factors That Place the Older Adult at Risk During Surgery

Alterations	Risks	Nursing Implications
Cardiovascular System		
Degenerative change in myocardium and valves	Decreased cardiac reserve puts older adults at risk for decreased cardiac output, especially during times of stress (AORN, 2010)	Assess baseline vital signs for tachycardia, fatigue, and arrhythmias (AORN, 2010).
Rigidity of arterial walls and reduction in sympathetic and parasympathetic innervation to the heart	Alterations predispose patient to postoperative hemorrhage and rise in systolic and diastolic blood pressure	Maintain adequate fluid balance to minimize stress to the heart. Ensure that blood pressure level is adequate to meet circulatory demands.
Increased calcium and cholesterol deposits within small arteries; thickened arterial walls	Predispose patient to clot formation in lower extremities	Instruct patient in techniques of leg exercises and proper turning. Apply elastic stockings or intermittent pneumatic compression (IPC) devices. Administer anticoagulants as ordered by health care provider. Provide education regarding effects, side effects, and dietary considerations.
Integumentary System		
Decreased subcutaneous tissue and increased fragility of skin	Prone to pressure ulcers and skin tears	Assess skin every 4 hours; pad all bony prominences during surgery. Turn or reposition at least every 2 hours.
Pulmonary System		
Decreased respiratory muscle strength and cough reflex (AORN, 2010)	Increased risk for atelectasis	Instruct patient in proper technique for coughing, deep breathing, and use of spirometer. Ensure adequate pain control to allow for participation in exercises.
Reduced range of movement in diaphragm	Residual capacity (volume of air left in lung after normal breath) increased, reducing amount of new air brought into lungs with each inspiration	When possible, have patient ambulate and sit in chair frequently.
Stiffened lung tissue and enlarged air spaces	Blood oxygenation reduced	Obtain baseline oxygen saturation; measure throughout perioperative period.
Gastrointestinal System		
Gastric emptying delayed	Increases risk for reflux and indigestion (AORN, 2010)	Position patient with head of bed elevated at least 45 degrees. Reduce size of meals in accordance with ordered diet.
Renal System		
Decreased renal function, with reduced blood flow to kidneys	Increased risk of shock when blood loss occurs; increased risk for fluid and electrolyte imbalance (AORN, 2010)	For patients hospitalized before surgery, determine baseline urinary output for 24 hours.
Reduced glomerular filtration rate and excretory times	Limited ability to eliminate drugs or toxic substances	Assess for adverse response to drugs.
Decreased bladder capacity	Increased risk for urgency, incontinence, and urinary tract infections (AORN, 2010) (Sensation of need to void often does not occur until bladder is filled.)	Instruct patient to notify nurse immediately when sensation of bladder fullness develops. Keep call light and bedpan within easy reach. Toilet every 2 hours or more frequently if indicated.
Neurological System		
Sensory losses, including reduced tactile sense and increased pain tolerance	Decreased ability to respond to early warning signs of surgical complications	Inspect bony prominences for signs of pressure that patient is unable to sense. Orient patient to surrounding environment. Observe for nonverbal signs of pain.
Blunted febrile response during infection (AORN, 2010)	Increased risk of undiagnosed infection	Ensure careful, close monitoring of patient temperature; provide warm blankets; monitor heart function; warm intravenous fluids (AORN, 2010).
Decreased reaction time	Confusion and delirium after anesthesia; increased risk for falls	Allow adequate time to respond, process information, and perform tasks. Perform fall-risk screening and institute fall precautions. Screen for delirium with validated tools. Orient frequently to reality and surroundings.

TABLE 50-3	**Physiological Factors That Place the Older Adult at Risk During Surgery—cont'd**	
Alterations	**Risks**	**Nursing Implications**
Metabolic System		
Lower basal metabolic rate	Reduced total oxygen consumption	Ensure adequate nutritional intake when diet is resumed but avoid intake of excess calories.
Reduced number of red blood cells and hemoglobin levels	Reduced ability to carry adequate oxygen to tissues	Administer necessary blood products. Monitor blood test results and oxygen saturation.
Change in total amounts of body potassium and water volume	Greater risk for fluid or electrolyte imbalance	Monitor electrolyte levels and supplement as necessary. Provide cardiac monitoring (telemetry) as needed.

often have difficulty closing surgical wounds because of the thick adipose layer.

Obstructive Sleep Apnea. **Obstructive sleep apnea (OSA)** is a disorder of sleep and wakefulness resulting from periodic, partial, or complete obstruction of the upper airway during sleep. An individual's throat muscles intermittently relax and block the airway. The disorder is a combination of structural and neuromuscular dysfunction. Patients with OSA experience periodic episodes of apnea (stops breathing), resulting in significant **oxygen desaturation,** also referred to as intermittent hypoxia. During the apnea there is increasing negative intrathoracic pressure (down to −80 mm Hg), which makes it difficult for the heart to pump effectively against such a negative pressure; thus cardiac output decreases. In response to the oxygen desaturation, there is an arousal, which ends the apnea. The arousal is accompanied by a huge increase in sympathetic output, which causes a significant increase in blood pressure.

The disorder hinders daily functioning because of chronic fatigue and sleepiness and adversely affects health and longevity. Patients who suffer from OSA develop numerous complications, including hypertension, heart disease, vascular disease, neurological disease, and diabetes. Approximately 75% of adults with OSA are unaware they have OSA (Simpson et al., 2013). In addition, perioperative health care providers often fail to screen for OSA, resulting in a high prevalence of undiagnosed patients (Lockhart et al., 2013).

Patients with OSA who are to undergo surgery present a significant risk. Receiving sedatives, opioid analgesics, and general anesthesia causes relaxation of the upper airway and may worsen OSA. The risk is higher when a patient is sedated and lying on his or her back. Patients have experienced severe apnea and hypoxemia leading to death following surgical and diagnostic procedures under conscious sedation. Careful screening of patients for OSA is essential before surgery.

Immunosuppression. Patients with conditions that alter immune function (e.g., primary immune deficiency, acquired immunodeficiency syndrome (AIDS), cancer, bone marrow alterations, and organ transplants) are at an increased risk for developing infection after surgery. The risk for infection increases when patients receive radiation or chemotherapy for cancer treatment, take immunosuppressive medications to treat AIDS or prevent rejection after organ transplant, and require steroids to treat a variety of inflammatory or autoimmune conditions. Radiation sometimes is given before surgery to reduce the size of a cancerous tumor so it can be removed surgically. Ideally a surgeon waits to perform surgery 4 to 6 weeks after completion of radiation treatments because of the unavoidable effects that radiation has on normal tissue. Radiation thins the layers of the skin, destroys collagen, and impairs tissue perfusion. Otherwise the patient may face serious wound-healing problems.

Fluid and Electrolyte Imbalance. The body responds to surgery as a form of trauma. Severe protein breakdown causes a negative nitrogen balance (see Chapter 42) and hyperglycemia. Both of these effects decrease tissue healing and increase the risk of infection. As a result of the adrenocortical stress response, the body retains sodium and water and loses potassium in the first 2 to 5 days after surgery. The severity of the stress response influences the degree of fluid and electrolyte imbalance. Extensive surgery results in a greater stress response. A patient who is hypovolemic before surgery or who has serious electrolyte alterations is at significant risk during and after surgery. For example, an excess or depletion of potassium increases the chance of dysrhythmias during or after surgery. The risk of fluid and electrolyte alterations is even greater in patients with preexisting diabetes mellitus, renal disease, gastrointestinal (GI), or cardiovascular abnormalities.

Postoperative Nausea and Vomiting. The experience of having nausea and vomiting after surgery is uncomfortable and often immobilizing. PONV affects approximately 30% of patients in recovery rooms after surgery (Fetzer, 2015). It can lead to serious complications, including pulmonary aspiration, dehydration, and arrhythmias resulting from fluid and electrolyte imbalance. A patient who vomits frequently after surgery runs the risk of pulling apart surgical sutures. Patients predisposed to developing PONV include females, nonsmokers, those who have had a history of PONV or motion sickness, use of volatile anesthetics or nitrous oxide, and those who receive intraoperative or postoperative opioids (Kapoor et al., 2008). Patients with four or more risk factors have a higher incidence of PONV (Rothrock, 2015). Management of PONV begins before surgery.

Venous Thromboembolism. The Centers for Medicare and Medicaid Services (CMS, 2010) ruled deep vein thrombosis (DVT) (clot formed in the deep veins) after total knee and hip surgery as a never event. If a patient develops a DVT after surgery, Medicare and some private insurance companies withhold payment to the hospital because DVTs are typically preventable. The Joint Commission (TJC, 2015) has a set of accountability measures (i.e., quality measures that produce the greatest positive impact on patient outcomes when hospitals demonstrate improvement in them). One of the accountability measures is treatment and prevention of VTE. Some VTEs are subclinical (without symptoms), whereas others present as sudden pulmonary embolus or symptomatic DVT. Patients most at risk for developing VTE are those who undergo surgical procedures with a total anesthetic and surgical time of more than 90 minutes, or 60 minutes if the surgery involves the pelvis or lower limb; acute surgical admissions with inflammatory or intraabdominal conditions; and those expected to have significant reduction in mobility after surgery. In addition, patients are at higher risk if they have one or

more risk factors (National Institute for Health and Clinical Excellence [NICE], 2010):

- Active cancer or cancer treatment
- Age over 60 years
- Critical care admission
- Dehydration
- Known clotting disorders
- Obesity (body mass index [BMI] of 30 kg/m^2 or greater)

NURSING KNOWLEDGE BASE

Perioperative Communication

Perioperative nurses recognize the importance of providing continuity of care for surgical patients. In some settings perioperative nurses follow patients throughout the operative experience, assessing a patient's health status before surgery, identifying specific patient needs, teaching and counseling, preparing for the operating room (OR), and following a patient's recovery. However, different nurses and other health care providers usually care for a patient during each phase of the surgical experience. A smooth communication "hand-off" between caregivers is needed to ensure continuity of care and reduce risk of medical errors. Transitions from one care provider to another place patients at risk for injuries, missed care, and errors in translating information. TJC National Patient Safety Goals address the importance of accurate patient identification and communication (TJC, 2016). Nursing research shows that having a standardized checklist or protocol for hand-off communication between perioperative health care providers minimizes these risks (Boat and Spaeth, 2013; Petrovic et al., 2012).

Glycemic Control and Infection Prevention

Evidence supports a relationship between wound and tissue infection and surgical patients' blood glucose levels. Poor control of blood glucose levels (specifically hyperglycemia) during and after surgery increases patients' risks for adverse outcomes such as wound infection and mortality. Controlling blood sugars perioperatively reduces mortality in patients with or without diabetes who have general surgery and in patients who have cardiac surgery (Giakoumidakis et al., 2013; Kwon et al., 2013). Perioperative evaluation of patients coupled with appropriate insulin administration is a critical standard of care.

Pressure Ulcer Prevention

Patients who have surgery pose a unique challenge in pressure ulcer prevention. Patients are at risk intraoperatively for pressure ulcers as a result of sustained pressure from positioning on OR tables, changes in hemodynamics (blood pressure and perfusion) from anesthesia, use of multiple layers of drapes, and exposure of the skin to fluids used to irrigate wounds during surgery (Bulfone et al., 2012). You prevent pressure ulcers intraoperatively by carefully positioning patients and using pressure-relieving surfaces. After surgery, perform careful skin assessment and use appropriate pressure reduction strategies (see Chapter 48).

CRITICAL THINKING

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require you to anticipate information, analyze the data, and make decisions regarding your patient's care. During assessment, consider

Knowledge
- Anatomy and physiology of affected body systems
- Surgical risk factors
- Type of surgical procedure to be performed
- Surgical stress response
- Infection control practices

Experience
- Caring for patients who have had surgery
- Personal experience with surgery

ASSESSMENT
- Patient's and family members' expectations of surgery and recovery
- Physical examination focused on the patient's history and planned surgery
- Assessment of factors that pose surgical risks for the patient
- Patient's previous experience with surgery
- Patient's cultural perspectives for surgery
- Patient's coping resources
- Results of preoperative diagnostic tests

Standards
- Apply intellectual standards of specificity, accuracy, and completeness
- Apply AORN perioperative standards and practices
- Apply ASPAN standards for perianesthesia nursing
- Apply The Joint Commission Patient Safety Goals

Attitudes
- Use discipline in collecting a complete patient history
- Responsibility
- Use perseverance to ensure a comprehensive assessment

FIGURE 50-1 Critical thinking model for surgical patient assessment. *AORN,* Association of periOperative Registered Nurses; *ASPAN,* American Society of PeriAnesthesia Nurses.

all elements that build toward making an appropriate nursing diagnosis (Figure 50-1).

When caring for a patient having surgery, integrate knowledge regarding the patient's specific clinical situation along with previous experiences in caring for surgical patients. Apply this knowledge using a patient-centered care approach, partnering with your patient to make clinical decisions. Using critical thinking attitudes (see Chapter 15) ensures that a plan of care is comprehensive and incorporates evidence-based principles for successful perioperative care. A key attitude for a perioperative nurse is responsibility (i.e., being responsible not only for standards of care but being a patient advocate as well). The use of professional perioperative standards developed by the Agency for Health Care Research and Quality (AHRQ) (http://www.ahrq.gov), the **Association of periOperative Registered Nurses (AORN)** (http://www.aorn.org), and the **American Society of PeriAnesthesia Nurses (ASPAN)** (http://www.aspan.org/) provides valuable guidelines for perioperative management and evaluation of process and outcomes. TJC Hospital National Patient Safety Goals include two sets of recommendations for perioperative care: prevent infection and prevent mistakes in surgery (TJC, 2016). Always review these guidelines within the

context of new emerging evidence-based practice, agency policies, and the scope of practice of the state in which you practice.

PREOPERATIVE SURGICAL PHASE

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care.

Patients having surgery enter the health care setting in different stages of health. For example, a patient enters the hospital or ambulatory surgery center (ASC) on a predetermined day feeling relatively healthy and prepared to face elective surgery, while another person in a motor vehicle crash faces emergency surgery with no time to prepare. The ability to establish rapport and maintain a professional relationship with a patient is essential during the preoperative phase. Patients having surgery meet many health care personnel, including surgeons, nurse anesthetists, anesthesiologists, surgical technologists, and nurses. All play a role in a patient's care and recovery. Family members attempt to provide support through their presence but face many of the same stressors as the patient. You need to form a caring relationship (see Chapter 7) and effectively communicate (see Chapter 24) with the patient and family to gain a patient's trust. This helps you to learn the depth of information needed to provide a relevant and appropriate plan of care. Be culturally sensitive when you assess a patient's physical, psychological, emotional, sociocultural, and spiritual well-being; recognize the degree of surgical risk; coordinate diagnostic tests; identify nursing diagnoses and nursing interventions; and establish outcomes in collaboration with patients and their families. Communicate pertinent data and the plan of care to surgical team members.

◆ Assessment

During the assessment process, thoroughly assess each patient and critically analyze findings to ensure you make patient-centered clinical decisions required for safe nursing care. The goal of the preoperative assessment is to identify a patient's normal preoperative function and the presence of any risks to recognize, prevent, and minimize possible postoperative complications. The thoroughness of your assessment will depend on the surgical setting, the time you have with a patient, and the urgency of a procedure. Ambulatory and same-day surgical programs offer challenges in gathering a complete assessment in a short time. A multidisciplinary team approach is essential. Patients are admitted only hours before surgery; thus it is important for you to organize and verify data obtained before surgery and implement a perioperative plan of care. This occurs both in ASCs and with patients who require a hospital stay.

Most assessments begin before admission for surgery in a health care provider's office, preadmission clinic, or anesthesia clinic or by telephone. Some patients answer a self-report inventory before arriving to a center. Other times a health care provider performs a physical examination or orders laboratory tests. Nurses begin teaching, answering questions, and completing paperwork before surgery to streamline patient care on the day of surgery. When surgery is emergent, often little time is available; thus assessment must be prioritized to a patient's presenting clinical condition and risk factors.

Through the Patient's Eyes. When there is time to conduct a thorough assessment, begin by determining a patient's expectations of surgery and the road to recovery. Is the patient able to identify or describe the type of surgery scheduled? Does he or she understand the

expected care and anticipated length of stay after surgery? If not, what does the patient or family want to know? Does the patient expect full pain relief or simply to have his or her pain reduced after surgery? Does the patient expect to be independent immediately after surgery, or does he or she expect to be fully dependent on the nurse or family? These are only a few of the questions that you need to ask to establish a plan of care that matches a patient's needs and expectations. Listen to the patient's explanation, be attentive, and begin to explain what surgery will involve. You need to form a relationship with the patient so shared decision making will occur. By opening an assessment with these types of questions, the patient will become your partner and share the details you need to learn about his or her health.

Nursing History. A preoperative nursing history includes information similar to that described in Chapter 31. If a patient is unable to relay all of the necessary information, rely on family members (if appropriate) as resources. As with any admission to a health care agency, include information about advance directives. Ask if a patient has a durable power of attorney for health care or a living will (see Chapter 23) and include a copy in the patient's medical record. The law requires advance directive identification for patients of all ages and for all surgical procedures. Often directives are modified before surgery but are reestablished after postoperative stabilization. To help ensure a thorough and accurate nursing assessment, electronic health records provide standardized documentation forms for preoperative assessment. Be sure to use all drop-down menus to most clearly portray a patient's history but also be willing to enter full text descriptions as needed.

Medical History. A review of a patient's medical history includes past illnesses and surgeries and the primary reason for seeking medical care. A history screens candidates for surgery for major medical conditions that increase the risk for complications during or after surgery (Table 50-4). For example, a patient who has a history of heart failure is at risk for a further decline in cardiac function during and after surgery. The patient with heart failure in the preoperative period often requires beta-blocker medications, intravenous (IV) fluids infused at a slower rate, or administration of a diuretic after blood transfusions. Box 50-1 provides a list of assessment questions for a patient with a cardiac history. If a patient has any surgical risk from a medical condition, surgery as an outpatient may not be advisable, or it will be necessary to take special precautions. Also ask about a family history for anesthetic complications such as malignant hyperthermia (an inherited disorder). Malignant hyperthermia is a life-threatening condition that can occur during surgery.

Surgical History. A review of a patient's past experience with surgery reveals physical and psychological responses that may occur during the current planned procedure. Complications such as anaphylaxis or malignant hyperthermia during previous surgery alert you to the need for preventive measures and availability of appropriate emergency equipment. A history of postoperative complications such as persistent vomiting or uncontrolled pain helps in the selection of appropriate medications (as ordered by the medical team). Reports of severe anxiety before a previous surgery identify the need for additional emotional support, medications, and preoperative teaching. Inform the surgeon or anesthesiologist of your findings, especially when you believe that medications are indicated.

Risk Factors. Your knowledge of potential surgical risk factors allows you to focus your assessment and screen patients carefully so you can take necessary precautions in planning perioperative care.

TABLE 50-4   Medical Conditions That Increase Risks of Surgery

Type of Condition	Reason for Risk
Bleeding disorders (thrombocytopenia, hemophilia)	Increases risk of hemorrhage during and after surgery.
Diabetes mellitus	Increases susceptibility to infection and impairs wound healing from altered glucose metabolism and associated circulatory impairment. Stress of surgery often results in hyperglycemia (Lewis et al., 2014).
Heart disease (recent myocardial infarction, dysrhythmias, heart failure) and peripheral vascular disease	Stress of surgery causes increased demands on myocardium to maintain cardiac output. General anesthetic agents depress cardiac function.
Hypertension	Increases risk for cardiovascular complications during anesthesia (e.g., stroke, inadequate tissue oxygenation).
Obstructive sleep apnea	Administration of opioids increases risk of airway obstruction after surgery. Patients desaturate as revealed by drop in oxygen saturation by pulse oximetry.
Upper respiratory infection	Increases risk of respiratory complications during anesthesia (e.g., pneumonia and spasm of laryngeal muscles).
Renal disease	Alters excretion of anesthetic drugs and their metabolites, increasing risk for acid-base imbalance and other complications.
Liver disease	Alters metabolism and elimination of drugs administered during surgery and impairs wound healing and clotting time because of alterations in protein metabolism.
Fever	Predisposes patient to fluid and electrolyte imbalances and sometimes indicates underlying infection.
Chronic respiratory disease (emphysema, bronchitis, asthma)	Reduces patient's means to compensate for acid-base alterations (see Chapter 41). Anesthetic agents reduce respiratory function, increasing risk for severe hypoventilation.
Immunological disorders (leukemia, acquired immunodeficiency syndrome [AIDS], bone marrow depression, and use of chemotherapeutic drugs or immunosuppressive agents)	Increases risk of infection and delayed wound healing after surgery.
Abuse of alcohol, street drugs	People abusing drugs sometimes have underlying disease (human immunodeficiency virus [HIV], hepatitis) that affects healing. Alcohol addiction causes unpredictable reactions to anesthesia. People go into withdrawal during and after surgery.
Chronic pain	Regular use of pain medications often results in higher tolerance. Increased doses of analgesics are sometimes necessary to achieve postoperative pain control.

BOX 50-1   Nursing Assessment Questions: Cardiac History

Nature of the Problem
- Do you have a history of heart attack, heart failure, angina (chest pain), irregular heartbeat, or valve disease?
- Which medications do you take?
- Are you taking any vitamins or other supplements?
- Have you had any recent medical testing or procedures on your heart (e.g., cardiac catheterization or echocardiogram)?

Signs and Symptoms
- Are you having any chest pain?
- How do you sleep at night (position, use of pillows, awakened with chest pain)?
- Do your feet swell?
- Are you short of breath, or do you have any difficulty breathing?

Onset and Duration
- How often do you have chest pain, when does it start, how long does it last, what alleviates it?

- When do your feet swell (all the time, end of the day, only after a busy day)?
- When do you become short of breath?

Severity
- On a scale of 0 to 10 (with 0 being no pain and 10 the worst pain), what number do you give your chest pain?
- Describe your usual activity level. Can you climb stairs; can you do housework?
- Do you exercise regularly? What exercise?

Self-Management and Culture
- Have you changed your activity level, sleep amount, diet, or fluid intake recently?
- Are you taking any herbal or over-the-counter medications?

Through the Patient's Eyes
- How are you feeling about your upcoming surgery? Has it affected your symptoms?
- Are you having any additional stress currently?

BOX 50-2 The STOP-BANG Questionnaire

Height _____ cm /inches Weight _____ lbs/kg
  Age _____
  Male/Female
  BMI _____
  Collar size of shirt: S, M, L, XL, or _____ cm /inches
  Neck circumference* _____ cm

1. **S**noring
   Do you *s*nore loudly (louder than talking or loud enough to be heard through closed doors)?
   Yes No
2. **T**ired
   Do you often feel *t*ired, fatigued, or sleepy during daytime?
   Yes No
3. **O**bserved
   Has anyone *o*bserved you stop breathing during your sleep?
   Yes No
4. Blood **P**ressure
   Do you have or are you being treated for high blood *p*ressure?
   Yes No
5. **B**MI
   *B*MI more than 35 kg/m^2?
   Yes No
6. **A**ge
   *A*ge over 50 years old?
   Yes No
7. **N**eck circumference (measure with approved measuring tape)*
   *N*eck circumference greater than 40 cm?
   Yes No
8. **G**ender
   *G*ender male?
   Yes No

Score of 4—High sensitivity of 88% for identifying severe obstructive sleep apnea (OSA)
Score of 5 or more—High risk of OSA; a score of 6 is more specific

Modified from Chung F et al: Predictive performance of the STOP-BANG score for identifying obstructive sleep apnea in obese patients, *Obes Surg* 23(12):2050, 2013.
BMI, Body mass index.
*Neck circumference is measured by staff.

Consider if any of the risk factors described earlier affect your patient. Collaborate closely with the health care provider when you identify a risk factor that requires therapy. For example, some patients need to stop taking estrogen-containing oral contraceptives or hormone-replacement therapy 4 weeks before elective surgery to reduce risk of thromboembolism (NICE, 2010). Carefully screen patients who have signs and symptoms of suspected OSA. Include the patient's sleeping partner as appropriate to assess for signs of OSA such as snoring. Also determine if the patient uses a continuous positive airway pressure (CPAP), noninvasive positive-pressure ventilation (NIPPV), or apnea monitoring at home. Instruct patients who use CPAP or NIPPV to bring their machine to the hospital or surgery center. Many hospitals are now making OSA screening mandatory using evidence-based tools, such as the STOP-BANG sleep apnea assessment tool (Box 50-2) (Chung et al., 2013).

Some patients need a detailed nutritional assessment to determine surgical risk. If a patient presents with signs of malnourishment, perform a nutritional screening using your agency's tool or confer with a clinical dietitian (see Chapter 45). If a patient has a smoking history, use the information to plan aggressive postoperative pulmonary hygiene, including more frequent turning, use of incentive spirometry, deep breathing, and coughing. Smoking causes hypercoagulability of the blood and increased risk for clot formation. Provide preventive measures to decrease the risk for clots such as pneumatic compression stockings, leg exercises, and early ambulation.

Medications. Review whether a patient is taking any medications that increase the risk for surgical complications (Table 50-5). Many medications interact unpredictably with anesthetic agents during surgery (Lehne, 2016). Sometimes surgeons temporarily discontinue or adjust doses of a patient's prescription or over-the-counter (OTC) medications or herbal supplements before surgery. If you are in an outpatient setting, instruct patients to ask their surgeons whether they should take their usual medications the morning of surgery. Often preprinted instruction sheets given to patients in physician offices contain this information. If you are in an acute care setting, determine if your patient discontinued medications appropriately. If a patient is having inpatient surgery, all prescription medications taken before surgery are discontinued automatically after surgery unless reordered. Be vigilant in reviewing a surgeon's preoperative orders so you administer the correct medications and hold those not to be given. It is important that, as a patient moves through different areas (e.g., holding area to the OR), a complete list of medications is communicated accurately during hand-off report (TJC, 2016).

Allergies. Allergies to medications, latex, and topical agents used to prepare the skin for surgery create significant risks for patients during surgery. An allergic response to any agent is potentially fatal, depending on severity. Latex allergies are on the rise, with 1% to 6% of the general population and 8% to 12% of the health care workforce sensitive to latex (CDC, 2011). Patients most at risk for a latex allergy include people with genetic predisposition to latex allergy, children with spina bifida, patients with urogenital abnormalities or spinal cord injury (because of a long history of urinary catheter use), patients with a history of multiple surgeries, health care professionals, and workers who manufacture rubber products. Patients with an allergy to certain foods such as bananas, chestnuts, kiwi fruit, avocadoes, potatoes, strawberries, nectarine, tomatoes, and wheat often have a cross-sensitivity to latex (Cleveland Clinic, 2014). Symptoms of a latex allergy vary in severity (e.g., contact dermatitis with redness, inflammation, and blisters; contact urticaria with pruritus, redness, and swelling; hay fever–like symptoms; and anaphylaxis).

If you identify that a patient has an allergy, provide an allergy identification band at the time of admission that remains on until discharge. List all allergies in the patient's medical record. It is also common to list allergies on the front of paper charts.

Smoking Habits. Screen all patients for a history of smoking, including cigarettes, cigars, and pipes. This is usually included in the nursing health history. Ask how long a patient has smoked and the number of cigarettes/cigars smoked daily. Use this information to plan for aggressive pulmonary hygiene, including more frequent turning, deep breathing, coughing, and use of incentive spirometry after surgery.

Alcohol Ingestion and Substance Use and Abuse. Habitual use of alcohol and illegal drugs predisposes patients to adverse reactions to anesthetic agents. Some patients experience a cross-tolerance to anesthetic agents and analgesics, resulting in the need for

TABLE 50-5	Medications with Special Implications for the Surgical Patient
Drug Class	**Effects During Surgery**
Antibiotics	Potentiate (enhance action of) anesthetic agents. If taken within 2 weeks before surgery, aminoglycosides (gentamicin, neomycin, tobramycin) may cause mild respiratory depression from depressed neuromuscular transmission.
Antidysrhythmics	Medications (e.g., beta blockers) can reduce cardiac contractility and impair cardiac conduction during anesthesia.
Anticoagulants	Medications such as warfarin (Coumadin) or aspirin alter normal clotting factors and thus increase risk of hemorrhaging. Discontinue at least 48 hours before surgery.
Anticonvulsants	Long-term use of certain anticonvulsants (e.g., phenytoin [Dilantin] and phenobarbital) alters metabolism of anesthetic agents.
Antihypertensives	Medications such as beta blockers and calcium channel blockers interact with anesthetic agents to cause bradycardia, hypotension, and impaired circulation. They inhibit synthesis and storage of norepinephrine in sympathetic nerve endings.
Corticosteroids	With prolonged use, corticosteroids such as prednisone cause adrenal atrophy, reducing the ability of the body to withstand stress. Before and during surgery, dosages are often increased temporarily.
Insulin	A patient's insulin requirements fluctuate after surgery. For example, some patients need increased doses due to the stress response from surgery. Other patients need less insulin due to decreased nutritional intake following surgery.
Diuretics	Diuretics such as furosemide (Lasix) potentiate electrolyte imbalances (particularly potassium) after surgery.
Nonsteroidal antiinflammatory drugs (NSAIDs)	NSAIDs (e.g., ibuprofen) inhibit platelet aggregation and prolong bleeding time, increasing susceptibility to postoperative bleeding.
Herbal therapies: ginger, gingko, ginseng	These herbal therapies have the ability to affect platelet activity and increase susceptibility to postoperative bleeding. Ginseng increases hypoglycemia with insulin therapy.

higher-than-normal doses. Patients with a history of excessive alcohol ingestion are often malnourished, which delays wound healing. These patients are also at risk for liver disease, portal hypertension, and esophageal varices (which increase the risk of bleeding). A patient who habitually uses alcohol and is required to remain in the hospital longer than 24 hours is also at risk for acute alcohol withdrawal and its more severe form, delirium tremens (DTs). It is important to assess all age-groups because there is a high prevalence of at-risk drinking and binge drinking (17% overall) in adults ages 18 years and older (CDC, 2012b). The CDC further reports that individuals with household incomes greater than $75,000 have the highest binge-drinking prevalence (20.2%), but those with household incomes less than $25,000 had the highest frequency (5 episodes per month) and intensity (8.5 drinks on occasion).

Pregnancy. During preoperative assessment routinely ask women of childbearing age who are scheduled for surgery about their last menstrual period and if it was "typical" for them. Also ask if they have had unprotected sex in the last month. Because many women do not know they are pregnant early in the first trimester, many institutions require a pregnancy test when a patient is scheduled for surgery. The perioperative plan of care addresses not one, but two patients: the mother and the developing fetus. A pregnant patient has surgery only on an emergent or urgent basis. Because all of the mother's major systems are affected during pregnancy, the risk for intraoperative complications is increased. General anesthesia is administered with caution because of the increased risk of fetal death and preterm labor. Regional anesthesia is used in preference to general anesthesia when appropriate (Reitman and Flood, 2011). Psychological assessment of mother and family is also essential.

Perceptions and Knowledge Regarding Surgery. A patient's past experience with surgery influences physical and psychological responses to a procedure. Assess the patient's previous experiences with surgery as a foundation for anticipating his or her needs, providing teaching, addressing fears, and clarifying concerns. Ask him or her to discuss the previous type of surgery, level of discomfort, extent of disability, and overall level of care required. Address any complications that the patient experienced. Prior anesthesia records are a useful source of information if previous surgical problems occurred.

The surgical experience affects the family unit as a whole. Therefore prepare both the patient and the family for the surgical experience. Understanding a patient's and family's knowledge and expectations (during recovery and convalescence and following discharge) allows you to plan teaching and provide individualized emotional support measures.

Each patient fears surgery. Some fears are the result of past hospital experiences, warnings from friends and family, or lack of knowledge. Assess the patient's understanding of the planned surgery, its implications, and planned postoperative activities. Ask questions such as, "Tell me what you think will happen before and after surgery" or "Explain what you know about surgery." Nurses face ethical dilemmas when patients are misinformed or unaware of the reason for surgery. Confer with the surgeon if a patient has an inaccurate perception or knowledge of the surgical procedure before the patient is sent to the surgical suite. Also determine whether the health care provider explained routine preoperative and postoperative procedures and assess the patient's readiness and willingness to learn. When a patient is well prepared and knows what to expect, reinforce his or her knowledge.

Support Sources. Always assess who comprises a patient's family and their level of support. The patient usually cannot immediately assume the same level of physical activity enjoyed before surgery. With **ambulatory surgery,** patients and/or family caregivers assume responsibility for postoperative care. The family caregiver frequently is an important resource for a patient with physical limitations and provides the emotional support needed to motivate the patient to return to his or her previous state of health. Ask the family caregiver if he or she is able to provide support. Sometimes the caregiver remembers preoperative and postoperative teaching better than the patient. Patients having ambulatory surgery will receive a postdischarge phone call to evaluate their recovery. Because patients, especially older adults, are

unable to hear or reach a phone after surgery, identify if a family member will be staying with the patient to answer the phone. Your responsibility is to fully prepare a patient and any family caregiver for patient self-care if the patient returns home. This includes providing information so the patient can anticipate any problems, know how to act, and be able to perform care measures (e.g., medication administration, dressing changes, exercises). Often a family member becomes the patient's coach, offering valuable support after surgery when a patient's participation in care is vital.

Occupation.   Surgery often results in physical changes and limits that prevent a person from immediately returning to work. Assess the patient's occupational history to anticipate the possible effects of surgery on recovery, return to work, and eventual work performance. Explain postoperative restrictions such as lifting, walking, or climbing stairs before a patient returns to work. When a patient is unable to return to a job, refer to a social worker and/or occupational therapist for job-training programs or to seek economic assistance.

Preoperative Pain Assessment. Surgical manipulation of tissues, treatments, and positioning on the OR table contribute to postoperative pain. Conduct a comprehensive pain assessment before surgery (see Chapter 44), including the patient's and family's expectations for pain management following surgery. Ask patients to describe their perceived tolerance to pain, past experiences, and prior successful interventions. Providing patient education about pain reduces preoperative anxiety, which is frequently associated with postoperative pain (Alanazi, 2014). Teach patients before surgery how to use a pain scale so they are prepared to rate their pain after surgery (see Chapter 44).

Review of Emotional Health.   Surgery is psychologically stressful and often creates anxiety in patients and their families. Patients often feel powerless over their situation. Potential disruptions in lifestyle, a lengthy recovery period at home, and uncertainty about the long-term effects of surgery on a patient's life place stress on patients and their families. When a patient has a chronic illness, the family is either fearful that surgery will result in further disability or hopeful that it will improve the patient's lifestyle. To understand the effect of surgery on a patient's and family's emotional health, assess the patient's feelings about surgery, self-concept, body image, and coping resources.

It is difficult to assess a patient's feelings thoroughly when ambulatory surgery is scheduled because you do not have much time to establish a therapeutic relationship with the patient. You can address these concerns initially with the patient during a home visit or on the telephone before surgery. In a hospital room choose a private time for discussion after completing admitting procedures or diagnostic tests. Explain that it is normal to have fears and concerns. A patient's ability to share feelings partially depends on your willingness to listen, be supportive, and clarify misconceptions. Assure patients of their right to ask questions and seek information.

Self-Concept.   Patients with a positive self-concept are more likely to approach surgical experiences appropriately. Assess self-concept by asking patients to identify personal strengths and weaknesses (see Chapter 34). Patients who quickly criticize or scorn their own personal characteristics may have little self-regard or may be testing your opinion of their character. Poor self-concept hinders the ability to adapt to the stress of surgery and aggravates feelings of guilt or inadequacy.

Body Image.   Surgery or surgical removal of any body part often leaves permanent scars, alteration in body function, or concern over mutilation. Loss of body functions (e.g., with a colostomy or amputation) compound a patient's fears. Assess patients' perceptions of body image alterations from surgery. Individuals respond differently depending on their culture, self-concept, and self-esteem (see Chapter 34).

Surgery, such as removal of a breast, an ostomy, or removal of the prostate gland, sometimes changes the physical or psychological aspects of a patients' sexuality. Some surgeries, such as a hernia repair or cataract extraction, require patients to temporarily refrain from sexual intercourse until they return to normal physical activity. Encourage patients to express concerns about their sexuality. A patient facing even temporary sexual dysfunction requires understanding and support. Hold discussions about the patient's sexuality with his or her sexual partner so the partner gains a shared understanding of how to cope with limitations in sexual function (see Chapter 35).

Coping Resources. Assessment of patients' feelings and self-concept reveals whether they have the ability to cope with the stress of surgery. Thus you need to ask patients about stress management and how they typically cope with stress. Physiologically, stress causes activation of the endocrine system, resulting in the release of hormones and catecholamines, which increases blood pressure, heart rate, and respiration. Platelet aggregation also occurs, along with many other physiological responses. Be aware of these responses and help with stress management by offering healthy coping strategies, such as relaxation exercises (see Chapters 33 and 38). Involve social work or clergy as needed.

Cultural and Spiritual Factors.   Culture is a system of beliefs and values developed over time and passed on through many generations. Patients come from diverse cultural, educational, geographical, and spiritual backgrounds that affect the way each patient perceives and reacts to the surgical experience. A recent study shows that sometimes there is a discrepancy between the information provided before surgery and a patient's expectation, which highlights why nurses need to listen to patients to identify their expectations (Tocher, 2014). If you do not acknowledge and plan for cultural and spiritual differences in the perioperative plan of care, your patient may not achieve desired surgical outcomes (Box 50-3). To bridge cultural differences, you explore and respect your patients' beliefs as well as their meaning of illness, preferences, and needs. Understanding a patient's cultural and ethnic heritage helps you better care for a patient having surgery. Although it is important to recognize and plan for differences on the basis of culture, it is also necessary to recognize that members of the same culture are individuals and do not always hold these shared beliefs.

Physical Examination.   Conduct a partial or complete physical examination, depending on the amount of time available and the patient's preoperative condition. Chapter 31 describes physical assessment techniques. Assessment focuses on a patient's medical history and on body systems that the surgery is likely to affect. While completing a nursing assessment, you validate existing information, reinforce preoperative teaching, and review discharge instructions.

General Survey.   Observe a patient's general appearance. Gestures and body movements (gait, posture, purposeful movement) may reflect decreased energy or weakness caused by illness. Height, body weight, and history of recent weight loss are important indicators of nutritional status and are used to calculate medication dosages. Preoperative vital signs, including blood pressure while sitting and standing, and pulse oximetry provide important baseline data with which to compare alterations that occur during and after surgery, including response to anesthetics and medications and fluid and electrolyte abnormalities (see Chapter 42). An elevated temperature is cause for concern. If a patient has an underlying infection, elective surgery is often postponed until the infection is treated or resolved. An

elevated body temperature also alters drug metabolism and increases the risk for fluid and electrolyte changes. Notify the surgeon immediately if a patient has an elevated temperature.

Head and Neck. To determine if your patient is dehydrated, you assess your patient's oral mucous membranes. Dehydration increases the risk for serious fluid and electrolyte imbalances during surgery. Inspect the area between the gums and cheek, the soft palate, and the nasal sinuses. Sinus drainage that is yellow or greenish may indicate respiratory or sinus infection. To rule out the presence of local or

---

---

systemic infection, palpate the cervical lymph nodes and note any enlargement, which indicates systemic disease.

During the examination of the oral mucosa, identify any loose or capped teeth because they can become dislodged during endotracheal intubation. Note the presence of dentures, prosthetic devices, or piercings so they can be removed before surgery, especially if the patient receives general anesthesia.

Integument. The overall condition of the skin reveals a patient's level of hydration. Carefully inspect the skin, especially over bony prominences such as the heels, elbows, sacrum, back of head, and scapula. In patients who are obese, separate the body folds to ensure that you examine the skin thoroughly. During surgery patients often lie in a fixed position for several hours, placing them at increased risk for pressure ulcers (see Chapter 48). Although physiological blood and lymphatic flow rates vary among patients, capillary pressures may increase to as much as 150 mm Hg during prolonged, unrelieved pressure without a position change (AORN, 2015). The normal pressure needed to keep capillaries open (12 to 32 mm Hg) was identified in classic research (Landis, 1930; Williams et al., 1988). When the intensity of pressure exerted on capillaries exceeds 12 to 32 mm Hg, ischemic injury to the skin can develop. Consider the type of surgery a patient will undergo and the position that is required on the OR table (Figure 50-2) to identify areas at risk for pressure ulcer formation.

Multiple factors affect skin integrity during and after surgery. For example, chronic use of steroids increases a patient's susceptibility to skin tears. Older adults are at high risk for alteration in skin integrity from decrease in epidermis, positioning (pressure forces), and repositioning on the OR table (shearing forces).

Thorax and Lungs. Assess a patient's breathing pattern and chest excursion to detect presence of a decline in ventilation. When ventilation is reduced, a patient is at increased risk for respiratory complications (e.g., atelectasis) following surgery. Auscultation of breath sounds indicates whether the patient has pulmonary congestion or narrowing of airways, which can postpone a surgery. Breath sounds provide an important baseline for a patient's condition. Certain anesthetics potentially cause laryngeal muscle spasm. If you auscultate wheezing in the airways before surgery, a patient is at risk for further airway narrowing during surgery and after extubation (removal of the endotracheal tube); therefore notify health care providers immediately.

Heart and Vascular System. If a patient has a history of heart disease, assess the character of the apical pulse and listen to heart sounds. Assessment of peripheral pulses, capillary refill, and color and

FIGURE 50-2 Examples of patient positions requiring a lithotomy position during surgery. **A,** Low. **B,** Standard. **C,** High. **D,** Exaggerated. (From Rothrock J: *Alexander's care of the patient in surgery,* ed 15, St Louis, 2015, Mosby.)

temperature of extremities is particularly important for patients undergoing vascular or orthopedic surgery and when you know that a patient will have constricting bandages or casts on an extremity after surgery. Screen a patient for one or more of the three primary causative factors of DVT formation (Virchow's triad: venous stasis, vessel wall injury, and hypercoagulability [noted in coagulation laboratory tests]) (AORN, 2015). If peripheral pulses are not palpable, use a Doppler instrument for assessment of their presence. Acceptable capillary refill occurs in less than 2 seconds. Postoperative changes in circulatory status in a patient who had adequate circulation before surgery indicates impaired circulation.

Abdomen. Alterations in GI function after surgery often result in decreased or absent bowel sounds and abdominal distention. Assess the patient's usual abdominal anatomy for size, shape, symmetry, and presence of distention before surgery. Ask how often the patient has bowel movements and inquire about the color and consistency of stools. Auscultate bowel sounds over all four abdominal quadrants.

Neurological Status. A surgical patient's level of consciousness changes as a result of anesthesia, sedatives, and complications that may develop during surgery. Preoperative assessment of baseline neurological status is important for all patients. The baseline neurological status helps with the assessment of ascent (awakening) from anesthesia. Observe a patient's level of orientation, alertness, mood, and ease of speech, noting whether he or she answers questions appropriately and is able to recall recent and past events. Patients who have surgery for neurological disease (e.g., brain tumor or aneurysm) may demonstrate an impaired level of consciousness or altered behavior. If a patient is scheduled for spinal or regional anesthesia, preoperative assessment of gross motor function and strength is important. Spinal anesthesia causes temporary paralysis of the lower extremities (see Chapter 44). Be aware of a patient entering surgery with weakness or impaired mobility of the lower extremities and communicate this to the perioperative team so care providers do not become alarmed when full motor function does not return as the anesthetic wears off.

Diagnostic Screening. Patients undergo diagnostic tests and procedures for preexisting abnormalities before surgery. Patients scheduled for elective or ambulatory surgery usually have tests done several days before surgery. Testing done the day of surgery is usually limited to tests such as glucose monitoring for a patient with diabetes, or an electrocardiogram (ECG) for patients with heart disease. If tests reveal severe problems, a surgeon or anesthesiologist will postpone surgery until the condition stabilizes. As a preoperative nurse you coordinate the completion of tests and verify that a patient is properly prepared. Be familiar with the purpose of diagnostic tests, know a patient's results, and alert a surgeon or anesthesiologist when findings are abnormal.

A patient's medical history, physical assessment findings, and surgical procedure determine the type of tests ordered. For example, a type and cross-match for blood are indicated before surgery for procedures in which blood loss is expected (e.g., hip and knee replacements) in case a patient needs a blood transfusion during surgery. The surgeon designates the number of blood units to have available during surgery. Table 50-6 gives the purpose and normal values for common blood tests.

Maintenance of circulating blood volume is critical for any patient undergoing surgery and is accomplished with administration of whole blood or blood components. Patients undergoing elective surgery who will most likely need blood products will have a pretransfusion type and screen sample taken 1 to 7 days before surgery (see agency policy) (Rothrock, 2015). This test ensures blood compatibility (if a

transfusion is needed) and avoids antibodies that may emerge in response to exposure through transfusions or a patient's disease. Autotransfusion (i.e., the reinfusion of a patient's own blood intraoperatively), is more common today (Rothrock, 2015). During intraoperative autotransfusion (cell salvage) blood is collected as it is lost during the surgery and reinfused to the patient after it is filtered and washed. Predated (up to 1 month before surgery) autologous blood donation is in decreasing use (Rothrock, 2015).

◆ **Nursing Diagnosis**

Cluster the patterns of defining characteristics from your assessment to identify nursing diagnoses relevant for a surgical patient (Box 50-4). A patient with preexisting health problems is likely to have a variety of risk diagnoses. For example, a patient with preexisting bronchitis who has abnormal breath sounds and a productive cough is at risk for *Ineffective Airway Clearance.* The nature of the surgery and assessment of the patient's health status provide defining characteristics and risk factors for a number of nursing diagnoses. For example, because a patient will have a surgical incision and an IV infusion, there is a risk for developing infection at the surgical site, in the bloodstream (sepsis), or phlebitis. A diagnosis of *Risk for Infection* requires attention from admission through recovery.

The related factors for each diagnosis establish directions for nursing care that is provided during one or all surgical phases. For example, the diagnosis of *Ineffective Airway Clearance related to abdominal pain* requires different interventions than the diagnosis *Ineffective Airway Clearance related to excess mucus.* Preoperative nursing diagnoses allow nursing staff to take precautions and actions so care provided during the intraoperative and postoperative phases is consistent with the patient's needs.

Nursing diagnoses made before surgery also focus on the potential risks a patient may face after surgery. Preventive care is essential to manage the surgical patient effectively. The following are common nursing diagnoses relevant to the patient having surgery:

- *Ineffective Airway Clearance*
- *Anxiety*
- *Ineffective Coping*
- *Impaired Skin Integrity*
- *Risk for Aspiration*
- *Risk for Perioperative Positioning Injury*
- *Risk for Infection*
- *Deficient Knowledge (Specify)*
- *Impaired Physical Mobility*
- *Ineffective Thermoregulation*
- *Nausea*
- *Acute Pain*
- *Delayed Surgical Recovery*

◆ **Planning**

During planning synthesize information to establish a plan of care based on a patient's nursing diagnoses (see the Nursing Care Plan). Apply critical thinking in the selection of nursing interventions (Figure 50-3). For example, apply knowledge of adult learning principles, standards for preoperative education (AORN, 2014), and a patient's unique learning needs and anticipated needs following discharge to formulate a well-designed **preoperative teaching plan** for the diagnosis of *Deficient Knowledge.* Critical thinking ensures that a patient's plan of care integrates knowledge, previous experiences, critical thinking attitudes, and established standards of practice. Previous experience in caring for surgical patients helps establish approaches to patient care (e.g., complications to prevent and anticipate and methods to reduce anxiety). Use professional standards when selecting interventions for

TABLE 50-6   Common Laboratory Tests for Surgical Patients

Test	Normal Values*	SIGNIFICANCE Low	SIGNIFICANCE High
Complete Blood Count (CBC)			
Hemoglobin (Hgb)	Female: 12-16 g/dL; male: 14-18 g/dL	Anemia	Polycythemia (elevated red blood cell count)
Hematocrit (Hct)	Female: 37%-47%; male: 42%-52%	Fluid overload	Dehydration
Platelet count	150,000-400,000/mm^3	Decreased clotting	Increased risk of blood clot
White blood cell count	5000-10,000/mm^3	Decreased ability to fight infection	Infection
Blood Chemistry			
Sodium (Na)	136-145 mEq/L	Fluid overload	Dehydration
Potassium (K)	3.5-5.0 mEq/L	Cardiac rhythm irregularities	Cardiac rhythm irregularities
Chloride (Cl)	98-106 mEq/L	Follows shifts in sodium blood levels	Follows shifts in sodium blood levels
Carbon dioxide (CO$_2$)	23-30 mEq/L	Affects acid base balance in blood	Affects acid base balance in blood
Blood urea nitrogen (BUN)	10-20 mg/dL	Liver disease/fluid overload	Renal disease/dehydration
Glucose	70-110 mg/dL fasting	Insulin reaction, inadequate glucose intake	Diabetes mellitus and stress of surgery
Creatinine	Female: 0.5-1.1 mg/dL; male: 0.6-1.2 mg/dL	Malnutrition	Renal disease
Coagulation Studies			
International Normalized Ratio (INR)	0.76-1.27	Risk of clot	Risk of bleeding
Prothrombin time (PT)	11-12.5 sec; 85%-100%	Risk of clot	Risk of bleeding
Partial thromboplastin time (PTT)	60-70 sec	Risk of clot	Risk of bleeding
Activated PTT	30-40 sec	Risk of clot	Excess heparin; risk of spontaneous bleeding (activated PTT)

*Normal ranges vary slightly among laboratories.

BOX 50-4   Nursing Diagnostic Process

Fear Related to Knowledge Deficit and Previous Surgical Experience

Assessment Activities	Defining Characteristics
Ask patient to describe previous surgical experiences.	Apprehension over anesthesia and postoperative pain
Ask patient about understanding of preoperative education/preparation before admission.	Expresses feeling of dread, worry over complications that may result; unaware of preoperative testing
Observe patient's nonverbal behavior.	Has trouble making decisions about including family member in discussion

the nursing plan of care. These standards often use evidence-based guidelines for preferred nursing interventions.

Successful planning requires a patient-centered approach involving the patient and family to set realistic expectations for care. Early involvement of a patient and family caregiver when developing the surgical care plan minimizes surgical risks and postoperative complications and improves transition of care through discharge. A patient informed about the planned surgical experience is less likely to be fearful and is better able to participate in the postoperative recovery phase so expected outcomes are met. Establish diagnosis, interventions, and outcomes to ensure recovery or maintenance of the preoperative state.

Goals and Outcomes.   Base the goals and outcomes of care on the individualized nursing diagnoses. Review and modify the plan during the intraoperative and postoperative periods. Outcomes established for each goal of care provide measurable evidence to gauge a patient's progress toward meeting stated goals. As an example, the goal "Patient will be able to perform postoperative exercises during postoperative recovery" is measured through the following expected outcomes:
- Patient performs deep-breathing and coughing exercises on awakening from anesthesia.
- Patient performs postoperative leg exercises and early ambulation 12 hours after surgery.
- Patient performs incentive spirometry on return to patient care unit after surgery.
- Patient verbalizes rationale for early ambulation 24 hours after surgery.

Setting Priorities.   Use clinical judgment to prioritize nursing diagnoses and interventions based on the unique needs of each patient. Patients requiring emergent surgery often experience changes in their physiological status that require urgent reprioritizations. For example,

Knowledge
- Adult learning principles to apply when educating the patient and family
- Role other health care professionals may play in preoperative preparation
- Principles of communication in establishing trust
- Physiological risk factors for surgery

Experience
- Previous patient responses to planned preoperative care
- Personal experience with surgery

PLANNING
- Involve the patient and family in preoperative instruction
- Provide therapies aimed at minimizing the patient's fear or anxiety regarding surgery
- Plan therapies to reduce surgical risks
- Consult with other health care professionals

Standards
- Support the patient's autonomy and right to informed consent
- Apply AORN standards for preoperative teaching and practice
- Apply practice guidelines developed by agency

Attitudes
- Use creativity when preparing patients for outpatient surgery
- Speak with confidence when providing preoperative teaching

FIGURE 50-3 Critical thinking model for surgical patient planning. *AORN,* Association of periOperative Registered Nurses.

if a patient's blood pressure begins to drop, hemodynamic stabilization becomes a priority over education and stress management. Ensure that the approach to each patient is thorough and reflects an understanding of the implications of a patient's age, physical and psychological health, educational level, cultural and religious practices, and stated and/or written wishes concerning advance medical directives.

Teamwork and Collaboration. For patients having ambulatory surgery, those admitted the day of their scheduled surgery, and those with special issues (e.g., morbid obesity), the health care team needs to collaborate to ensure continuity of care. Preoperative planning ideally occurs days before admission to a hospital or surgical center. The collaboration between the health care provider's office and the surgical center is crucial to prepare a patient for a procedure and ensure that the proper equipment/supplies are available. Preoperative instruction gives patients time to think about their surgical experience, make necessary physical preparations (e.g., altering diet or discontinuing medication use), and ask questions about postoperative procedures. A patient having ambulatory surgery usually returns home on the day of surgery. Thus well-planned preoperative care ensures that he or she is well informed and able to be an active participant during recovery. The family or significant others also play an active supportive role for a patient.

◆ **Implementation**

Preoperative nursing interventions provide patients (and families) with a complete understanding of the surgery and anticipated

postoperative activities and prepare them physically and psychologically for surgical intervention and recovery.

Informed Consent. Except in emergencies, surgery cannot be performed legally or ethically until a patient fully understands a surgical procedure and all implications. Surgical procedures are not performed without documentation of a patient's consent in the medical record. Chapter 23 discusses a nurse's responsibilities for **informed consent**. It is the surgeon's responsibility to explain the procedure, associated risks, benefits, alternatives, and possible complications before obtaining the patient's oral and documented informed consent (Rothrock, 2015). The patient also needs to know who will perform the procedure. To ensure that a patient understands information about surgery, TJC (2014) recommends that consent materials be written at a fifth-grade or lower reading level. After the patient or power of attorney signs the consent form, place it in the medical record. The record goes to the OR with the patient. As a nurse, if you have concerns about a patient's understanding of surgery, report them to the operating surgeon or anesthesia provider before the patient goes to surgery (Rothrock, 2015).

Privacy and Social Media. Although patients can now access their medical records electronically, confidentiality risks exist. Inappropriate discussions of a patient and any planned surgery in elevators, cafeterias, or social settings after work can end up being communicated "worldwide" (Rothrock, 2015). You have an obligation to protect each patient's privacy by avoiding inappropriate discussions and not using social media to convey information. Posting patient information and photos on websites is prohibited; 26 state boards of nursing have taken disciplinary action against nurses who practice such behavior (Rothrock, 2015). In addition, you are violating federal and state patient privacy laws.

Health Promotion. Health promotion activities during the preoperative phase focus on health maintenance, patient safety, prevention of complications, and anticipation of continued care needed after surgery.

Preoperative Teaching. Patient education is an important aspect of a patient's surgical experience (see Chapter 25). The topics and principles discussed depend on the type of surgery scheduled, whether a procedure is inpatient or outpatient, and the ability of a patient to attend to and learn content provided. Research shows that patient education often reduces patients' preoperative anxiety, which often leads to an increase in postoperative pain, poor outcomes, and prolonged hospital stays (Alanazi, 2014). In addition, education about the surgical experience increases patient satisfaction and knowledge, speeds up the recovery process, and facilitates a return to functioning (Lewis et al., 2014). Structured teaching throughout the perioperative period influences the following:
- *Ventilatory function*: Teaching improves the ability and willingness to deep breathe and cough effectively.
- *Physical functional capacity*: Teaching increases understanding and willingness to ambulate and resume activities of daily living.
- *Sense of well-being*: Patients who are prepared for surgery have less anxiety and report a greater sense of psychological well-being (Haufler and Harrington, 2011).
- *Length of hospital stay*: Being informed reduces a patient's length of hospital stay by preventing or minimizing complications.
- *Anxiety about pain and its management*: Patients who learn about pain and ways to relieve it before surgery are less anxious about it, ask for what they need, and require less analgesia after surgery (Grawe et al., 2010).

◎ **NURSING CARE PLAN**

Deficient Knowledge

ASSESSMENT

Mrs. Campana is an 80-year-old patient scheduled for admission in 5 days for elective bowel resection to remove a cancerous tumor. You are the nurse in the ambulatory surgery center (ASC) preoperative testing area assigned to prepare her for surgery. During your initial discussion with Mrs. Campana, you assess that she is alert and oriented to person, place, time, and situation. She states that she has severely reduced visual acuity but is able to hear your questions clearly. The last time she had surgery was 10 years ago. She lives alone but has a daughter who is coming in town the evening before surgery and will stay with her 2 weeks after surgery.

Assessment Activities	*Findings/Defining Characteristics**
Ask Mrs. Campana what she has been told by her surgeon regarding her surgery.	She states that her surgeon explained where her tumor is located using a drawing of the bowel. She had **difficulty seeing the drawing** clearly and states, "I know I have a cancer in my colon, and the surgeon said I might require a colostomy, but **I am not sure what that is.**" She further states, "**My doctor didn't explain the care I will receive after surgery is over.**"
Ask Mrs. Campana what she understands about preoperative preparation and what to expect after surgery.	She correctly verbalizes understanding of medicines to take the morning of surgery, her diet before surgery and when to stop eating, and who to call for questions. **She cannot explain what to expect after surgery. She states, "Will I be able to eat anything? And what do I need to do to go home?"**
Assess Mrs. Campana's concerns about surgery.	She appears slightly anxious. **She states, "I'm afraid how this might change my life. I don't know what to expect. My neighbor told me I am having a dangerous surgery."**

*****Defining characteristics** are shown in bold type.

NURSING DIAGNOSIS: Deficient knowledge related to insufficient information

PLANNING

Goals	*Expected Outcomes (NOC)*†
	Knowledge: Treatment Procedures
Mrs. Campana will express understanding of expected postoperative care by the morning of surgery.	Mrs. Campana describes the importance of postoperative exercises by the morning of surgery.
	Mrs. Campana describes the schedule for walking the evening of surgery and type of pain therapy she will receive by the first postoperative evening.
	Mrs. Campana explains the dietary schedule to be ordered for her by the second postoperative day.
Mrs. Campana will participate actively in postoperative recovery activities by postoperative day 1.	Mrs. Campana successfully performs postoperative exercises (turning, coughing, and deep breathing [TCDB], diaphragmatic breathing [DB], incentive spirometry [IS], and leg exercises) on the evening of surgery.
Mrs. Campana and daughter will describe expectations regarding home care by postoperative day 2.	Mrs. Campana and daughter explain expected activity restrictions, diet schedule, and wound care for home care guidelines by day 2 after surgery.

†Outcome classification labels from Moorhead S et al: *Nursing outcomes classification (NOC),* ed 5, St Louis, 2013, Mosby.

INTERVENTIONS (NIC)‡	**RATIONALE**
Preoperative Teaching	
Before admission to the hospital, provide Mrs. Campana with audiotape program that explains preoperative and postoperative routines. Supply instruction booklet designed for patients with visual impairments. Make a follow-up call 24 hours before surgery to patient encouraging her to ask questions and voice concerns.	Preoperative education is effective in reducing patients' postoperative fatigue and pain and improving their knowledge (Ronco et al., 2012).
On admission to hospital, demonstrate to Mrs. Campana and daughter how patient is to perform postoperative exercises and how to get out of bed with assistance.	Demonstration is an effective method to reinforce instruction.
Coach Mrs. Campana during a return demonstration of postoperative exercises before surgery.	Learning occurs when a patient is actively involved in an education session (Edelman and Mandle, 2014). When possible, have patient perform return demonstration of use of incentive spirometer (Rothrock, 2015).
Using audiotape and information sheets, explain to patient and daughter the activity restrictions likely to be followed at home, expected diet schedule, and wound care guidelines.	Influential factors in patient satisfaction for surgery are receiving information at admission and being given home care information (Mira et al., 2009).

‡Intervention classification labels from Bulechek GM, et al: *Nursing interventions classification (NIC),* ed 6, St Louis, 2013, Mosby.

NURSING CARE PLAN

Deficient Knowledge—cont'd

EVALUATION

Nursing Actions	Patient Response/Finding	Achievement of Outcome
Ask Mrs. Campana to describe activity and diet therapies to expect while in hospital after surgery.	She verbalizes understanding of diet progression from NPO to full liquids but is not sure how quickly she will be expected to ambulate.	Mrs. Campana requires additional discussion of activity and long-term diet plan.
Observe Mrs. Campana demonstrate postoperative exercises.	She correctly demonstrates leg exercises and turning, coughing, and deep breathing (TCDB) but is having difficulty using incentive spirometer.	Mrs. Campana demonstrates most postoperative exercises but needs further teaching and practice on incentive spirometer use.
Have Mrs. Campana and daughter describe activity limits following surgery and pain-management expectations or concerns.	Both Mrs. Campana and her daughter are able to describe safety of taking analgesics after surgery and importance of pain control. Both are able to describe limits on lifting objects but are unsure of other restrictions.	Patient and daughter show understanding of pain management. Require reinforcement of all activity restrictions to expect once returning home.
Ask Mrs. Campana and her daughter to describe signs of a wound infection.	Mrs. Campana's daughter is able to describe tenderness, drainage, and fever as signs of wound infection. Patient is unclear of signs of wound complications.	Patient requires further education and reinforcement.

The health care provider's office or hospital often provide preoperative information and instructions by telephone calls and home mailings. Instructions are available as preprinted teaching guidelines and checklists or in the form of videotapes or educational websites. The American College of Surgeons developed a patient education website titled *Surgical Patient Education Program,* which provides patient information and education materials on types of surgeries, health resources, insurance information, and even some home care skills training (American College of Surgeons, 2015). When a patient is scheduled for surgery (outpatient or inpatient), preadmission nurses call patients up to 1 week before the surgery to clarify questions and reinforce explanations (Rothrock, 2015) For example, they:

- Describe time for a patient to arrive at facility and time of surgery (approximately).
- Explain extent and purpose of food and fluid restrictions.
- Teach about physical preparation (e.g., bowel preparation, bathing or showering with antiseptic).
- Explain procedures performed in preanesthesia (holding area) just before transport to the OR (IV line insertion, preoperative medications).

Including family members in preoperative instruction is advisable. Often a family member is the coach for postoperative exercises when a patient returns from surgery. A family often has better retention of preoperative teaching and will be with the patient and able to help him or her in recovery. If anxious relatives do not understand routine postoperative events, it is likely that their anxiety heightens the patient's fears and concerns. Preoperative preparation of family members lessens anxiety and misunderstanding. To ensure comprehensive preoperative instruction, include the following topics (AORN, 2015).

Reasons for Preoperative Instructions and Exercises. When given a rationale for preoperative and postoperative procedures, patients are better prepared to participate in care. Patients who undergo ambulatory surgery need to learn how their instructions and exercises will promote healthy recovery, prevent complications, and allow them to return to a normal lifestyle as soon as possible. For example, a patient needs to know how recommended care activities (e.g., regular antibiotics, wound care) in the home will prevent wound infection, avoid complications (e.g., activity restrictions prevent wound stress), and maintain a level of health (e.g., diet and progressive exercise allowed). Patients having ambulatory surgery also need to know the signs of complications and when to call their surgeon.

Patients who have inpatient surgery need to understand what is required to facilitate their recovery, including pain control, anticipated activity level, diet progression, wound care, and postoperative exercises (e.g., diaphragmatic breathing, incentive spirometry, coughing, turning, and leg exercises). Postoperative exercises help to prevent pulmonary and vascular complications (see Skill 50-1 on pp. 1297-1302). After you explain each exercise, demonstrate it for the patient and use Teach Back to confirm his or her understanding. Guide your patient through each exercise. Ask your patient to perform a return demonstration of the skill to reinforce it and increase the confidence in performing it.

Changes in the circulatory system, a patient's immobility during surgery, and a patient's underlying health condition create risks for development of DVT. Patients need to know which precautions are taken after surgery to avoid DVT (e.g., leg exercises and use of compression hose or intermittent pneumatic compression [IPC] devices). Teach about the purposes and the specific nursing care associated with the device (see Chapter 28).

Preoperative Routines. Explain the preoperative routines that a patient can expect. Knowing which tests and procedures are planned and why increase a patient's sense of control. Explain that an anesthesiologist will visit a patient to complete a preanesthesia assessment either during the preoperative admission process or in the presurgical care unit of a hospital.

A patient usually takes nothing by mouth for several hours before surgery to reduce risks for vomiting and aspirating emesis during surgery. Instruct a patient to eat and drink sufficient amounts during the week before surgery to ensure an adequate fluid and nutrient intake. Recommend foods high in protein with sufficient amounts of carbohydrates, fat, and vitamins in the diet. Explain to a patient and family the importance of following oral intake instructions for food and liquids before surgery.

Surgical Procedure. After the surgeon explains the basic purpose of a surgical procedure and its steps, some patients ask you additional questions. First clarify with the patient what was discussed with the surgeon. Avoid using technical medical terms because this adds to a patient's confusion. Avoid saying anything that contradicts the surgeon's explanation. If a patient has little or no understanding about the surgery, notify the surgeon that the patient requires further explanation. You can augment the surgeon's explanations.

Time of Surgery. The scheduled operative time is only an anticipated time. Unanticipated delays occur for many reasons that often

have nothing to do with the patient. Emphasize that the scheduled time is a rough estimate and the actual time can be sooner or later. Make the family aware that delays occur for various reasons and do not necessarily indicate a problem. Communicate excessive delays when they do occur.

Postoperative Unit and Location of Family During Surgery and Recovery. Few patients are admitted to a hospital unit before surgery unless their case is emergent or a complication develops during hospitalization. When surgery is elective, patients and families will come to the surgical center admission area first. During the admission process, the patient and family will find out which unit the patient most likely will be admitted to after surgery. Be sure to explain where the family can wait and where the surgeon will come to find family members after surgery. In many institutions the circulating nurse gives periodic reports to the family in the waiting room for surgeries that are expected to be prolonged. If a patient will be taken to a special unit, it helps to orient the patient and family members to the environment of the unit before surgery.

Anticipated Postoperative Monitoring and Therapies. A patient and family need to know about routine postoperative monitoring and therapies (e.g., frequency of vital signs, IV therapy, dressings and drains, planned activity, and physical therapy). If they understand the frequency of anticipated monitoring and procedures, they are less apprehensive when nurses perform care activities. Try not to overprepare or underprepare a patient. It is easier to prepare a patient appropriately in elective cases when a surgeon has care guidelines for a specific procedure and you have adequate time for patient education. You cannot predict all of a patient's care requirements. Contradictions between your explanations and reality cause anxiety.

Sensory Preparation. Provide patients with information about the sensations typically experienced after surgery. Preparatory information helps them anticipate the steps of a procedure and thus form realistic images of the surgical experience. For example, warn that the OR is very bright and cold. Patients often undergo prewarming or are given warm blankets. A patient will have a cuff for a noninvasive blood pressure monitor placed around his or her arm. The monitor makes a hum and a beep, and the cuff tightens to take a reading. Informing a patient about these and other sensations in the OR reduces anxiety before the patient is anesthetized, which helps reduce the amount of anesthetic needed for induction. Postoperative sensations to describe include blurred vision from ophthalmic ointment in the eyes, expected pain at the surgical site and in areas of the body affected by prolonged positioning, the tightness of dressings, dryness of the mouth, and the sensation of a sore throat resulting from an endotracheal tube.

Postoperative Activity Resumption. The type of surgery determines how quickly patients can resume normal physical activity and regular eating habits. Explain what to expect after surgery. It is normal in most surgical cases for patients to progress gradually in activity and eating.

Pain-Relief Measures. Pain following surgery is one of a patient's most common fears. The family is also concerned for the patient's comfort. Pain after surgery is expected. Inform the patient and family of the need to manage pain so patients can resume activity and the type of therapies likely to be used for pain relief (e.g., splinting, and relaxation exercises). Patient-controlled analgesia (PCA) is common and provides patients with control over pain. Explain and demonstrate to a patient how to operate a pump and the importance of administering medication as soon as pain becomes persistent (see Chapter 44). Patients who receive epidural analgesia need a thorough understanding of how it will affect their movement and sensation after surgery.

Some patients avoid taking pain-relief drugs after surgery for fear of the negative side effects or becoming dependent on the drugs.

Encourage a patient to use analgesics as ordered. Unless pain is controlled, it is difficult for a patient to participate in postoperative therapy. Encourage the patient to take pain medications at the ordered intervals. Pain relief has been shown to be more effective when analgesics are given around the clock (ATC) rather than as needed (prn) (Paice et al., 2005), especially if pain is expected throughout the day. However, prn administration of analgesics after surgery is still very common. When pain is not addressed regularly, it often becomes excruciating, and the analgesic does not provide relief at the dose ordered. Explain to a patient the length of time it takes for a drug to begin working. Information from preoperative pain assessment is helpful when teaching about pain-relief measures (such as positioning and splinting). Remember that pain is a subjective experience of a patient, and you must accept his or her perception of pain.

Rest. Rest is essential for normal healing. Anxiety about surgery interferes with the ability to relax and sleep. Meet each patient's individual needs.. If a patient is in the hospital, make the environment quiet and comfortable. The surgeon often orders a sedative-hypnotic or antianxiety agent for the night before surgery. Sedative-hypnotics promote sleep. Antianxiety agents (e.g., alprazolam [Xanax]) act on the cerebral cortex and limbic system to relieve anxiety. The advantage of ambulatory surgery is that a patient is able to sleep at home the night before surgery.

Feelings Regarding Surgery. Some patients feel like part of an assembly line before surgery. Frequent visits by staff, diagnostic testing, and physical preparation for surgery consume time; and the patient has few opportunities to reflect on the experience. Recognize the patient as a unique individual. The patient and family need time to express feelings about surgery and ask questions. The patient's level of anxiety influences the frequency of discussions. While delivering preoperative instruction, encourage expression of concerns, be patient, and listen attentively. The family may wish to discuss concerns without the patient present so their fears do not frighten the patient and vice versa. Establishing a trusting and therapeutic relationship with the patient and family allows this process to happen.

Acute Care. Acute care activities in the preoperative phase focus on the preparation of a patient on the morning of surgery or before an emergent surgery.

Minimizing Risk for Surgical Wound Infection. A surgical site infection (SSI) is one of the National Quality Forum (NQF)–endorsed patient safety measures that hospitals are encouraged to report (NQF, 2010). As of 2008 the CMS (2010) no longer pays a higher reimbursement for hospitalizations complicated by certain types of surgical site infections (e.g., mediastinitis after heart surgery, select orthopedic procedures, and certain bariatric procedures for obesity) if they were not present on admission. Thus there is great emphasis within hospitals on preventing the occurrence of SSIs. Antibiotics are sometimes ordered in the preoperative period. A reduction in wound infection rates occurs when an antibiotic is administered 60 minutes before the surgical incision is made and the antibiotics are stopped within 24 hours after surgery (CDC, 2012a). The surgeon orders a specific time before surgery for the patient to have an oral or IV antibiotic.

Preoperative care involves skin antisepsis (i.e., removing soil and transient microorganisms at the surgical site) to reduce the risk of a patient developing an SSI (Dumville et al., 2013). Routine components of skin antisepsis include preoperative bathing (showers or baths) and hair management, both of which reduce the number of microorganisms on the skin. Research has not confirmed that preoperative bathing reduces SSI (AORN, 2015), but the benefits outweigh harm. Most patients bathe the evening before surgery or that morning. There is no one antiseptic agent found to be most effective, although 2%

chlorhexidine gluconate is becoming a preferred solution (AORN, 2015). Whatever product is recommended, it is very important for patients to follow package directions. Patients who have head and neck surgery typically shampoo the hair before surgery to reduce resident flora on the scalp.

The AORN (2015) recommends that you remove hair at the surgical site only in select clinical situations. The current evidence supports leaving hair at the surgical site in place unless it interferes with exposure, closure, or dressing of the surgical site. When hair removal is required, clipping it is likely to result in less SSI than removal with a razor (AORN, 2015). Use single-use clipper heads for each patient and remove hair as close to the time of surgery as possible.

Maintaining Normal Fluid and Electrolyte Balance. A patient having surgery is vulnerable to fluid and electrolyte imbalance as a result of the stress of surgery, inadequate preoperative intake, and the potential for excessive fluid losses during surgery (see Chapter 42). The American Society of Anesthesiologists (ASA) recommendations for fluid and food intake before nonemergent procedures requiring general and regional anesthesia or sedation/analgesia, including fasting from intake of clear liquids for 2 or more hours, breast milk for 4 hours, formula and nonhuman milk for 6 hours, and a light meal of toast and clear liquids for 6 hours. A patient also cannot have any meat or fried foods 8 hours before surgery, unless explicitly specified by the anesthesiologist or surgeon (ASA, 2011). When a patient is hospitalized before surgery, remove all fluids and solid foods as ordered from the bedside and post a sign over the bed to alert personnel to fasting restrictions.

Despite the ASA standards, many surgeons still have patients maintain nothing by mouth after midnight. Ensure that you follow the health care provider's orders. During general anesthesia the muscles relax, and gastric contents can reflux into the esophagus. The anesthetic alters the patient's gag reflex. Therefore a patient is at risk for aspiration of food or fluids from the stomach into the lungs. The surgeon's orders will provide additional guidance for routines (e.g., IV line placement and preoperative medications). Some patients are allowed to take specific medications (e.g., anticoagulants, cardiovascular medications, anticonvulsants, and antibiotics) with a sip of water as ordered by their health care providers. Allow patients time to rinse their mouths with water or mouthwash and brush their teeth immediately before surgery as long as they do not swallow water. Notify the surgeon and anesthesia provider if a patient eats or drinks during the fasting period.

If a patient cannot eat because of GI alterations or impairments in consciousness, you will probably start an IV route for fluid replacement. The health care provider assesses serum electrolyte levels to determine the type of IV fluids and electrolyte additives to administer before and during surgery. Patients with severe nutritional imbalances sometimes require supplements with concentrated protein and glucose such as total parenteral nutrition (see Chapter 45).

Preventing Bowel Incontinence and Contamination. Some patients receive a bowel preparation (e.g., a cathartic or enema) if the surgery involves the lower GI system. Manipulation of parts of the GI tract during surgery results in absence of peristalsis for 24 hours and sometimes longer. Enemas and cathartics (see Chapter 47) such as a polyethylene glycol electrolyte solution (e.g., GoLytely®, NuLytely®) clean the GI tract to prevent intraoperative incontinence. An empty bowel reduces risk of injury to the intestines and minimizes contamination of the operative wound if colon surgery is planned or a part of the bowel is incised or opened accidentally. In addition, bowel cleansing reduces postoperative constipation. If a surgeon's order reads "give enemas until clear," this means that you administer enemas until the enema return solution contains no solid fecal material (see Chapter 47). Too many enemas given over a short time can cause serious fluid

and electrolyte imbalances (see Chapter 42). Most agencies limit the number of enemas (usually three) that a nurse may administer successively. Verify a patient's potassium level following bowel preparation. Diarrhea may cause hypokalemia.

Preparation on the Day of Surgery. Complete several routine procedures before releasing patients for surgery.

Hygiene. Basic hygiene measures provide additional comfort before surgery. If a patient is unwilling to take a complete bath, a partial bath is refreshing and removes irritating secretions or drainage from the skin. A patient cannot wear personal nightwear to the OR because it is restrictive and is a flammable hazard. Thus you provide a clean hospital gown. When a patient is NPO for the last several hours, his or her mouth is often very dry. Offer the patient mouthwash and toothpaste, again cautioning the patient not to swallow water.

Preparation of Hair and Removal of Cosmetics. During major surgery an anesthesiologist positions a patient's head to place an endotracheal tube into the airway (see Chapter 41). This involves manipulation of the hair and scalp. To avoid injury ask the patient to remove hairpins or clips before leaving for surgery. Electrocautery is frequently used during surgery. Hairpins and clips can become an exit source for the electricity and cause burns. Remove hairpieces or wigs as well. Patients can braid long hair and wear disposable hats to contain hair before entering the OR.

During and after surgery the anesthesia provider and nurse assess skin and mucous membranes to determine a patient's level of oxygenation, circulation, and fluid balance. A pulse oximeter is often applied to a finger to monitor oxygen saturation (see Chapter 31). Anesthesia providers also use end-tidal carbon dioxide, by way of capnography, to assess patients' physical status. When using a pulse oximeter, have patients remove all makeup (lipstick, powder, blush, nail polish) and at least one artificial fingernail to expose normal skin and nail color. Anything in or around the eye irritates or injures the eye during surgery. Have patients remove contact lenses, false eyelashes, and eye makeup. Give the patient's eyeglasses to the family immediately before the patient leaves for the OR. Document all valuables per agency policy.

Removal of Prostheses. It is easy for any type of prosthetic device to become lost or damaged during surgery. Have patients remove all removable prosthetics (e.g., artificial limbs, partial or complete dentures, artificial eyes, and hearing aids) for safekeeping just before leaving for surgery. If a patient has a brace or splint, check with the health care provider to determine whether it should remain in place. For many patients it is embarrassing to remove dentures, wigs, or other devices that enhance personal appearance. Always offer privacy as a patient removes personal items. Patients are sometimes allowed to keep these until they reach the preoperative holding area. Place dentures in special containers labeled with the patient's name and other identification required by the agency for safekeeping to prevent loss or breakage. In many agencies you complete an inventory of all prosthetic devices or personal items and place them in a secured area. It is also common practice for nurses to give prostheses to family members or to keep the devices at the patient's bedside. Document these actions in the nursing notes, surgical checklist, or per agency policy.

Safeguarding Valuables. If a patient has valuables, give them to family members or place in a secure designated location. Many hospitals require patients to sign a release to free the facility of responsibility for lost valuables. Prepare a list with a description of items, place a copy with a patient's medical record (see agency policy), and give a copy to a designated family member. Patients are often reluctant to remove wedding rings or religious medals. A wedding band can be taped in place, but this is not the preferred practice. If there is a risk that the patient will experience swelling of the hand or fingers (mastectomy,

hand surgery, fluid shifts), remove the band. Many hospitals allow patients to pin religious medals to their gowns, although the risk of loss increases. Remove other metal items such as piercings to reduce risk of burns.

Preparing the Bowel and Bladder. Some patients receive an enema or cathartic the morning of surgery (see Chapter 47). If so, give at least 1 hour before a patient leaves for surgery, allowing time for him or her to defecate without rushing. Instruct a patient to void just before leaving for the OR and before giving preoperative medications. An empty bladder reduces discomfort and the risk of incontinence during surgery and makes abdominal organs more accessible to the surgeon. If a patient is unable to void, record this information on the preoperative checklist. The surgeon may order insertion of an indwelling catheter if the surgery is to be long or the incision is in the lower abdomen (see Chapter 46).

Vital Signs. Monitor preoperative vital signs before surgery. The anesthesia provider uses these values as a baseline for intraoperative vital signs. If preoperative vital signs are abnormal, surgery is sometimes postponed. Notify the surgeon of any abnormalities before sending a patient to surgery. In addition, assess the patient for presence and character of pain (see Chapter 44). Many patients have pain before surgery caused by the condition requiring surgery.

Prevention of Deep Vein Thrombosis—Antiembolism Devices. Preventing DVTs is a priority quality measure. The AORN (2015) recommends that each health care organization implement a DVT prevention protocol. A patient's condition and type of surgery determine the preventive measures you take before surgery. For example, patients who have cardiac, GI, genitourinary (GU), gynecological (GYN), neurological, and orthopedic surgeries will likely have mechanical VTE prophylaxis applied the morning of surgery. This includes application of one of the following devices: antiembolism stockings (thigh or knee length), foot-impulse devices, or IPC devices (thigh or knee length) (NICE, 2010). In addition, some patients receive pharmacological VTE prophylaxis, which includes medications such as low-molecular-weight heparin (LMWH) (NICE, 2010). The health care provider needs to screen patients carefully for the risk of bleeding before ordering pharmacological VTE prophylaxis.

When correctly sized and applied, antiembolism devices reduce the risk for DVT. Antiembolic stockings maintain compression of small veins and capillaries of the legs. The constant compression forces blood into larger vessels, thus promoting venous return and preventing venous stasis. You attach **intermittent pneumatic compression (IPC) stockings** to an air pump that inflates and deflates the stockings, allowing intermittent pressure sequentially from the ankle to the knee and alternating calves, mimicking normal venous return when walking. Foot-inflation devices simulate natural walking by compressing the plantar venous plexus (AORN, 2015). See Chapter 28 for the correct procedure for applying antiembolism devices. Do not use antiembolism devices when patients have an allergy to the material (e.g., latex) or an unusual leg size or shape or a history of peripheral arterial disease, peripheral arterial bypass grafting, or peripheral neuropathy (NICE, 2010).

Administering Preoperative Medications. The increase in ambulatory surgeries has reduced the use of preoperative medications. However, the anesthesia provider or surgeon may order preanesthetic drugs ("on-call medications," "preops") to reduce patient anxiety; the amount of general anesthesia required; respiratory tract secretions; and the risk of nausea, vomiting, and possible aspiration. Typically you administer preoperative medications before a patient leaves for the OR. Complete all nursing care measures first. Preoperative drugs such as benzodiazepines, opioids, antiemetics, and anticholinergics usually cause dry mouth, drowsiness, and dizziness but do not induce sleep.

BOX 50-5   Example of Elements of a Preoperative-to-Intraoperative Hand-Off Using SBAR Communication

Situation
- Name of patient, date of birth
- Name of operative procedure to be performed, including site and modifiers
- Pertinent documents present and consistent

Background
- Elements of patient history pertinent to surgery
- Medical clearance
- Patient allergies and NPO status
- Patient's vital signs and pain level
- Medication profile and medications taken today; laboratory results; imaging results
- Code status of patient

Assessment
- Patient's current level of understanding of the surgery
- Special patient needs or precautions
- Pertinent cultural or emotional factors
- Anesthesia requests

Recommendations
- State whether patient has been seen before surgery by a surgeon and anesthesia care provider.
- Determine if patient is ready for surgery.
- Allow chance for all staff members to ask questions and voice concerns.

Adapted from Amato-Vealey EJ et al: Hand-off communication: a requisite for patient safety, *AORN J* 88(5):766, 2008.

To maintain patient safety, keep side rails in the up position, the bed in the low position, and the call light within easy reach. Instruct the patient to stay in bed until the surgical nursing assistant or transporter arrives to take him or her to the OR. If the patient needs to get out of bed to void, explain the importance of using the call light to ask for assistance. A patient can easily fall, thinking nothing is wrong. Be sure that the patient has signed surgical consent before administering drugs that will alter consciousness.

Documentation and Hand-Off. Before the patient goes to the OR, an accurate medical record is essential to ensure safe and appropriate patient care. Check the contents of the medical record for presence of ordered laboratory and imaging test results, accuracy and completeness of consent forms, and the preoperative checklist that agencies use as a tool to document all preoperative preparation activities. Check your nurses' notes to be sure your documentation is current. Also have a current medication administration record prepared for the OR. Once a patient is ready to go to the OR, a written (or electronic) record is inadequate to communicate information to the receiving health care team. The transfer of information about the patient from one health care provider to another requires an effective hand-off (Rothrock, 2015). Box 50-5 lists critical elements for hand-offs from preoperative to intraoperative providers. The AORN (2015) and TJC (2015) recommend hand-off reports occur in person to ensure that the right patient receives the right surgery at the right surgical site.

Eliminating Wrong Site and Wrong Procedure Surgery. Because of errors made in the past with patients undergoing the wrong surgery or having surgery performed on the wrong site, TJC instituted Universal Protocol guidelines for preventing such mishaps. The

Universal Protocol is part of TJC ongoing National Patient Safety Goals (TJC, 2016). The preoperative-to-intraoperative hand-off described previously is an example of part of the protocol. Implement the Universal Protocol whenever an invasive surgical procedure is to be performed no matter the location (e.g., hospital, ASC, or health care provider office). The three principles of the protocol are: (1) a preoperative verification that ensures all relevant documents (e.g., consent forms, allergies, medical history, physical assessment findings) and results of laboratory tests and diagnostic studies are available before the start of the procedure and that the type of surgery scheduled is consistent with the patient's expectations; (2) marking the operative site with indelible ink to mark left and right distinction, multiple structures (e.g., fingers), and levels of the spine; and (3) a "time-out" just before starting the procedure for final verification of the correct patient, procedure, site, and any implants (TJC, 2016). The marking and "time-out" most commonly occur in the holding area, just before the patient enters the OR. The individual performing surgery and who is accountable for it must personally mark the site and involves the patient if possible (Rothrock, 2015). All members of the surgical/procedure team perform the time-out. This protocol includes the patient or a legally designated representative in the entire process. If the patient refuses a mark, document this on the procedure checklist.

QSEN BUILDING COMPETENCY IN SAFETY You are the nurse in the preoperative holding area and are preparing a patient for the operating room. You completed all preliminary procedures (i.e., storing valuables, checking the preoperative checklist, and assisting the patient to the bathroom). You are preparing to perform the Universal Protocol with patient verification. When is the right time to administer the preoperative sedative?

Answers to QSEN Activities can be found on the Evolve website.

◆ **Evaluation**

The nurse caring for a patient in the preoperative area evaluates initial patient outcomes (Figure 50-4). Although limited time is available to evaluate outcomes before surgery, compare the patient's current status with expected outcomes to determine whether new or revised interventions and/or nursing diagnoses need to be implemented intraoperatively.

Through the Patient's Eyes. Evaluate whether the patient's expectations were met with respect to surgical preparation. For example, ask patients if they require additional information, if they desire to have their family members more involved, and if they have any unidentified needs. During evaluation include a discussion of any misunderstandings so patient concerns can be clarified. When patients have expectations about pain control, this is a good time to reinforce how it will be managed after surgery.

Patient Outcomes. Evaluate a patient's response to interventions designed for preoperative nursing diagnoses such as *Deficient Knowledge* or *Anxiety*. For example, ask the patient to describe the reason for postoperative exercises and the type of care activities to expect when he or she returns from surgery. Observe the patient's behaviors and discuss concerns to see if anxiety remains. Be thorough in your evaluation to determine if further instruction or emotional support is needed after surgery. Interventions continue during and after surgery; thus the evaluation of many goals and outcomes does not occur until after surgery.

Knowledge
- Behaviors that demonstrate learning
- Characteristics of anxiety and/or fear
- Signs and symptoms of conditions that contraindicate surgery

Experience
- Previous patient responses to planned preoperative care
- Personal experience with surgery

EVALUATION
- Evaluate the patient's knowledge of surgical procedure and planned postoperative care
- Have the patient demonstrate postoperative exercises
- Observe behaviors or nonverbal expressions of anxiety or fear
- Ask if the patient's and family members' expectations are being met

Standards
- Use established expected outcomes to evaluate the patient's response to care (e.g., ability to perform postoperative exercises)

Attitudes
- Demonstrate perseverance when patients have difficulty performing postoperative exercises
- Display curiosity when a clinical change occurs before surgery

FIGURE 50-4 Critical thinking model for surgical patient evaluation.

TRANSPORT TO THE OPERATING ROOM

Personnel in the OR notify the nursing unit or ambulatory surgery area when it is time for surgery. In many facilities a transporter brings a stretcher to transport the patient to surgery. The transporter checks the patient's identification bracelet for two identifiers (name, birthday, or hospital number) (refer to institutional or agency policy) against the patient's medical record to ensure that the correct person is going to surgery. Because some patients receive preoperative sedatives, the nurses, nursing assistive personnel, and transporter help the patient transfer from bed to stretcher to prevent falls. A patient in ambulatory surgery ambulates to the OR if able and not medicated. Provide the family an opportunity to visit before the patient is transported to the OR. Direct the family to the appropriate waiting area. If a patient has been hospitalized before surgery and will be returning to the same nursing unit, prepare the bed and room for his or her return.

Preanesthesia Care Unit

In most hospitals a patient enters a **preanesthesia care unit** (PCU) or presurgical care unit (PSCU) (sometimes called the *holding area*) outside the OR where preoperative preparations are completed. Nurses in the PCU are members of the OR staff and wear surgical scrub suits, hats, and footwear in accordance with infection control policies. In some ambulatory surgical settings a perioperative primary nurse admits the patient, circulates during the operative procedure, and manages the patient's recovery and discharge.

If an IV catheter is not present already, a nurse or anesthesia provider inserts one into a vein to establish a route for fluid replacement, IV drugs, or blood products. The nurse also administers preoperative

medications and/or begins conscious sedation at this time. He or she monitors vital signs, including pulse oximetry. The anesthesia provider usually performs a patient assessment at this time. Because of the preoperative medications, explain to the patient that he or she will begin to feel drowsy. The temperature in the PCU and adjacent OR suites is usually cool; therefore offer the patient an extra blanket. The patient will stay in the PCU only briefly.

INTRAOPERATIVE SURGICAL PHASE

Care of a patient intraoperatively requires careful preparation and knowledge of the events that occur during the surgical procedure. Another important feature of intraoperative care is safety of OR personnel. The OR environment poses unique risks resulting from the procedures followed. Members of the surgical team can suffer injury from skin sticks or cuts (e.g., needle or scalpel) or mucous membrane exposure (splashing of irrigated fluids) to contaminated body fluids. Proper use of personal protective equipment is critical. When nurses participate in laser surgical procedures, they use special safety precautions (e.g., use of laser protective eyewear or shields) to prevent injury to the eyes and skin.

NURSING ROLES DURING SURGERY

There are two traditional nursing roles in the OR: circulating nurse and scrub nurse. The **circulating nurse** is an RN who does not scrub in and uses the nursing process in the management of patient care activities in the OR suite. The circulating nurse also manages patient positioning, antimicrobial skin preparation, medications, implants, placement and function of IPC devices, specimens, warming devices, and surgical counts of instruments and dressings (AORN, 2015; Rothrock, 2015). The **scrub nurse** is either an RN or surgical technologist who is often certified (CST). The scrub nurse must have a thorough knowledge of each step of a surgical procedure and the ability to anticipate each and every instrument and supply needed by the surgeons (Rothrock, 2015). A circulating nurse and scrub nurse partner together to ensure patient safety by minimizing risk of error. The team also works together to ensure cost-efficient use of supplies.

A new role in the OR includes the RN first assistant (RNFA). This is an expanded role that requires formal academic education (AORN, 2012). The RNFA collaborates with the surgeon by handling and cutting tissue, using instruments and medical devices, providing exposure of the surgical area and hemostasis, and suturing (Rothrock, 2015).

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision making approach for you to develop and implement an individualized plan of care.

◆ Assessment

During the assessment process in the OR, the circulating nurse thoroughly assesses the patient and critically analyzes findings to make patient-centered clinical decisions required for safe nursing care. Assessment focuses on a patient's immediate clinical status, skin integrity (over surgical site and dependent areas where patient will lay on operating table bed), and joint function (when unusual positions on the OR table are required). This allows the nurse to anticipate problems that predispose the patient to injury if he or she is not positioned on the OR table correctly. Because patients are not able to speak for

themselves while under general anesthesia, this assessment in the OR is very important for their safety. As the nurse, review the preoperative care plan to establish or revise the intraoperative care plan as indicated.

◆ Nursing Diagnosis

Review preoperative nursing diagnoses and modify them to individualize the care plan in the OR. The following are common nursing diagnoses relevant to the patient intraoperatively:

- *Ineffective Airway Clearance*
- *Risk for Deficient Fluid Volume*
- *Risk for Perioperative Positioning Injury*
- *Impaired Skin Integrity*
- *Risk for Thermal Injury*
- *Risk for Injury*

◆ Planning

Goals and Outcomes. Patient-centered goals and outcomes of preoperative nursing diagnoses extend into the intraoperative phase. For example, a goal for the nursing diagnosis of *Risk for Thermal Injury* is "Skin will remain free of burn injury through surgical procedure." An expected outcome for this goal is:

- Patient is free of burns from the grounding pad at end of surgery.

Setting Priorities. The circulating nurse uses judgment to provide a safe operative experience for the patient. Ensuring an aseptic environment, conducting instrument and sponge counts according to policy, managing tissue and specimens correctly, and ensuring proper use of equipment and instruments are top priorities. If an unsafe practice occurs (e.g., break in sterility, missing sponge in wound), the circulating nurse is integral in ensuring the safety of the patient and operative personnel.

Teamwork and Collaboration. For optimal patient safety the preoperative health care team communicates assessment findings and patient problems via a formal hand-off with the surgical team to ensure a smooth transition in care (see Box 50-5). For example, alerting the operative team of a latex allergy or risk factors for complications during surgery (smoker) requires collaboration and timely communication among all team members.

◆ Implementation

A primary focus of intraoperative care is to prevent injury and complications related to anesthesia, surgery, positioning, and equipment use. The perioperative nurse is an advocate for the patient during surgery and protects his or her dignity and rights at all times.

Acute Care

Physical Preparation. A patient is usually still awake and notices health care providers in their surgical attire and masks when entering the OR. You transfer a patient to the OR bed by being sure that the stretcher and bed are locked in place. Explain to the patient all the activities you are completing. After safely securing the patient on the OR table with safety straps, you apply monitoring devices such as continuous ECG electrodes, a pulse oximeter sensor, and blood pressure cuff. For ECG, place electrodes on the chest and extremities correctly to record electrical activity of the heart accurately. The anesthesia provider will use the cuff to monitor the patient's blood pressure. An electronic monitor in the OR will display the patient's heart rate, vital signs, and pulse oximetry continuously. Capnography is also used frequently to measure the patient's ongoing end-tidal carbon dioxide values. Apply an electrical cautery grounding pad to the skin so

cauterizing instruments can be used safely. If not applied before surgery, now is the time to apply antiembolism devices. You help insert temperature probes via the bladder, esophagus, or rectum if required to continuously measure a patient's body temperature.

Intraoperative Warming. The unplanned occurrence of perioperative hypothermia is now minimized with the use of active intraoperative warming. Prevention of hypothermia (core temperature less than 36° C [96.8° F]) helps to reduce complications such as shivering, cardiac arrest, blood loss, SSI, pressure ulcers, and mortality (Hart et al., 2011; Seamon et al., 2012). Evidence suggests that prewarming for a minimum of 30 minutes may reduce occurrence of hypothermia (Hart et al., 2011; Stuart et al., 2011). The nurse in the OR applies warm cotton blankets, forced-air warmers, or circulating-water mattresses to patients. Forced-air warmers tend to be the most effective when used before surgery or intraoperatively (Hart et al., 2011).

Latex Sensitivity/Allergy. As the incidence and prevalence of **latex sensitivity** and allergy increase, the need for recognition of potential sources of latex is extremely critical. All medical supplies contain a label notifying the consumer of the latex content. The OR and PCU have many products that contain latex (e.g., gloves, IV tubing, syringes, and rubber stoppers on bottles and vials). It is also present in common objects such as adhesive tape, disposable electrodes, endotracheal tube cuffs, protective sheets, and ventilator equipment. Signs and symptoms of a latex reaction include local effects ranging from urticaria and flat or raised red patches to vesicular, scaling, or bleeding eruptions. Acute dermatitis is sometimes present. Rhinitis and/or rhinorrhea are other common reactions to mild and severe latex allergy. Immediate hypersensitivity reactions are life threatening, with the patient exhibiting focal or generalized urticaria and edema, bronchospasm, and mucus hypersecretion, all of which can compromise respiratory status. Vasodilation compounded by increased capillary permeability sometimes lead to circulatory collapse and eventual death. The draping of a patient during surgery blocks your ability to visualize the skin. Thus be prepared to investigate any unexplained acute deterioration in a previously healthy patient for possible latex allergy.

A latex-free cart needs to be available at all times in the OR to create a latex-safe environment. All of the contents must be latex free. The American Association of Nurse Anesthetists (AANA, 2015) recommends that, when facilities are not latex safe, you need to take steps to prepare an OR the night before to avoid the release of latex particles. Any patient with a latex allergy needs to receive scheduling priority and be the first case in the morning. It is important to know that patients may develop anaphylaxis 30 to 60 minutes after being exposed to latex. Box 50-6 lists latex precautions.

Introduction of Anesthesia. The nature and extent of a patient's surgery and current physical status influence the type of anesthesia administered during surgery. Know the complications to anticipate after surgery for each type (Table 50-7).

General Anesthesia. Under **general anesthesia** a patient loses all sensation, consciousness, and reflexes, including gag and blink reflexes. The patient's muscles relax, and the patient experiences amnesia. Amnesia is a protective measure from the unpleasant events of the procedure. An anesthesia provider gives general anesthetics by IV infusion and inhalation routes through the three phases of anesthesia: induction, maintenance, and emergence. Surgery requiring general anesthesia involves major procedures with extensive tissue manipulation. During emergence anesthetics are decreased, and the patient begins to awaken. Because of the short half-life of today's medications, emergence often occurs in the OR. The duration of anesthesia depends on the length of surgery.

Regional Anesthesia. **Regional anesthesia** results in loss of sensation in an area of the body by anesthetizing sensory pathways. This

---

BOX 50-6 Latex Avoidance Precautions

1. Health care workers can transmit the allergen by hand to patients after touching any object with latex. *Caution:* Keep the powder from the gloves away from patients because the powder acts as a carrier for the latex protein. Do not snap gloves on and off.
2. Identify patients who are latex sensitive. The operating room (OR) needs to be labeled latex free to prevent personnel from bringing rubber products (e.g., wristbands, chart labels) into the room.
3. Develop programs to educate health care workers in the care of latex-sensitive patients.

Recommendations for Patient Care (Patients with Latex Allergy or Latex Risk)
The Operating Room
- Notify the OR of patients who have potential latex allergies. Remove all latex products from the OR and bring a latex-free cart (if available) into the room.
- Use a latex-free reservoir bag, airways and endotracheal tubes, and laryngeal mask airways.
- Use a nonlatex anesthesia breathing circuit with plastic mask and bag.
- Place all monitoring devices and cords/tubes (oximeter, blood pressure, electrocardiograph wires) in stockinette and secure with tape to prevent direct skin contact. Rinse items sterilized in ethylene oxide before use. Residual ethylene oxide reacts and can cause an allergic response in a patient with a latex allergy.

Intravenous Line Preparation
- Use intravenous (IV) tubing without latex ports; use stopcocks if available.
- If unable to obtain IV tubing without latex ports, cover latex ports with tape.
- Cover all rubber injection ports on IV bags with tape and label as follows: *Do not inject or withdraw fluid through the latex port. NOTE: Pulmonary artery catheters (especially the balloon), central venous catheters, and arterial lines may contain latex components.*

Operating Room Patient Care
- Use nonlatex gloves. (*Caution:* Not all substitutes are equally impermeable to bloodborne pathogens; ensure that you select substitute gloves that provide appropriate protection.)
- Use nonlatex tourniquets or nonlatex examination gloves or polyvinyl chloride tubing.
- Draw medication directly from opened multidose vials (remove stoppers) if medications are not available in ampules.
- The rubber allergen can possibly move from the plunger of a syringe into the medication, which sometimes causes an allergic reaction. The intensity of this reaction increases over time. Therefore you draw up medications immediately before the beginning of the surgery or just before administration.
- Use latex-free or glass syringes.
- Use stopcocks to inject drugs rather than latex ports.
- Notify pharmacy and central supply that your patient is latex sensitive so these departments can use appropriate procedures when preparing medications and instruments. Also notify radiology, respiratory therapy, housekeeping, food service, and postoperative care units so they will take appropriate precautions to protect the patient.
- Place clear and readily visible signs on the doors of the OR to inform all who enter that the patient has a latex allergy.

Modified from *Perioperative Standards and Recommended Practices: AORN latex guideline*, Denver, 2011, AORN.

TABLE 50-7	Examples of Complications of Anesthesia
Type	**Complications**
General	Aspiration of vomitus, cardiac irregularities, decreased cardiac output, hypotension, hypothermia, hypoxemia, laryngospasm, malignant hyperthermia, nephrotoxicity, and respiratory depression
Regional: epidural, spinal and caudal blocks	Hypotension, hypothermia, injury to spinal cord, respiratory paralysis, spinal headache
Local	Hives, rash, anaphylaxis
Conscious sedation	Aspiration, decreased level of consciousness, hypoxemia, respiratory depression

type of anesthesia is accomplished by injecting a local anesthetic along the pathway of a nerve from the spinal cord. A patient requires careful monitoring during and immediately after regional anesthesia for return of sensation and movement distal to the point of anesthetic injection. As the nurse, you protect a patient's limbs from injury until sensation returns. Serious complications such as respiratory paralysis occur if the level of anesthesia rises, moving upward in the spinal cord. Elevation of the upper body helps prevents respiratory paralysis. Some patients have a sudden fall in blood pressure, which results from extensive vasodilation caused by the anesthetic block to sympathetic vasomotor nerves and pain, and motor nerve fibers. Remember that burns and other trauma can occur on the anesthetized part of the body without the patient being aware of the injury. It is necessary to observe the position of extremities and the condition of the skin frequently.

Local Anesthesia. **Local anesthesia** involves loss of sensation at the desired site (e.g., a skin growth or the cornea of the eye) by inhibiting peripheral nerve conduction. It is commonly used in ambulatory surgery. A local can also be used in addition to general or regional anesthesia. The anesthetic agent (e.g., lidocaine [Xylocaine]) inhibits nerve conduction until the drug diffuses into the circulation. It is injected locally or applied topically. The patient experiences a loss in pain and touch sensation and motor and autonomic activities (e.g., bladder emptying). It is necessary to monitor patients continually during a local procedure. The frequency of observation and monitoring of patients are tailored to the patient, procedure, and the medications used (Rothrock, 2015).

Moderate (Conscious) Sedation. IV moderate sedation (i.e., **conscious sedation**) is used routinely for short-term surgical, diagnostic, and therapeutic procedures that do not require complete anesthesia but rather a depressed level of consciousness. A patient maintains spontaneous ventilation and a patent airway and requires no interventions during conscious sedation (Rothrock, 2015). In addition, the patient responds appropriately to physical (light touch) and verbal stimuli. The preferred sedative for conscious sedation is short-acting IV sedatives such as midazolam (Versed).

Advantages of conscious sedation include adequate sedation, reduction of fear and anxiety, amnesia, relief of pain and noxious stimuli, mood alteration, elevation of pain threshold, enhanced patient cooperation, stable vital signs, and rapid recovery. Nurses assisting with the administration of conscious sedation need to demonstrate competency in the care of these patients. Knowledge of anatomy, physiology, cardiac dysrhythmias, procedural complications, and pharmacological principles related to the administration of individual agents is essential. You also need to assess, diagnose, and intervene in the event of

unexpected reactions, such as an adverse reaction to a medication, and demonstrate skill in airway management and oxygen delivery. Resuscitation equipment must be readily available when using conscious sedation The AORN (2014) publishes recommendations for managing patients undergoing conscious sedation.

Positioning the Patient for Surgery. Prevention of positioning injuries requires anticipation of the position and surgical approach to be used during a surgical procedure, the positioning equipment to be used, and whether a patient has conditions causing risk for injury (AORN, 2015). During general anesthesia the nursing personnel and surgeon often wait to position a patient until the full stage of relaxation so an injury is less likely to be caused by moving and lifting the patient's body parts. Ideally a patient's position provides clear access to the operative site; sustains adequate circulatory and respiratory function; and ensures the patient's safety, comfort, and skin integrity. If a patient has conditions such as morbid obesity, malnourishment, existing pressure ulcers, or chronic disease, special considerations are needed in positioning. It is important for the circulating nurse to assess circulatory, respiratory, integumentary, musculoskeletal, and neurological structures during surgery (AORN, 2015).

An alert person maintains normal range of joint motion by pain and pressure receptors. If a joint is extended too far, pain stimuli provide a warning that muscle and joint strain is too great. In a patient who is anesthetized, normal defense mechanisms cannot guard against joint damage, muscle stretch, and strain. The muscles are so relaxed that it is relatively easy to place the patient in a position that the individual normally could not assume while awake. He or she often remains in a given position for several hours. Although it is sometimes necessary to place a patient in an unusual position, try to maintain correct alignment and protect skin from pressure, abrasion, and other injuries. Special mattresses, use of foam padding, and attachments to the OR table provide protection to extremities and bony prominences. Positioning should not impede normal movement of the diaphragm or interfere with circulation to body parts. If restraints are necessary, pad the skin to prevent trauma.

Documentation of Intraoperative Care. Throughout the surgical procedure, the circulating nurse keeps an accurate record of patient care activities and procedures performed by OR personnel (e.g., surgical count status, special equipment, IV and irrigation fluids, specimens, and medications). A standardized documentation format helps practitioners ensure continuity of information from the OR to the postanesthesia care unit (PACU) or recovery area (AORN, 2015). The AORN recommends the use of verbal and standardized forms to transfer patient information between care providers.

◆ Evaluation

The circulating nurse conducts an ongoing evaluation to ensure that interventions such as patient position are implemented correctly during the intraoperative phase of surgery.

Through the Patient's Eyes. While a patient is undergoing surgery, it is important to keep the family informed. Hospitals vary on their policies for when and how often families are given updates of the patient's condition. Families expect an estimate of when surgery begins and the length of time it will likely last. When you give an update to family members, ask if they have further questions or concerns and if their needs are being met.

Patient Outcomes. Evaluate a patient's ongoing clinical status during surgery. The anesthesia provider continuously monitors vital signs. The circulating nurse monitors and records intake and output (I&O), specimens obtained, medications and irrigations, type

of dressing packing, and other treatments. Measure the patient's body temperature during and at completion of the surgery, with the goal of keeping the patient normothermic. Inspect the skin under the grounding pad and at areas where positioning exerts pressure.

POSTOPERATIVE SURGICAL PHASE

A patient's surgical recovery is divided into three phases: immediately after surgery, an intermediate time period in which a patient is hospitalized, and a convalescent phase, which occurs while a patient transitions from hospital discharge to full recovery. After surgery a patient's care is often complex as a result of physiological changes. The type of anesthesia, nature of surgery, and the patient's previous condition determine the phases of recovery and the length of time spent on an acute care nursing unit. Typically at the end of surgery the anesthesia provider and the circulating nurse accompany the patient to the PACU and provide a thorough hand-off report to the nursing staff.

For a patient following ambulatory surgery, the immediate recovery period normally lasts only 1 or 2 hours in phase II recovery, and convalescence occurs at home. However, phase I recovery may be necessary, depending on a patient's condition and anesthesia. For a patient in the hospital, the immediate postoperative recovery (phase I) period often lasts a few hours in the PACU, and phase II recovery occurs on a surgical unit. The patient typically remains on the surgical unit for 1 or more days to recover before going home.

IMMEDIATE POSTOPERATIVE RECOVERY (PHASE I)

When a PACU nurse receives a patient during hand-off, he or she obtains data from the surgical team to prepare for proper support of a patient's recovery status. This includes anticipating possible clinical problems on the basis of assessment and being sure that special equipment needed for nursing care is available. Careful planning allows the nursing staff to consider placement of patients in the PACU. For example, patients who undergo spinal anesthesia are aware of their surroundings and benefit from being in a quieter part of the PACU, away from patients needing frequent monitoring. You isolate patients with a serious infection such as tuberculosis from other patients. Use standard precautions for infection control (see Chapter 29) for all patients.

When a patient is admitted to phase I recovery, personnel notify the nurses on the acute care nursing unit of his or her arrival. This allows the nursing staff to inform family members. Family members usually remain in the designated waiting area so they can be found when the surgeon arrives to explain the patient's condition. *It is the surgeon's responsibility to describe the patient's status, the results of surgery, and any complications that occurred.* You are a valuable resource to the family if complications occurred in the operative phase and clarifying explanations are necessary.

When a patient enters the PACU, the nurse and members of the surgical team discuss his or her status. A standardized approach or tool for "hand-off" communications helps to provide accurate information about a patient's care, treatment and services, current condition, and any recent or anticipated changes (Rothrock, 2015). The hand-off is interactive, multidisciplinary, and done at the patient's bedside, allowing for a communication exchange that gives caregivers the chance to dialogue and ask questions. The surgical team's report includes topics such as the type of anesthesia provided, vital sign trends, intraoperative medications, IV fluids, estimated blood and urine loss, and pertinent information about the surgical wound (e.g., dressings, tubes, drains) (Rothrock, 2015). The information obtained from hand-off report allows a recovery nurse to anticipate how quickly a patient should regain consciousness, any likely complications, and what his or her

---

> **BOX 50-7   Initial Postanesthesia Care Assessment: Parameters to Assess**
>
> Initial assessment in the PACU includes documentation of the following:
> - Integration of data received at hand-off for transfer of care
> - Vital signs
>   - Respiratory status—airway patent, breath sounds, type of artificial airway, mechanical ventilator settings, oxygen saturation, and end-tidal CO_2 values
> - Intake and output
> - Pain/sedation/comfort assessment (including psychoemotional status), presence of nausea or vomiting
> - Neurological function: level of consciousness (may use Glascow Coma scale), pupillary response (if indicated)
> - Position of patient
> - Condition and color of skin, status of any suspected pressure areas
> - Patient safety needs
> - Neurovascular status: peripheral pulses and sensation of extremity or extremities
> - Condition of surgical dressings or suture line, drains, tubes, receptacles
> - Amount, appearance, and type of drainage
> - Muscular response and strength/mobility
> - Fluid therapy—location of intravenous (IV) lines, patency of IV lines, amount and type of solution (crystalloids or blood products) infused, next fluid to be administered
> - Procedure-specific assessments, such as expected drainage amount, specific positioning aids for orthopedic surgery

Adapted from Rothrock JC: *Alexander's care of the patient in surgery,* ed 15, St Louis, 2015, Mosby.

---

analgesic needs will be. A report on IV fluids or blood products administered during surgery from the anesthesia provider or perfusionist alerts the nurse to the patient's fluid and electrolyte balance. The surgeon or anesthesia provider often reports special concerns (e.g., whether the patient is at risk for hemorrhaging or infection) and whether there were complications during surgery such as excessive blood loss or cardiac irregularities. The circulating nurse also reports intraoperative patient positioning and condition of the skin. Frequently this report takes place while PACU nurses are admitting the patient. The PACU nurse attaches the patient to monitoring equipment such as the noninvasive blood pressure monitor, ECG monitor, and pulse oximeter. Patients often receive some form of oxygen in this immediate recovery period.

After receiving hand-off communication from the OR, the PACU nurse conducts a complete systems assessment during the first few minutes of PACU care (Rothrock, 2015) (Box 50-7). You perform assessments at least every 15 minutes or more frequently, depending on the patient's condition and unit policy. This assessment usually continues until discharge from the PACU. Perform assessments quickly and thoroughly and target them to a patient's unique needs and type of surgery.

Evaluate the patient's status and eventual readiness for discharge from the PACU on the basis of vital sign stability compared with the preoperative data. Other outcomes for discharge include body temperature control, good ventilation and oxygenation status, orientation to surroundings, absence of complications, minimal pain and nausea, controlled wound drainage, adequate urine output, and fluid and electrolyte balance. Patients with more extensive surgery requiring anesthesia of longer duration usually recover more slowly. It is common for hospitals and ambulatory care centers to use objective scoring systems to identify when patients are ready for discharge.

Standard tools include the modified Aldrete score (Aldrete, 1998) or the modified **postanesthesia recovery score (PARS)** and the DASAIM discharge assessment tool (Gärtner et al., 2010). Each tool has criteria assessed at select time intervals (e.g., 5, 15, 30, 45, and 60 minutes) and on discharge from the PACU (see agency policy). A patient must receive a predetermined score before discharge from the PACU. If the patient's condition is still poor after 2 or 3 hours or the stay lengthens, the surgeon may transfer him or her to an intensive care unit (ICU).

When the patient is discharged from the PACU, another hand-off communication occurs at the patient's bedside between the PACU nurse and the nurse on the acute nursing unit or in the ICU. The nurses verify the patient's identification using two identifiers. The hand-off includes review of vital signs, the type of surgery and anesthesia performed, blood loss, level of consciousness, general physical condition, medications administered during surgery and in PACU, and the presence of IV lines, drainage tubes, and dressings. The PACU nurse's report helps the receiving nurse anticipate special patient needs and obtain necessary equipment. It is important to have uninterrupted time to review the recent pertinent events and ask questions. It is also important at this time for patient's family members to be informed as soon as possible of the patient's transfer plan.

The PACU staff transport the patient on a stretcher to the nursing unit. Staff members from the unit help to safely transfer the patient to a bed (see Chapter 39). The PACU nurse shows the receiving nurse the recovery room record and reviews the patient's condition and course of care. The PACU nurse also reviews the surgeon's orders that require attention. *Before the PACU nurse leaves the acute care area, the staff nurse assuming care for the patient takes a complete set of vital signs to compare with PACU findings.* Minor vital sign variations normally occur after transporting the patient.

RECOVERY IN AMBULATORY SURGERY (PHASE II)

The thoroughness and extent of postoperative recovery after ambulatory surgery depends on a patient's condition, type of surgery, and anesthesia. In some cases a patient goes through both phase I (PACU) and phase II recovery. Assess and care for patients in need of close monitoring in the same fashion as inpatients in phase I. It is common to assess patients using an objective recovery score tool. After patients stabilize and no longer require close monitoring, transfer them to phase II recovery. With new anesthetic agents and minimally invasive surgical techniques, *fast-track surgery* is becoming more common, with patients experiencing a more rapid awakening in the OR, quicker recovery, and reduced morbidity (Kehlet and Wilmore, 2008). Many ambulatory surgery patients are able to bypass phase I.

Phase II recovery is performed in a room equipped with medical recliner chairs, side tables, and foot rests. Kitchen facilities for preparing light snacks and beverages are usually located in the area, along with bathrooms. The phase II environment promotes a patient's and family's comfort and well-being until discharge. Monitor patients but not at the same intensity as during phase I. In phase II recovery initiate postoperative teaching with patients and family members (Box 50-8).

Patients are discharged to home following ambulatory surgery after they meet certain criteria. When you are using a tool for assessing a patient's recovery score such as the PARS, the patient must achieve a certain score before being discharged. Patients with known OSA or at high risk for the condition are not discharged from the recovery area to home until they are no longer at risk for postoperative respiratory depression, which may require a longer stay (ASA, 2014). Postoperative nausea and vomiting (PONV) sometimes occurs once the patient is home, even if the symptoms were not present in the surgery center. Options for therapy include the prophylactic use of drugs such as

BOX 50-8 PATIENT TEACHING

Postoperative Instructions for an Ambulatory Surgical Patient

Objective
- Patient will describe signs and symptoms of postoperative problems to report to health care provider.

Teaching Strategies
- Give instruction sheet with contact information, including health care provider's telephone number, number of surgery center, and follow-up appointment date and time. Allow patient and family to ask questions.
- Explain to family member the signs and symptoms of infection.
- Explain name, dose, schedule, and purpose of medications and possible side effects. Provide printed drug information.
- Explain activity restrictions, diet progression, wound care guidelines, and the signs of any associated problems. Provide instruction sheet with clear, focused explanations.

Evaluation
- Have patient explain when and how to call health care provider with problems.
- Have patient recite date for follow-up appointment.
- Have patient and family member describe signs and symptoms of infection.
- Have patient verbalize name of drug, dose, when to take, and common side effects.
- Have patient demonstrate proper activity/movement and wound care.

ondansetron (Zofran) aprepitant, dolasetron and transcutaneous AccuPoint electrical stimulation, or a transdermal scopolamine patch (McCaffrey, 2007; Rothrock, 2015).

Review written postoperative instructions and prescriptions with the patient and family before releasing the patient and ensure that they verbalize understanding of these instructions. Always discharge the patient to a responsible adult.

POSTOPERATIVE RECOVERY AND CONVALESCENCE

Inpatients remain in the PACU until their condition stabilizes; they then return to the postoperative nursing unit. Nursing care in both settings focuses on returning the patient to a relatively functional level of wellness as soon as possible. The speed of recovery depends on the type or extent of surgery, risk factors, pain management, and postoperative complications.

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision making approach for you to develop and implement an individualized plan of care. Once a surgical patient is transferred to an acute care nursing unit, ongoing postoperative care is essential to support recovery.

◆ Assessment

During the assessment process, thoroughly assess each patient and critically analyze findings to ensure you make patient-centered clinical decisions required for safe nursing care. During a postoperative assessment, apply critical thinking while relying on information from the preoperative nursing assessment, knowledge regarding the surgical

procedure performed, and events occurring during surgery. This analysis will help you focus your postoperative assessment. A variation from the patient's norm possibly indicates the onset of surgically related complications.

Before a patient arrives on the nursing unit, prepare the bed and room for his or her return if he or she is returning to the same nursing unit. You are better prepared to care for the patient after surgery if the room is readied before the patient's return. A postoperative bedside unit includes the following:

1. Sphygmomanometer and/or automated noninvasive blood pressure monitor, stethoscope, and thermometer
2. Emesis basin
3. Incentive spirometer
4. Clean gown, washcloth, towel, and facial tissues
5. IV pole and infusion pump (if needed)
6. Suction equipment (if needed)
7. Oxygen equipment and oximetry monitor (if needed)
8. Extra pillows for positioning the patient comfortably
9. Bed pads to protect bed linen from drainage
10. Bed raised to stretcher height with bed linens pulled back and furniture moved to accommodate the stretcher and equipment (such as IV lines)

When a patient arrives on the acute care unit, monitor vital signs according to institution policy. Generally you check vital signs every 15 minutes twice, every 30 minutes twice, hourly for 2 hours, and then every 4 hours or per orders. As the patient's condition stabilizes, you usually assess the patient at least once a shift until discharge. Always base the frequency of assessment on a patient's current condition. *Do not assume that further monitoring is unnecessary if the patient appears normal during the initial assessment.* A patient's condition can change rapidly, especially during the postoperative period.

Thoroughly document the initial nursing assessment, including vital signs, level of consciousness, airway status, condition of dressings and drains, pulses distal to site of surgery, comfort level, IV fluid status, and urinary output measurements. Enter patient data into the medical record on flow sheets, surgical assessment drop-down menus, or written progress notes. The initial findings provide a baseline for comparing postoperative changes.

Through the Patient's Eyes.

When a patient initially returns to the acute care nursing unit, the family and patient have expectations of receiving prompt and attentive care. There is also the expectation that a nurse will explain the patient's immediate status and the plan of care for the next few hours. Seeing the patient return from surgery is a relief in many ways; but, if the patient has had complications or is not responding well, anxiety easily returns. As a patient stabilizes it is important to assess the patient's and family's expectations for recovery and convalescence once he or she returns home. Be sure to review their expectations for management of pain and other symptoms. What do they expect from staff during the hospitalization? What are their expectations after the patient is discharged from the hospital? Are family members prepared to assume care at discharge? Make the patient and family partners in your assessment so you can gather information necessary to develop a relevant plan of care. For example, determine a patient's and family's values and beliefs as they pertain to the meaning of the surgical condition and how it will affect the patient's ability to reassume his or her role in the family.

Airway and Respiration.

The first priority in the care of a patient after anesthesia is to establish a patent airway. Assess airway patency, respiratory rate, rhythm, depth of ventilation, symmetry of chest wall movement, breath sounds, and color of mucous membranes.

Also know that certain anesthetic agents cause respiratory depression. A patient may present with snoring, little or no air movement on auscultation of the lungs, retraction of intercostal muscles, asynchronous movements of the chest, and decreased oxygen saturation. Be alert for shallow, slow breathing and a weak cough. If breathing is unusually shallow, place your hand near the patient's nose or mouth to feel exhaled air. Normal pulse oximetry values range between 92% and 100% saturation. Postoperative confusion is frequently secondary to hypoxia, especially in older adults.

An oral or nasal airway (see Chapter 41) is sometimes inserted in the OR or PACU after removal of the endotracheal tube. It maintains a patent airway until patients can protect their airway. However, aspiration or the passage of regurgitated material into the lungs occurs most often with removal of endotracheal tubes (Rothrock, 2015). As patients awaken they spit out the airway, or you ask them to spit it out. The ability to do so signifies the return of a normal gag reflex. Be alert for nausea and vomiting, which may precipitate regurgitation, avoid any rapid movement of the patient, and keep his or her head elevated while lying on the side.

One of your greatest concerns is airway obstruction. A number of factors contribute to obstruction, including history of OSA; weak pharyngeal/laryngeal muscle tone from anesthetics; secretions in the pharynx, bronchial tree, or trachea; and laryngeal or subglottic edema. After anesthesia, a patient's tongue causes the majority of airway obstructions. Ongoing assessment of airway patency is crucial. Patients remain in a side-lying position until airways are clear. Continue to assess respiratory status and breath sounds. Older patients, smokers, and patients with a history of respiratory disease are prone to developing complications such as atelectasis or pneumonia. Patients with OSA are often required to have continuous pulse oximetry while receiving IV opioids to detect oxygen desaturation quickly. Use of the Pasero Opioid-Induced Sedation Scale (POSS) in the PACU helps assess patients more accurately and meets the pain needs of the patient, while preventing oversedation (Kobelt et al., 2014).

Circulation.

The patient is at risk for cardiovascular complications resulting from actual or potential blood loss from the surgical site, side effects of anesthesia, electrolyte imbalances, and depression of normal circulatory-regulating mechanisms and ischemia. Careful assessment of heart rate and rhythm, along with blood pressure, reveals a patient's cardiovascular status. Compare preoperative vital signs with postoperative values. If a patient's blood pressure drops progressively with each check or if the heart rate changes or becomes irregular, notify the health care provider. A rhythm strip of the heart is obtained after surgery, compared with preoperative ECG tracings, and placed in the medical record.

Assess circulatory perfusion by noting capillary refill, pulses, and the color and temperature of the nail beds and skin. If a patient had vascular surgery or has casts or constricting devices that may impair circulation, assess peripheral pulses and capillary refill distal to the site of surgery. For example, after surgery to the femoral artery, assess posterior tibial and dorsalis pedis pulses. In addition, compare pulses in the affected extremity with those in the nonaffected extremity.

A common early circulatory problem is bleeding or hemorrhage. Blood loss may occur internally or externally through a drain or incision. Either type of hemorrhage results in a fall in blood pressure; elevated heart and respiratory rates; thready pulse; cool, clammy, pale skin; and restlessness. Notify the surgeon if these changes occur. Maintain IV fluid infusion. Monitor the patient's vital signs every 15 minutes or more frequently until the patient's condition stabilizes. Continue oxygen therapy. The surgeon may consider medications or volume replacement and order blood counts and coagulation studies.

Temperature Control.   The OR and recovery room environments are extremely cool. A patient's anesthetically depressed level of body function results in a lowering of metabolism and fall in body temperature. When patients begin to awaken more fully, they complain of feeling cold and uncomfortable. Older adults and pediatric patients are at higher risk for developing problems associated with postoperative hypothermia (temperature less than 36° C [96.8° F]). Also closely assess body temperature of other at-risk patients, including those of female gender, patients with burns, patients who received general anesthesia, patients who are cachexic or had low temperatures intraoperatively, and those whose surgery involved use of cold irrigants (Rothrock, 2015).

In rare instances a genetic disorder known as **malignant hyperthermia**, a life-threatening complication of anesthesia, develops. Malignant hyperthermia causes hypercarbia (elevated carbon dioxide), tachypnea, tachycardia, premature ventricular contractions (PVCs), unstable blood pressure, cyanosis, skin mottling, and muscular rigidity. Despite the name, an elevated temperature occurs late. The increased expired carbon dioxide is one of the first signs. Although it often occurs during the induction phase of anesthesia, symptoms can occur after surgery or with repeated exposures to anesthesia (Rothrock, 2015). Without prompt detection and treatment, it is potentially fatal.

Monitor temperature closely in the acute care area. Because an elevated temperature may be the first indication of an infection, assess the patient for a potential source of infection, including the IV site (if present), the surgical incision/wound, and the respiratory and urinary tracts. Notify the health care provider because further evaluation is often necessary.

Fluid and Electrolyte Balance.   Because of the risk for fluid and electrolyte abnormalities after surgery, assess the patient's hydration status and monitor for signs of electrolyte alterations (see Chapter 42). Monitor and compare laboratory values with the patient's baseline. An important responsibility of the nurse is maintaining patency of IV infusions. The patient's only source of fluid intake immediately after surgery is through IV catheters until the gag reflex and bowel sounds resume. Inspect the patient's catheter insertion site to ensure that the catheter is properly positioned within a vein, fluid flows freely, and the site is free of phlebitis or infiltration. Accurate recording of I&O assesses renal and circulatory function. Measure all sources of output, including urine, surgically placed drains, and gastric and wound drainage; note any insensible loss from diaphoresis. Assess daily weight for the first several days after surgery and compare with the preoperative weight. If the patient has a known cardiac history such as heart failure, continue daily weights. It is important to use a consistent scale, amount of clothing, and time of day to obtain accurate weight measurement.

Neurological Functions.   In the PACU the patient is often drowsy. As anesthetic agents begin to metabolize, his or her reflexes return, muscle strength is regained, and a normal level of orientation returns. Continue monitoring neurological status on the nursing unit. Ensure that the patient is oriented to self and the hospital and responds to questions appropriately. Assess pupil and gag reflexes, hand grips, and movement of extremities (see Chapter 31). If a patient had surgery involving part of the neurological system, conduct a more thorough neurological assessment. For example, if the patient had low-back surgery, assess leg movement, sensation, and strength.

Patients with regional anesthesia experience a return in motor function before tactile sensation returns. Check the patient's sensation to touch (see Chapter 31). Knowing where regional anesthesia was introduced helps you check the distribution of the spinal nerves affected. Typically assess sensation by touching the patient bilaterally in the same area (e.g., lower arm on both sides or leg on both sides) and note where the patient feels touch. Test the sense of touch using hand pressure or a gentle pinch of the skin. Extremity strength assessment is important if a patient had spinal or epidural anesthesia. Patients remain in the PACU until sensation and voluntary movement of the lower extremities are reestablished.

Skin Integrity and Condition of the Wound.   During recovery and acute postoperative care assess the condition of the skin, noting pressure areas, rashes, petechiae, abrasions, or burns. A rash often indicates a drug sensitivity or allergy. Abrasions or petechiae sometimes result from a clotting disorder or inappropriate positioning or restraining that injures skin layers. Burns may indicate that an electrical cautery grounding pad was placed incorrectly on the patient's skin. Document burns or serious injury to the skin on an occurrence or adverse-event report according to agency policy (see Chapter 23). Note if the patient is complaining of any burning or pain in the eye, which could indicate a corneal abrasion.

After surgery a patient may only have butterfly tape, skin staples, or even glue to close small wounds. Look at the incision carefully and notice any drainage or swelling. Most surgical wounds that are larger have dressings that protect the wound site and collect drainage. Observe the amount, color, odor, and consistency of drainage on dressings. It is most common to see serosanguineous drainage immediately after surgery. Estimate the amount of drainage by noting the number of saturated gauze sponges. If drainage appears on the outer surface of a dressing, another way of assessing it is marking the outer perimeter of the drainage with tape or marking and dating it with the time noted. This way you can easily note if drainage is increasing (see Chapter 48). However, this is not the most accurate measure of volume of fluid lost. Reinforce the dressing as needed and call the surgeon if wound drainage is leaking through the dressing.

Many surgeons prefer to change surgical dressings the first time so they can inspect the incisional area. This applies to both outpatients and inpatients. You have the opportunity on the acute care nursing unit to view and thoroughly assess and document the status of the incision/wound at the time of this initial dressing change. Assess if wound edges are approximated and whether bleeding or drainage is present. It is also important to assess the patient's mobility level. If he or she is unable or unwilling to turn because of pain from the incisional area, pressure ulcer development is a concern. Institute the use of the Braden Scale or another assessment tool to determine a patient's risk of developing pressure ulcers.

Metabolism.   Research over the past decade shows postoperative hyperglycemia (blood glucose greater than 180 mg/dL) is associated with surgical wound infection and longer hospital stays in surgical patients. Normoglycemia or a glucose level less than 150 mg/dL and reducing blood glucose variability is usually both safe and effective for patient management and are now recommended as an evidenced-based practice (Lipshutz and Gropper, 2009). Nurses need to monitor blood glucose levels routinely on the basis of surgeon order or hospital policy.

Genitourinary Function.   Depending on the surgery, some patients do not regain voluntary control over urinary function for 6 to 8 hours after anesthesia. An epidural or spinal anesthetic often prevents a patient from feeling bladder fullness. Palpate the lower abdomen just above the symphysis pubis for bladder distention. Another option is to use a bladder scan or ultrasound to assess bladder volume. If the patient has a urinary catheter, there should be a continuous flow of urine of approximately 30 to 50 mL/hr in adults (see agency policy). Observe the color and odor of urine. Surgery involving parts of the urinary tract

normally causes bloody urine for at least 12 to 24 hours, depending on the type of surgery. A urine output of less than 0.5 mL/kg/hr is reported to the surgeon or health care provider (Lewis et al., 2014).

Gastrointestinal Function. General anesthetics slow GI motility and often cause nausea. In addition, manipulation of the intestines during abdominal surgery further impairs peristalsis. Faint or absent bowel sounds are typical immediately after surgery. Normally patients who undergo abdominal or pelvic surgery have decreased peristalsis for at least 24 hours or longer (Rothrock, 2015). **Paralytic ileus** (i.e., loss of function of the intestine), which causes abdominal distention, is always possible after surgery. Auscultate bowel sounds in all four quadrants, noting faint or absent bowel sounds. Inspect the abdomen for distention caused by accumulation of gas. Ask whether a patient is passing flatus, an important sign indicating return of normal bowel function. The return of flatus is usually more indicative of normal bowel function return than the return of bowel sounds (Massey, 2012). If a nasogastric (NG) tube is in place for decompression, assess the patency of the tube and the color and amount of drainage (see Chapter 47).

Comfort. As patients awaken from general anesthesia, the sensation of pain becomes prominent. They perceive pain before regaining full consciousness. Acute incisional pain causes them to become restless and is often responsible for temporary changes in vital signs. It is difficult for patients to begin coughing and deep-breathing exercises when they experience incisional pain. The patient who had regional or local anesthesia usually does not experience pain initially because the incisional area is still anesthetized. Ongoing assessment of the patient's discomfort and evaluation of pain-relief therapies are essential throughout the postoperative course. Pain scales are effective for assessing postoperative pain, evaluating the response to analgesics, and objectively documenting pain severity (see Chapter 44). Using preoperative pain assessments as a baseline, evaluate the effectiveness of interventions throughout the patient's recovery.

◆ **Nursing Diagnosis**

Determine the status of preoperative nursing diagnoses by clustering new postoperative assessment data. Then either revise or resolve preoperative diagnoses and identify relevant new diagnoses after surgery. A previously defined diagnosis such as *Impaired Skin Integrity* may continue as a postoperative problem, particularly if your assessment reveals continued risks such as reduced mobility or excess diaphoresis. It is common to identify new nursing diagnoses after surgery because of the risks or problems associated with it. Also consider the assessed needs of a patient's family when you identify nursing diagnoses. In the formulation of nursing diagnoses, be accurate in identifying a related factor (when appropriate). For example, *Impaired Physical Mobility related to reduced lower-extremity strength* compared with *Impaired Physical Mobility related to exercise intolerance* requires different nursing interventions. Potential nursing diagnoses for the postoperative patient include the following:

- *Ineffective Airway Clearance*
- *Anxiety*
- *Fear*
- *Risk for Infection*
- *Deficient Knowledge (specify)*
- *Impaired Physical Mobility*
- *Impaired Skin Integrity*
- *Nausea*
- *Acute Pain*
- *Delayed Surgical Recovery*

◆ **Planning**

During the convalescent phase use current physical assessment data and analysis of the preoperative nursing history to plan the patient's care. The surgeon's postoperative orders and surgical team's report of the patient's operative condition also provide valuable data. Typical postoperative orders include:

- Frequency of vital sign monitoring and special assessments.
- Types of IV fluids and rates of infusion.
- Postoperative medications (especially those for pain and nausea).
- Resumption of preoperative medications as condition allows (some oral medications are converted to the IV route with appropriate dose adjustment).
- Fluids and food allowed by mouth.
- Level of activity that the patient is allowed to resume.
- Position that the patient is to maintain while in bed.
- I&O and daily weights.
- Laboratory tests and x-ray film studies.
- Special directions (e.g., surgical drains to suction, tube irrigations, dressing changes).

Goals and Outcomes. Review nursing diagnoses when establishing goals, expected outcomes, and interventions for your patient. Measurable outcomes provide specific guidelines for determining a patient's progress toward recovery from surgery. For example, a patient recovering from hip replacement surgery with the diagnosis of *Impaired Physical Mobility related to pain and lower-extremity weakness* has specific outcomes that include targeted ambulation (e.g., steps to take and distance down hallway), pain relief, and improved range of joint movement. After meeting each outcome, a patient ultimately achieves the goal of independent ambulation at a preoperative level or better. At times goals and outcomes extend from the convalescent period into the home setting. Also consider all goals of care established during the preoperative surgical phase that are still relevant. For example, a goal for the diagnosis of *Risk for Infection* would be "Patient will remain free of infection after surgery." Expected outcomes for this goal include:

- Patient's incision remains closed and intact.
- Patient's incision remains free of infectious drainage.
- Patient remains afebrile.

Setting Priorities. During the convalescent phase of recovery from general anesthesia, priorities for the first 24 hours continue to include maintenance of respiratory, circulatory, and neurological status; wound management; and pain control. In addition, most surgeons are aggressive in increasing a patient's activity as soon as possible. As a patient progresses, focus priorities on advancement of patient activity (e.g., mobility, diet tolerance) to return the patient to preoperative functioning or better. A patient generally has multiple nursing diagnoses (Figure 50-5). Reestablish priorities as the status of the patient's health problems change.

Teamwork and Collaboration. During recovery collaborate on the plan of care with respiratory therapy, physical therapy, occupational therapy, dietary, social work, home care, and others. Include family members as much as possible, especially if they will be assuming care responsibilities in the home. The goal of an interdisciplinary approach to care is to help the patient return to the best possible level of functioning with a smooth transition to home, rehabilitation, or long-term care. Acute care settings often have a nurse or social worker in a case-manager role to coordinate interdisciplinary care so the most appropriate resources are available to patients.

CONCEPT MAP

Nursing diagnosis: Acute pain
- Patient describes severity of incision pain as a 6 on a scale of 0 to 10
- Refused first PT session on postoperative day 1 due to pain
- Grimaces and splints abdomen when repositioning

▼

Interventions
- Monitor patient's use of PCA morphine infusion; encourage to use routinely until pain is controlled
- Have patient self-administer PCA before PT session
- Have two nurses reposition patient routinely

Nursing diagnosis: Risk for deficient fluid volume
- NG tube to low intermittent suction
- IV fluids infusing
- Urinary catheter in place
- Remains NPO

▼

Interventions
- Maintain careful intake and output
- Maintain IV access
- Monitor for flatus and return of bowel function

Primary health problem: Postoperative day 1 from a right colectomy (right-sided large bowel resection) for tumor
Priority assessments: Comfort level, risk for deficient fluid volume, risk for infection

Nursing diagnosis: Risk for infection
- 18-cm midline abdominal incision
- IV catheter in her right arm
- 80 years old
- Currently afebrile

▼

Interventions
- Monitor midline abdominal wound
- Change abdominal dressing as ordered
- Monitor temperature and white blood cell count
- Monitor condition of IV site every shift
- Keep IV dressing dry and intact

Nursing diagnosis: Self-care deficit: toileting, bathing and dressing
- Has difficulty reaching bathing supplies
- Cannot reach back and legs to wash or dry
- Activity restrictions limit ability to care for self

▼

Interventions
- Refer to occupational therapy to learn use of assistive devices for bathing
- Teach daughter how to assist with bathing/ dressing

——— Link between medical diagnosis and nursing diagnosis   ----- Link between nursing diagnoses

◆ **Implementation**

Acute Care. Primary causes for postoperative complications include impaired healing of the surgical wound, the effects of prolonged immobilization during surgery, recovery, and convalescence, and the influence of anesthesia and analgesics. If a patient has surgical risks before surgery (e.g., increased age, OSA, history of smoking, history of diabetes), the likelihood of complications is greater (Box 50-9). Direct your postoperative nursing interventions at preventing complications so the patient returns to the highest level of functioning possible. Failure of a patient to become actively involved in recovery adds to the risk of complications (Table 50-8). Virtually any body system can be affected. Consider the interrelationship of all systems and therapies provided. Purposeful hourly rounds meet patient needs and increase patient satisfaction. Rounds include the 4 *Ps* (i.e., *p*ain, *p*otty, *p*ositioning, and *p*eriphery). Nursing staff ask patients about their pain and if they need to toilet, the patients are positioned for comfort, and an environmental check is done of the periphery to

ensure that possessions such as a phone and call light are in reach (Olrich et al., 2012).

Maintaining Respiratory Function. To prevent respiratory complications begin pulmonary interventions early. The benefits of thorough preoperative teaching are reached when patients are able to participate actively in postoperative exercises. When patients awaken from anesthesia, help them maintain a patent airway. Position the patient on one side with the face downward and the neck slightly extended to facilitate a forward movement of the tongue and the flow of mucus secretions out of the mouth. A small folded towel supports the head. Another positioning technique to promote a patent airway involves elevating the head of the bed slightly and extending the patient's neck slightly, with the head turned to the side. In the PACU you sometimes need to perform a jaw-thrust maneuver and/or chin lift continuously to maintain the patient's airway. Never position a patient with arms over or across the chest because this reduces maximum chest expansion.

Place patients with known OSA or at risk for OSA in the lateral, prone, or upright position throughout the perioperative period, never

BOX 50-9	**FOCUS ON OLDER ADULTS**

Care of the Older Adult After Surgery

- Many older adults tolerate elective surgery well with effective preoperative and postoperative care. However, they do not tolerate emergency or long, complicated surgeries as well because of a decrease in physiological reserves (Clayton, 2008).
- Co-morbidities (preexisting medical conditions) and reduction in physiological reserve consistently predict poor postoperative outcomes in older adults. Adverse postoperative outcomes, particularly medical complications, are more common in older people when compared with young adults (Partridge et al., 2012).
- During the perioperative period assess for changes that occur as a result of infection, hemorrhage, alterations in blood pressure, and fluid/electrolyte abnormalities. Ongoing, focused assessments are necessary.
- Older patients are at greater risk for postoperative delirium associated with an acute onset. Reduced level of consciousness, reduced ability to maintain attention, perceptual disturbances, and memory impairment characterize the typical presentation (Meiner, 2015).
- Implement individualized measures to help the older adult achieve rest, sleep, and orientation in the postoperative period to reduce the risk of delirium development.
- Altered and unexpected drug responses are often related to different pharmacokinetics in the older adult. Thus be alert to the possibility of a high risk for adverse medication events with the administration of anesthetic agents and postoperative analgesics, especially narcotics (Meiner, 2015). "Start low and go slow" is the guiding principle when medicating older adults because of their slow drug-clearance capability.

TABLE 50-8	**Postoperative Complications**

Complication	Cause
Respiratory System	
Atelectasis: Collapse of alveoli with retained mucus secretions. Signs and symptoms include elevated respiratory rate, dyspnea, fever, crackles auscultated over involved lobes of lungs, and productive cough.	Inadequate lung expansion. Anesthesia, analgesia, and immobilized position prevent full lung expansion. There is greater risk in patients with upper abdominal surgery who have pain during inspiration and repress deep breathing.
Pneumonia: Inflammation of alveoli involving one or several lobes of lung. Development in lower dependent lobes of lung is common in patient who is immobilized after surgery. Signs and symptoms include fever, chills, productive cough, chest pain, purulent mucus, and dyspnea.	Poor lung expansion with retained secretions or aspirated secretions. Common resident bacterium in respiratory tract is *Diplococcus pneumoniae,* which causes most cases of pneumonia.
Hypoxemia: Inadequate concentration of oxygen in arterial blood. Signs and symptoms include restlessness, confusion, dyspnea, high or low blood pressure, tachycardia or bradycardia, diaphoresis, and cyanosis.	Anesthetics and analgesics depress respirations. Increased retention of mucus with impaired ventilation occurs because of pain or poor positioning. Patients with obstructive sleep apnea are at increased risk for hypoxemia.
Pulmonary embolism: Embolus blocking pulmonary arterial blood flow to one or more lobes of lung. Signs and symptoms include dyspnea, sudden chest pain, cyanosis, tachycardia, and drop in blood pressure.	Same factors lead to formation of thrombus or embolus. Patients with preexisting circulatory or coagulation disorders and who are immobile are at risk.
Circulatory System	
Hemorrhage: Loss of large amount of blood externally or internally in short period of time. Signs and symptoms include hypotension, weak and rapid pulse, cool and clammy skin, rapid breathing, restlessness, and reduced urine output.	Slipping of suture or dislodged clot at incisional site. Patients with coagulation disorders are at greater risk.
Hypovolemic shock: Inadequate perfusion of tissues and cells from loss of circulatory fluid volume. Signs and symptoms are same as for hemorrhage.	Hemorrhage usually causes hypovolemic shock after surgery.
Thrombophlebitis: Inflammation of vein often accompanied by clot formation. Veins in legs are most commonly affected. Signs and symptoms include swelling and inflammation of involved site and aching or cramping pain. Vein feels hard, cordlike, and sensitive to touch.	Prolonged sitting or immobilization aggravates venous stasis. Trauma to vessel wall and hypercoagulability of blood increase risk of vessel inflammation.
Thrombus: Formation of clot attached to interior wall of a vein or artery, which can occlude the vessel lumen. Symptoms include localized tenderness along distribution of the venous system, swollen calf or thigh, calf swelling >3 cm (1.2 inches) compared to asymptomatic leg, pitting edema in symptomatic leg, and decrease in pulse below location of thrombus (if arterial).	Venous stasis (see discussion of thrombophlebitis) and vessel trauma. Venous injury is common after surgery of hips and legs, abdomen, pelvis, and major vessels. Patients with pelvic and abdominal cancer or traumatic injuries to the pelvis or lower extremities are at high risk for thrombus formation.

TABLE 50-8	Postoperative Complications—cont'd
Complication	**Cause**
Embolus: Piece of thrombus that has dislodged and circulates in bloodstream until it lodges in another vessel (commonly lungs, heart, brain, or mesentery).	Thrombi form from increased coagulability of blood (e.g., polycythemia and use of birth-control pills containing estrogen).
Gastrointestinal System	
Paralytic ileus: Nonmechanical obstruction of the bowel caused by physiological, neurogenic, or chemical imbalance associated with decreased peristalsis. Common in initial hours after abdominal surgery.	Handling of intestines during surgery leads to loss of peristalsis for a few hours to several days.
Abdominal distention: Retention of air within intestines and abdominal cavity during gastrointestinal surgery. Signs and symptoms include increased abdominal girth, patient complaints of fullness, and "gas pains."	Slowed peristalsis from anesthesia, bowel manipulation, or immobilization. During laparoscopic surgeries influx of air for procedure causes distention and pain up to shoulders.
Nausea and vomiting: Symptoms of improper gastric emptying or chemical stimulation of vomiting center. Patient complains of gagging or feeling full or sick to stomach.	Abdominal distention, fear, severe pain, medications, eating or drinking before peristalsis returns, and initiation of gag reflex.
Genitourinary System	
Urinary retention: Involuntary accumulation of urine in bladder as result of loss of muscle tone. Signs and symptoms include inability to void, restlessness, and bladder distention. It appears 6-8 hours after surgery.	Effects of anesthesia and narcotic analgesics. Local manipulation of tissues surrounding bladder and edema interfere with bladder tone. Poor positioning of patient impairs voiding reflexes.
Urinary tract infection: Infection of the urinary tract as a result of bacterial or yeast contamination. Signs and symptoms include dysuria, itching, abdominal pain, possible fever, cloudy urine, presence of white blood cells, and leukocyte esterase positive on urinalysis.	Most frequently a result of catheterization of the bladder.
Integumentary System	
Wound infection: Invasion of deep or superficial wound tissues by pathogenic microorganisms; signs and symptoms include warm, red, and tender skin around incision; fever and chills; purulent material exiting from drains or from separated wound edges. Infection usually appears 3-6 days after surgery.	Infection is caused by poor aseptic technique or contaminated wound or surgical site before surgical exploration. For example, with a bowel perforation patient is at increased risk for a wound infection because of bacterial contamination from the large intestine.
Wound dehiscence: Separation of wound edges at suture line. Signs and symptoms include increased drainage and appearance of underlying tissues. This usually occurs 6-8 days after surgery.	Malnutrition, obesity, preoperative radiation to surgical site, old age, poor circulation to tissues, and unusual strain on suture line from coughing or positioning.
Wound evisceration: Protrusion of internal organs and tissues through incision. Incidence usually occurs 6-8 days after surgery.	See discussion of wound dehiscence. Patient with dehiscence is at risk for developing evisceration.
Skin breakdown: Result of pressure or shearing forces. Patients are at increased risk if alterations in nutrition and circulation are present, resulting in edema and delayed healing.	Prolonged periods on the operating room (OR) table and in the bed after surgery lead to pressure breakdown. Skin breakdown results from shearing during positioning on the OR table and improperly pulling patient up in bed.
Nervous System	
Intractable pain: Pain that is not amenable to analgesics and pain-alleviating interventions.	Intractable pain may be related to the wound or dressing, anxiety, or positioning.
Malignant hyperthermia: Severe hypermetabolic state and rigidity of the skeletal muscles caused by an increase in intracellular calcium ion concentration.	Rare genetic condition triggered with exposure to inhaled anesthetic agents and the depolarizing muscle relaxant succinylcholine.

the supine position (ASA, 2014). Suction artificial airways and the oral cavity for mucus secretions (see Chapter 41). Avoid continually eliciting the gag reflex, which might cause vomiting. Before you remove an artificial airway (or the patient removes it), suction the back of the airway so secretions are not retained. The following interventions promote expansion of the lungs:

- Encourage diaphragmatic breathing exercises every hour while patients are awake.

- Administer CPAP or NIPPV to patients who use this modality at home (ASA, 2014).
- Instruct patients to use an incentive spirometer for maximum inspiration. The patient should try to reach the inspiratory target volume achieved before surgery on the spirometer.
- Encourage early ambulation. Walking causes patients to assume a position that does not restrict chest wall expansion and stimulates an increased respiratory rate.

- Help patients who are restricted to bed to turn on their side every 1 to 2 hours while awake and to sit when possible.
- Keep the patient comfortable. A patient who is comfortable is able to participate in deep breathing and coughing. Administer analgesics on time so pain does not become severe.

The following measures promote removal of pulmonary secretions if they are present:

- Encourage coughing exercises every 1 to 2 hours while patients are awake and maintain pain control to promote a deep, productive cough. *For patients who have had eye, intracranial, or spinal surgery, coughing may be contraindicated because of the potential increase in intraocular or intracranial pressure.*
- Provide oral hygiene to facilitate expectoration of mucus. The oral mucosa becomes dry when patients are NPO or placed on limited fluid intake.
- Initiate orotracheal or nasotracheal suction for patients who are too weak or unable to cough (see Chapter 41).
- Administer oxygen as ordered and monitor oxygen saturation with a pulse oximeter. Continue monitoring oxygen saturation after discharge from the PACU for patients at risk for respiratory compromise from OSA (ASA, 2014). Administer oxygen to patients at risk for or diagnosed with OSA until they are able to maintain their baseline oxygen saturation while breathing room air.

Preventing Circulatory Complications. Interventions to prevent circulatory complications also prevent venous stasis and thrombus formation (Box 50-10). Some patients are at greater risk of venous stasis because of the nature of their surgery or medical history. The following interventions promote normal venous return and circulatory blood flow:

- Encourage patients to perform leg exercises at least every hour while awake. Exercise may be contraindicated in an extremity with a vascular repair or realignment of fractured bones and torn cartilage.
- Apply graded compression stockings or IPC devices as ordered by the health care provider. Remove the stockings or device at least once per shift. Perform a thorough reassessment of the skin of the lower extremities at this time.
- Encourage early ambulation. Most patients ambulate the evening of surgery, depending on the severity of the surgery and their condition. The degree of activity allowed progresses as the patient's condition improves. Encourage ambulation even if a patient has an epidural catheter or PCA device.
- Before ambulation, assess the patient's vital signs. Abnormalities such as hypotension or certain arrhythmias may contraindicate ambulation. If vital signs are at baseline, first help the patient sit on the side of the bed. Patient complaints of dizziness are a sign of postural hypotension. A recheck of blood pressure determines whether ambulation is safe. Assist with ambulation by standing on the patient's strong side and making sure that he or she is able to walk steadily. Patients may be able to walk only a few feet the first few times out of bed. This usually improves each time. Evaluate tolerance to activity by periodically assessing the pulse rate as the patient ambulates and note the rhythm and increase in rate. Know the patient's maximum heart rate achieved during maximum exercise. One simple method to calculate a predicted maximum heart rate is by using this formula (Cleveland Clinic, 2015):

$$220 - \text{Patient's age} = \text{Predicted maximum heart rate}$$

Example: A 60-year-old's predicted maximum heart rate is 160 beats/min. However, remember that a patient's acute surgical condition may

BOX 50-10   EVIDENCE-BASED PRACTICE

Prevention of Venous Thromboembolism in the Postsurgical Patient

PICO Question: Is mechanical prophylaxis compared with pharmacological prophylaxis the best method to prevent a venous thromboembolism (VTE) in the postsurgical patient?

Evidence Summary

VTE is a high-risk concern for almost all hospitalized patients. A VTE can lead to stroke, myocardial infarction, and death. It is the most common cause of preventable death in patients who are hospitalized (American College of Chest Physicians, 2012). Treatment targets two of the three components of Virchow's triad (stasis and hypercoagulability). Mechanical treatment measures focus on prevention of stasis, whereas pharmacological measures prevent hypercoagulability.

Mechanical prevention includes early ambulation, graded compression stockings, intermittent pneumatic compression devices, or venous foot pumps (Gould et al., 2012; AORN, 2015). Perioperative pharmacological antithrombotic management is based on risk assessment for thromboembolism and bleeding. Recommended approaches simplify patient management and minimize adverse clinical outcomes (Douketis et al., 2012). Guidelines for the use of antithrombotic medications and mechanical prophylaxis follow (Gould et al., 2012):

- When the risk for VTE is very low (less than 0.5%), no specific pharmacological or mechanical prophylaxis is used other than early ambulation.
- For patients at low risk for VTE, mechanical prophylaxis, preferably with intermittent pneumatic compression (IPC), is recommended.
- For patients having general or abdominal-pelvic surgery and at moderate risk for VTE who are not at high risk for major bleeding complications, low-molecular-weight heparin (LMWH), low-dose unfractionated heparin (LDUH), or mechanical prophylaxis, preferably with IPC, is recommended.
- For patients having general or abdominal-pelvic surgery and at high risk for VTE who are not at high risk for major bleeding complications, the same prophylaxis as moderate-risk patients is needed, with mechanical prophylaxis with elastic stockings or IPC added.
- For patients at moderate-to-high risk for VTE who are at high risk for major bleeding complications or those in whom the consequences of bleeding are believed to be particularly severe, mechanical prophylaxis, preferably with IPC, is recommended until the risk of bleeding diminishes and pharmacological prophylaxis may be initiated.

Application to Nursing Practice

- Monitor patients' INR levels: when using LMWH or LDUH, the target international normalized ratio (INR) is 2.5 with a range of 2-3, and dosing is based on renal function and manufacturer recommendations. Notify surgeon or health care provider of abnormal values.
- Check all orders or antithrombotic medications closely.
- Perform ongoing assessments of patient's lower extremities for signs of deep vein thrombosis: swelling in one or both legs; pain or tenderness in one or both legs, which may occur only while standing or walking; warmth in the skin of the affected leg; red or discolored skin in the affected leg.
- Early ambulation and the use of mechanical prophylaxis are recommended in all patients following surgery.

not allow him or her to reach this rate. *Confer with the patient's surgeon or physical therapist about a safe heart rate target.* Always ask patients how they feel during exercise and whether they note chest pain or shortness of breath.

- Avoid positioning patients in a manner that interrupts blood flow to extremities. Do not place pillows or rolled blankets under a patient's knees while in bed. Compression of the popliteal vessels can cause thrombi. When patients sit in chairs, elevate their legs on footstools. Never allow a patient to sit with one leg crossed over the other.
- Administer anticoagulant drugs as ordered. Patients at greatest risk for thrombus formation often receive prophylactic doses of anticoagulants such as LMWH (e.g., enoxaparin [e.g., Lovenox, Fragmin, Arixtra]) or low-dose unfractionated heparin (LDUH) for anticoagulation.
- Promote adequate fluid intake orally or intravenously. Adequate hydration prevents concentrated accumulation of formed blood elements such as platelets and red blood cells. When the plasma volume is low, these elements gather and form small clots within blood vessels.

Achieving Rest and Comfort. Pain control is a priority to facilitate a patient's recovery. Without pain control a patient will not move or ambulate as readily or initiate coughing exercises after surgery. The anesthesia provider orders medications for pain management in the PACU. IV opioid analgesics such as morphine sulfate are the drugs of choice for the immediate postoperative period. Advances have been made in the use of multimodal analgesia (more than one analgesic), which combines different drug classes delivered through various routes, including use of local anesthetics alone or in combination with other nerve blocks or therapies such as PCA. The goal is to enhance the efficacy of pain control while minimizing side effects of each modality (Costantini et al., 2011).

A patient's pain increases following surgery as the effects of anesthesia diminish. The patient becomes more aware of the surroundings and more perceptive of discomfort. The incisional area is only one source of pain. Irritation from drainage tubes, tight dressings, or casts and the muscular strains caused from positioning on the OR table also cause discomfort. Even in local procedures (e.g., **laparoscopy**), air inflation causes significant discomfort in the area of surgery.

When a patient requests pain medication or shows signs of discomfort, assess the nature and character of his or her pain thoroughly (see Chapter 44). Also determine if the ordered dose of analgesic is within the recommended range. Patients have the most surgical pain the first 24 to 48 hours after surgery. IV PCA or epidural analgesia may be ordered. A PCA device delivers analgesic medications by IV or subcutaneous infusion. The PCA system allows patients to administer their own IV analgesics from a specially prepared pump (see Chapter 44). If patients gain a sense of control over their pain, they usually have fewer postoperative problems. Many patients receive regional analgesia such as epidural analgesia continuously throughout the recovery period, especially for thoracic and abdominal surgery. Studies show that continuous epidural analgesia provides superior pain relief in terms of less analgesic use, better postoperative pain relief (especially first 24 hours), less sedation, and faster return of GI function (Hazem and Mokbel, 2014). Epidural techniques are especially useful in patients with OSA who are at increased risk of airway compromise and postoperative complications with the use of systemic opioids after surgery. Nonsteroidal antiinflammatory agents are an alternative to systemic opioids in patients with OSA (ASA, 2014). You care for patients with a variety of pain-control techniques. Monitor closely for side effects and educate the patient and family regarding the pain-management therapy and expected response.

As the patient begins to tolerate oral fluids, facilitate changing his or her pain medication from IV or epidural to oral administration. Do not overlook the importance of nonpharmacological interventions (see Chapter 44). Assess which care routines contribute to pain and use nonpharmacological measures to treat them. An example is to lower the head of the bed and use a pillow for incisional splinting while turning a patient with recent abdominal surgery. Use other methods of promoting pain relief such as positioning, back rubs, distraction, or imagery. Remember, *do not assume that a patient's pain is incisional.* When a patient without PCA or epidural analgesic asks for pain medication, provide analgesics as often as allowed ATC the first 24 to 48 hours after surgery to improve pain control. If pain medications are not relieving discomfort, notify the health care provider for additional orders. You need to recognize potential complications of analgesics and know what to do if they occur.

Temperature Regulation. Unless intraoperative warming is used, patients are usually cool when arriving in the PACU as a result of the cool temperature in the OR and evaporative heat loss. When a patient comes to the PACU or surgical unit, provide warmed blankets or heated air blankets if no other warming device is available. Increasing a patient's body temperature raises metabolism and improves circulatory and respiratory function.

Sometimes shivering is a side effect of certain anesthetic agents instead of hypothermia. Clonidine (Catapres) in small increments can decrease shivering as prescribed by the health care provider. When this happens, encourage your patient to use deep breathing and coughing to help to expel retained anesthetic gases.

Malignant hyperthermia is a hypermetabolic state occurring within skeletal muscle cells that become triggered by anesthesia. It results in an increase in intracellular calcium ion concentration. It is a potentially lethal condition that can occur in patients receiving various inhaled anesthetic agents and succinylcholine. The hyperthermic condition results in high carbon dioxide levels, metabolic and respiratory acidosis, increased oxygen consumption, production of heat, activation of the sympathetic nervous system, high serum potassium levels, and multiple organ dysfunction and failure. Early signs of malignant hyperthermia include tachypnea, tachycardia, heart arrhythmias, hyperkalemia, and muscular rigidity. Later signs include elevated temperature, myoglobinuria, and multiple organ failure (Johns et al., 2012; Chapin and Geibel, 2015). Monitor a patient's end-tidal carbon dioxide and anticipate clinical changes in patients at risk. When malignant hyperthermia develops, immediately administer dantrolene sodium as ordered by the health care provider (Malignant Hyperthermia Association of the United States, 2015).

Patients are at risk for infection following surgery for various reasons. If a patient becomes febrile, be aggressive in providing routine postoperative nursing interventions. For example, deep breathing and coughing, early ambulation, prompt removal of indwelling urinary and IV catheters, and aseptic care of the surgical wound decrease the risk of postoperative infections. Since microorganisms require time to incubate, infections are rare within the first 48 hours after surgery. If the health care provider suspects an infection, he or she orders wound and or blood cultures.

Maintaining Neurological Function. Deep breathing and coughing expel retained anesthetic gases and facilitate a patient's return to consciousness. Try to arouse a patient by calling his or her name in a moderate tone of voice. If that is not successful, waken him or her by using touch or gently moving a body part. If painful stimulation is needed to arouse a patient, notify anesthesia immediately. When patients are elderly, know the status of their renal function because delayed renal clearance of operatively administered anesthetic agents slows awakening. Orientation to the environment is important in maintaining the

patient's mental status. Reorient the patient, explain that surgery is completed, and describe procedures and nursing measures.

Maintaining Fluid and Electrolyte Balance. Immediately after surgery, patients receive fluids only intravenously. It is important to maintain patency of IV infusions in the postoperative period (see Chapter 42). You typically remove an IV catheter once a patient awakens after ambulatory surgery and is able to tolerate water without GI upset. A more seriously ill patient requires IV fluids for a longer period of time to achieve hydration and electrolyte balance. Some patients require blood products after surgery, depending on the amount of blood loss during surgery. A surgeon orders a prescribed solution and rate for each IV infusion. As a patient begins to take and tolerate oral fluids, you decrease the IV rate. When patients no longer need a continuous IV infusion, you will most likely saline lock the IV line to preserve the site for the administration of medications such as antibiotics or other types of intravenous therapy (see Chapter 42).

Promoting Normal Gastrointestinal Function and Adequate Nutrition. Normally a patient who received general anesthesia does not drink fluids in the PACU because of reduced peristalsis, risk of nausea and vomiting, and grogginess from general anesthesia. For patients at high risk for the development of nausea and vomiting or those who must not vomit, you administer a combination of antiemetics to block multiple receptors. A combination of antiemtic medications is often more effective than a single agent (Kovac, 2013). If a patient has a NG tube, keep it patent by irrigating it as ordered (see Chapter 47). Occlusion of a NG tube results in accumulation of gastric contents within the stomach.

Recent research provides a simple remedy for promoting return of GI peristalsis. Studies show that patients who chew gum after surgery experience a faster return of bowel function (bowel sounds), pass flatus significantly sooner, and have their first bowel movement significantly sooner (Jang et al., 2012; Marwah et al., 2012). Research also shows that patients who are fed soon after surgery are more likely to vomit than those who chew gum (Askarpour, 2010).

A patient likely begins taking ice chips or sips of fluids when arriving on an acute surgical care unit. If fluids are tolerated, the diet progresses with clear liquids next. Interventions for preventing GI complications promote return of normal elimination and faster return of normal nutritional intake. It takes several days for a patient who has had GI surgery (e.g., a colon resection) to resume a normal diet. Normal peristalsis often does not return for 2 to 3 days. In contrast, the patient whose GI tract is unaffected directly by surgery can resume dietary intake after recovering from the effects of anesthesia. The following measures promote return of normal elimination:

- Advance a patient's dietary intake gradually. One study showed that the return of flatus and the first postoperative bowel movement are more reliable than a return of bowel sounds in determining when to begin a normal diet in patients who have undergone abdominal surgery (Madsen et al., 2005). Most surgeons rely on the return of flatus or bowel sounds to order a normal diet. Patients usually receive a normal diet the first evening after surgery unless they had surgery on GI structures. Use patient assessment data to determine how quickly to advance your patient's diet. For example, provide clear liquids such as water, apple juice, broth, or tea after nausea subsides. Ingesting large amounts of fluids leads to distention and vomiting. If a patient tolerates liquids without nausea, advance the diet as ordered. Patients who had abdominal surgery are usually NPO the first 24 to 48 hours. As flatus and peristalsis return, provide clear liquids, followed by full liquids, a light diet of solid foods, and finally a patient's usual diet. Encourage intake of foods high in protein and vitamin C.

- Promote ambulation and exercise. Physical activity stimulates a return of peristalsis. A patient who has abdominal distention and "gas pain" may obtain relief when walking.
- Maintain an adequate fluid intake. Fluids keep fecal material soft for easy passage. Fruit juices and warm liquids are especially effective.
- Promote adequate food intake by stimulating a patient's appetite; remove sources of noxious odors and provide small servings of nonspicy foods.
- Avoid moving a patient suddenly to minimize nausea.
- Help the patient get into a comfortable position during mealtime. If possible, have him or her sit to minimize pressure on the abdomen.
- Provide desired servings of food. For example, some patients are more willing to eat the first meal when servings are not large.
- Provide frequent oral hygiene. Adequate hydration and cleaning of the oral cavity eliminate dryness and bad tastes.
- Administer fiber supplements, stool softeners, and rectal suppositories as ordered. If constipation or distention develops, the health care provider orders cathartics or enemas to stimulate peristalsis.
- Provide meals when the patient is rested and free from pain. Often a patient loses interest in eating if mealtime follows exhausting activities such as ambulation, coughing and deep-breathing exercises, or extensive dressing changes. When a patient has pain, the associated nausea often causes a loss of appetite.

Promoting Urinary Elimination. The depressant effects of anesthetics and analgesics impair the sensation of bladder fullness. A full bladder is painful and causes a patient awakening from surgery to be restless or agitated. Patients who have abdominal surgery or surgery of the urinary system often have indwelling catheters inserted until voluntary urination returns. However, patients without a catheter need to void within 8 to 12 hours after surgery. Sometimes it is necessary to insert a straight catheter. If a patient has an indwelling urinary catheter, the goal is to remove it as soon as possible because of the high risk for the development of a health care–associated bladder or urinary tract infection (HAI). Use evidence-based protocols to ensure prompt removal of urinary catheters (Willson et al., 2009). The following measures promote normal urinary elimination (see Chapter 46):

- Help patients assume their normal position to void if possible.
- Check a patient frequently for the need to void when a catheter is not in place. The feeling of bladder fullness is often sudden, and you need to respond promptly when a patient calls for assistance.
- Assess for bladder distention. If a patient does not void within 8 hours of surgery or bladder distention is present, you will insert a straight urinary catheter if you have an order from a health care provider. Continued difficulty in voiding sometimes requires an indwelling catheter, which increases the risk for a urinary tract infection. Although the evidence is inconclusive, some agencies use bladder ultrasound to assess bladder volume and assist in the decision to place a urinary catheter.
- Monitor I&O. If a patient has an indwelling catheter, expect an output of about 30 to 50 mL/hr. Another way to gauge adequacy of output is by determining a patient's weight. An accepted level of urinary output is at least 1 mL/kg/hr for adults (Lewis et al., 2014). If the urine is dark, concentrated, and low in volume, notify a health care provider. Patients easily become dehydrated as a result of fluid loss from surgical wounds and inadequate fluid intake. Measure I&O for several days after surgery until a patient achieves normal fluid intake and urinary output.

Skin and Wound Care. A wound undergoes considerable stress after surgery from inadequate nutrition, impaired circulation, and metabolic alterations (see Chapter 48). A wound also undergoes considerable physical stress. Strain on sutures from coughing, vomiting, distention, and movement of body parts can disrupt wound layers. Protect a wound and promote healing. A critical time for wound healing is 24 to 72 hours after surgery, after which a seal is established. If infection of a clean surgical wound occurs, you will usually find symptoms of infection 4 to 5 days after surgery. Thus you monitor patients on an ongoing basis for fever, tenderness at a wound site, and presence of local drainage on dressings (i.e., yellow, green or brown, and odorous). A clean surgical wound usually does not regain strength against normal stress for 15 to 20 days after surgery.

Surgical dressings (if present) remain in place the first 24 hours after surgery to reduce risk of infection. During this time add an extra layer of gauze on top of the original dressing if drainage develops. After that, use aseptic technique during dressing changes and wound care (see Chapter 48). Time any dressing change to begin 5 to 30 minutes after you give a patient pain medication (depending on route: 5 minutes intravenously, 30 minutes oral). Keep surgical drains patent so accumulated secretions can escape from the wound bed.

Maintaining/Enhancing Self-Concept. The appearance of wounds, bulky dressings, drains, and tubes threatens a patient's self-concept. The effects of surgery such as disfiguring scars often create permanent changes in a patient's body image. If surgery leads to impairment in body function, a patient's role within the family can change significantly. Observe patients for behaviors reflecting alterations in self-concept (see Chapter 34). Some patients show revulsion toward their appearance by refusing to look at incisions, carefully covering dressings with bed clothes, or refusing to get out of bed because of tubes and devices. The fear of not being able to return to a functional family role causes some patients to avoid participating in the plan of care.

A family often plays an important role in efforts to improve a patient's self-concept. Explain the patient's appearance to the family and ways to avoid nonverbal expressions of revulsion or surprise. Encourage the family to accept the patient's needs and support his or her independence. The following measures help to maintain a patient's self-concept:

- Provide privacy during dressing changes or inspection of the wound. Keep room curtains closed around the bed and drape the patient to expose only the dressing or incisional area.
- Maintain the patient's hygiene. Wound drainage and antiseptic solutions from the surgical skin preparation dry on the surface of the skin, causing foul odor and skin irritation. A complete bath the first day after surgery renews the patient. Offer a clean gown and washcloth if a gown becomes soiled. Keep the patient's hair neatly combed and offer frequent oral hygiene every 2 hours while awake, especially if patient is NPO.
- Prevent drainage devices from overflowing. Measure contents of drainage collection devices every 8 hours for output recording. Measure and empty more often if drainage is excessive.
- Maintain a pleasant environment. Being in pleasant, comfortable surroundings heightens self-concept. Store or remove unused supplies. Keep the patient's bedside orderly and clean.
- Offer opportunities for the patient to discuss feelings about appearance. A patient who avoids looking at an incision possibly needs to discuss fears or concerns. A patient having surgery for the first time is often more anxious than one who has had multiple surgeries. When a patient looks at an incision for the first time, make sure that the area is clean. Eventually he or she will be able to care for the incision site by applying simple dressings or bathing the affected area.

- Provide the family with opportunities to discuss ways to promote the patient's self-concept. Encouraging independence is sometimes difficult for a family member who has a strong desire to help the patient in any way. Family members are more able to be supportive during dressing changes when they know about the appearance of a wound or incision. Help family members know when it is appropriate to discuss future plans. This allows the patient and family to discuss realistic plans for a patient's return home.

Restorative and Continuing Care. In the postoperative period, the nurse, patient, and family collaborate to prepare the patient for discharge. Patients often have to continue wound care, follow activity or diet restrictions, continue medication therapy, and observe for signs and symptoms of complications at home. Education regarding these activities is specific to the type of surgery and is an ongoing process throughout hospitalization. It is important to provide specific, culturally appropriate, and accurate verbal and written discharge instructions to enhance the ability of patients to care for themselves at home (Williams, 2008).

When caring for a patient who had ambulatory surgery, you need to prioritize education because of the limited time you have with the patient. Including the family or support system provides a resource for the patient once home. Provide a wide variety of written educational materials for all patients after surgery. For example, offer materials with more pictures and illustrations for patients who do not speak English or have limited reading ability. Ensure that all materials are sensitive to various cultures and religions. Patients receive a copy of signed discharge instructions, and one copy remains in the medical or electronic record.

Surgical recovery is slowed if patients are deconditioned and then fail to exercise regularly. Recent research shows the importance of keeping frail older adults active after surgery (Liu and Fielding, 2011). A person is considered frail if they have three of the following: unintentional weight loss, low physical activity, slowed motor performance, weakness, and fatigue or exercise intolerance. Aerobic exercise and physical resistance training sometimes improve patients' gait speed and ability to perform ADLs (Liu and Fielding, 2011). You need to find strategies to help patients adhere to recommended exercise programs. Involve family caregivers if a patient has dementia or mental alterations.

Some patients need home care assistance after discharge. For example, nurses make referrals to home care for skilled nursing requirements when patients need ongoing wound care, IV therapy, or drain management. In addition, patients who are more physically dependent often require assistance from nursing assistive personnel to provide bathing and hygiene needs. The case coordinator or social worker at the hospital helps with discharge coordination. Encourage patients to show their discharge instructions to home care providers.

Other patients, especially older adults, sometimes require discharge to a rehabilitation or skilled nursing facility after their hospital recovery. During their convalescence patients work to gain mobility and recovery of their independent living skills. In addition, nurses provide wound care and other specialized services. A case coordinator or social worker works with the patient, family, and nurse to coordinate transfer to the skilled facility.

◆ Evaluation

Through the Patient's Eyes. Consult with a patient and family to gather evaluation data and remember that evaluation is ongoing. Ask specific questions that evaluate patient expectations and perceptions during your hourly rounds. For example you ask, "Is your pain

being managed well?" "How well are you sleeping?" and "Is there any-thing I can for you at this time?" Evaluate your patient's level of comfort and ensure that the patient understands all aspects of nursing care. Resolve any concerns or issues and answer the patient's questions before discharge.

Patient Outcomes. Evaluate the effectiveness of your care on the basis of the patient-centered expected outcomes established after surgery for each nursing diagnosis. If a patient fails to progress as expected, revise his or her care plan on the basis of evaluation findings and the patient's needs.

Make sure to evaluate for pain relief, using a pain scale. Determine the efficacy of both pharmacological and nonpharmacological measures. Use appropriate evaluative measures; inspect the condition of a wound, monitor usage of the incentive spirometer, measure the distance or number of times that a patient is able to ambulate, and monitor the amount of fluid and food intake.

Part of your evaluation is determining the extent to which a patient and family caregiver learn self-care measures. Use the Teach Back method of patient education by having the patient restate information you taught in his or own words (Tamura-Lis, 2013). If a patient must perform any skill at home such as a dressing change or exercise, evaluate through return demonstration (see Chapter 25).

Many agencies call patients at home 24 hours after discharge to help evaluate patient outcomes. This allows you to monitor the progress of a patient's recovery and to identify the development of complications. This also allows you to evaluate and reinforce a patient's understanding of restrictions, wound care, medications, and necessary follow-up.

SAFETY GUIDELINES FOR NURSING SKILLS

Ensuring patient safety is an essential role of the professional nurse. To ensure patient safety, communicate clearly with the members of the health care team, assess and incorporate the patient's priorities of care and preferences, and use the best evidence when making decisions about your patient's care. When performing the skill in this chapter, remember the following points to ensure safe, individualized patient-centered care:

- Coughing and deep breathing is sometimes contraindicated after brain, spinal, head, neck, or eye surgery.
- Patients who are severely obese sometimes have more improved lung function and vital capacity in the reverse Trendelenburg or side-lying position.
- Report any signs of VTE such as pain, tenderness, redness, warmth, or swelling in the upper or lower extremities to the medical team immediately.

SKILL 50-1   DEMONSTRATING POSTOPERATIVE EXERCISES

DELEGATION CONSIDERATIONS
The skill of teaching postoperative exercises cannot be delegated to nursing assistive personnel (NAP). Direct the NAP to:
- Encourage patients to practice postoperative exercises regularly following instruction.
- Inform the nurse if patient is unwilling to perform these exercises.

EQUIPMENT
- Pillow or wrapped blanket (used to splint surgical incision during coughing)
- Incentive spirometer
- Positive expiratory pressure device

STEP	RATIONALE
ASSESSMENT	
1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
2. Assess patient's risk for postoperative respiratory complications. Review medical history to identify presence of chronic pulmonary conditions (e.g., emphysema, asthma), any condition that affects chest wall movement, history of smoking, and presence of reduced hemoglobin.	General anesthesia predisposes patient to respiratory problems because lungs do not inflate fully during surgery, cough reflex is suppressed, and mucus collects within airway passages. After surgery some patients have reduced lung volume and require greater efforts to cough and deep breathe; inadequate lung expansion commonly leads to atelectasis and pneumonia. Patient is at greater risk for developing respiratory complications if chronic lung conditions are present (Sifain and Papadakos, 2011). Smoking damages ciliary clearance and increases mucus. Reduced hemoglobin leads to inadequate oxygenation.
3. Auscultate lungs.	Establishes baseline for postoperative comparison.
4. Assess patient's ability to cough and deep breathe by having him or her take a deep breath and observing movement of shoulders, abdomen, and chest wall. Palpate chest excursion during deep breath. Ask patient to cough after taking deep breath.	Reveals maximum potential for chest expansion and ability to cough forcefully; serves as baseline to measure ability to perform exercises after surgery.
5. Assess patient's risk for postoperative thrombus formation (e.g., older patients, primary admitting diagnosis [e.g., trauma, orthopedic fracture, burn], patient's medical history [e.g., active cancer, atrial fibrillation, stroke, dehydration, previous clots], immobilization, women over 35 years who smoke and are taking oral contraceptives, position assumed on operating room table) (AORN, 2014).	Venous stasis, hypercoagulability, and vein trauma are the Virchow's triad for thrombus formation to occur (Lewis et al., 2014). After general anesthesia circulation slows, causing a greater tendency for clot formation. Immobilization results in decreased muscular contraction in lower extremities, which promotes venous stasis. Manipulation and positioning during surgery sometimes cause trauma to leg veins.
6. Observe calves for redness, warmth, and tenderness; swollen calf or thigh; calf swelling more than 3 cm (1.2 inches) compared with asymptomatic leg; pitting edema in symptomatic leg; and collateral superficial veins. Compare legs for bilateral equality (Lewis et al., 2014).	Signs of phlebitis and thrombus formation.

SKILL 50-1	DEMONSTRATING POSTOPERATIVE EXERCISES—cont'd

STEP	RATIONALE

CLINICAL DECISION: *If any of the signs of thrombus formation is present, notify the health care provider immediately and do not manipulate extremity further. Surgery will usually be postponed. Graduated compression stockings, intermittent pneumatic compression stockings, and/or coagulation may be ordered.*

STEP	RATIONALE
7. Assess patient's ability to move independently while in bed. Have patient turn, sit up in bed, and move all extremities.	Determines existence of mobility restrictions.
8. Assess patient's willingness and capability to learn exercises: note attention span, anxiety, level of consciousness, language level. Also assess family members' willingness to learn and support patient after surgery.	Determines ability of patient to learn exercises successfully. Prepares family member to encourage or coach patient in performing exercises after surgery.
9. Assess patient's medical orders before and after surgery.	Some patients require adaptations to perform exercises. In some cases certain exercises are contraindicated.

PLANNING

1. Explain postoperative exercises to patient and family caregiver, including importance to recovery and physiological benefits.	Information allows patient to understand significance of exercises and can motivate learning. People tend to learn new skills when they know their benefits.
2. Plan exercises when patient is not in pain.	Decreased pain enhances patient's ability to practice exercises.
3. Prepare equipment and room for instruction and demonstration.	Makes environment conducive to learning.

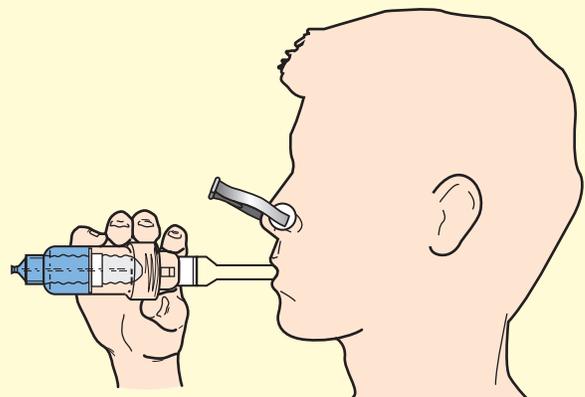
IMPLEMENTATION

1. Demonstrate exercises.	
a. Diaphragmatic breathing	
(1) Help patient to comfortable semi-Fowler's position or to sit on side of bed or in chair.	Upright position facilitates diaphragmatic excursion.
(2) Stand or sit facing patient.	Allows patient to observe breathing exercise.
(3) Instruct patient to place palms of hands across from one another, down and along lower borders of anterior rib cage. Place tips of fingers lightly together (see illustration). Demonstrate for patient.	Position of hands allows patient to feel movement of chest and abdomen as diaphragm descends and lungs expand.
(4) Show patient how to take slow, deep breaths, inhaling through nose and pushing abdomen against hands. Have patient feel middle fingers separate during inhalation. Explain that he or she will feel normal downward movement of diaphragm while inhaling and that abdominal organs descend and chest wall expands. Demonstrate again.	Taking slow, deep breaths prevents panting or hyperventilation. Inhaling through nose warms, humidifies, and filters air. Diaphragmatic breathing allows air to pass by, partially obstructing mucus plug, increasing force to expel mucus. Explanation and demonstration focus on normal ventilatory movement of chest wall. Patient learns how diaphragmatic breathing feels.
(5) Instruct patient to avoid using chest and shoulders while inhaling.	Using auxiliary chest and shoulder muscles during breathing wastes energy and does not promote full lung expansion.
(6) Have patient hold slow, deep breath for count of three and then slowly exhale through mouth as if blowing out a candle (through pursed lips). Demonstrate for patient. Tell patient that middle fingertips will touch as chest wall contracts during exhalation.	Pursed-lip exhalation allows for gradual expulsion of all air.
(7) Repeat complete breathing exercise 3 to 5 times.	Allows patient to observe slow, rhythmic breathing pattern. Repetition of exercise reinforces learning.
(8) Have patient practice exercise. Instruct him or her to take 10 slow, deep breaths every hour while awake during postoperative period.	Regular deep breathing prevents postoperative complications of atelectasis.

STEP 1a(3) Deep-breathing exercise—placement of hands during inhalation.

STEP	RATIONALE
b. Incentive spirometry	
(1) Perform hand hygiene.	Reduces transmission of microorganisms.
(2) Instruct patient to assume semi-Fowler's or high-Fowler's position.	Promotes optimal lung expansion during respiratory maneuver.
(3) For a patient who is severely obese, consider reverse Trendelenburg or side-lying position.	Patients who are severely obese are often able to move their diaphragm better in the reverse Trendelenburg or side-lying position than in a Fowler's position.
(4) Either set or indicate to patient on the incentive spirometer (IS) device scale the volume level to be attained with each breath (a targeted tidal volume). Use manufacturer guidelines to set volume.	Establishes goal of volume level necessary for adequate lung expansion. Package insert helps determine target on the basis of patient height and age (Pruitt, 2006).
(5) Explain to patient how to place mouthpiece of IS so lips completely cover mouthpiece (see illustration). Have patient demonstrate until position is correct.	Return demonstration is a reliable technique to validate patient's understanding of instructions, evaluate psychomotor skills, and enable patient to ask questions.
(6) Instruct patient to inhale slowly while maintaining constant flow through unit until reaching goal volume. Once maximal inspiration is reached, have patient hold breath for 2 to 3 seconds (see illustration) and exhale slowly (Davis, 2012). Ensure that number of breaths does not exceed 10 to 12 per minute.	Maintains maximal inspiration and reduces risk of progressive collapse of individual alveoli. Slow breath (less than 12 breaths/min) prevents or minimizes pain from sudden pressure changes in chest.
(7) Instruct patient to breathe normally for short period between each of the 10 breaths on IS.	Prevents hyperventilation and fatigue.
(8) Have patient repeat breaths until goals are achieved.	Ensures correct use of IS.
(9) Have patient end with two coughs after end of 10 IS breaths hourly while awake.	Cough helps with lung secretion mobilization (Pruitt, 2006).
(10) Perform hand hygiene.	Reduces transmission of microorganisms.
c. Positive expiratory pressure therapy and "huff" coughing	
(1) Perform hand hygiene.	Reduces transmission of microorganisms.
(2) Set positive expiratory pressure (PEP) device for setting ordered.	Higher settings require more ventilatory effort.
(3) Instruct patient to assume semi-Fowler's or high-Fowler's position and place nose clip on nose (see illustration).	Promotes optimum lung expansion, enabling patient to expectorate mucus. Clip prevents release of air through nose.

STEP 1b(6) Diagram of use of incentive spirometer.

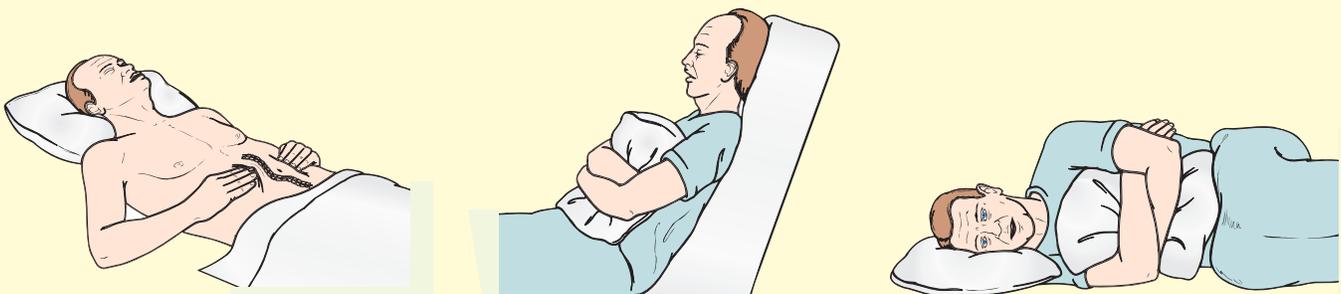
STEP 1b(5) Patient demonstrating incentive spirometry.


STEP 1c(3) Diagram of use of positive expiratory pressure device.

SKILL 50-1	DEMONSTRATING POSTOPERATIVE EXERCISES—cont'd

STEP	RATIONALE
(4) Instruct patient to place lips around mouthpiece or demonstrate placement. Instruct patient to take a full breath and exhale through device 2 or 3 times longer than inhalation. Repeat pattern for 10 to 20 breaths.	Ensures that patient does all breathing through mouth and uses device properly.
(5) Have patient remove device from mouth; take a slow, deep breath; and hold for 3 seconds.	Promotes lung expansion before coughing.
(6) Have patient exhale in quick, short, forced "huffs."	"Huff" coughing or forced expiratory technique promotes bronchial hygiene by increasing expectoration of secretions (Fink, 2007).
d. Controlled coughing	
(1) Explain importance of maintaining an upright semi-Fowler's or sitting position.	Position facilitates diaphragm excursion and enhances thorax expansion.
(2) If surgical incision will be either abdominal or thoracic, teach patient to place pillow (or bath blanket) over incisional area and place hands over pillow to splint incision. During breathing and coughing exercises, have patient press gently against incisional area for splinting or support (see illustration).	Surgical incision cuts through muscles, tissues, and nerve endings. Deep breathing and coughing place additional stress on suture line and cause discomfort. Splinting incision with hands or pillow provides firm support and reduces pulling.
(3) Demonstrate coughing. Instruct patient to take two slow, deep breaths, inhaling through nose and exhaling through mouth.	Deep breaths expand lungs fully so air moves behind mucus and facilitates effects of coughing.
(4) Instruct and show how to inhale deeply a third time and hold breath to count of three. Cough fully for two or three consecutive coughs without inhaling between coughs. (Tell patient to push all air out of lungs.)	Consecutive coughs help remove mucus more effectively and completely than one forceful cough.

CLINICAL DECISION: *Coughing is often contraindicated after brain, spinal, head, neck, or eye surgery because of potential increase in intracranial or intraocular pressure.*

STEP	RATIONALE
(5) Caution patient against just clearing throat instead of coughing. Explain that coughing does not cause injury to incision when done correctly.	Clearing throat does not remove mucus from deeper airways. Postoperative incisional pain makes it harder for patient to cough effectively.
(6) Have patient practice coughing exercises, splinting imaginary incision. Instruct patient to cough 2 or 3 times every 2 hours while awake.	Stresses value of deep coughing with splinting to effectively expectorate mucus with less discomfort.
(7) Instruct patient and family caregiver to look at sputum each time for consistency, odor, amount, and color changes and what to report to nurse.	Sputum characteristics indicate presence of pulmonary complication such as pneumonia.


STEP 1d(2) Techniques for splinting incision when coughing. (From Lewis S et al: *Medical-surgical nursing: assessment and management of clinical problems,* ed 9, St Louis, 2014, Mosby.)

STEP	RATIONALE

e. Turning (example shows turning to right side)

(1) Instruct patient to assume supine position and move to side of bed (in this case left side) if permitted by surgery. Instruct patient to move by bending knees and pressing heels against mattress to raise and move buttocks (see illustration). Top side rails on both sides of bed should be in up position.

Positioning begins on side of bed so turning to other side does not cause patient to roll toward edge of bed. Buttocks lift prevents shearing force from body movement against sheets. If patient bed has a turn-assist feature, use it to help positon him or her.

(2) Instruct patient to place right hand over incisional area to splint it *(optional)*

Supports and minimizes pulling on suture line during turning.

(3) Instruct patient to keep right leg straight and flex left knee up (see illustration). If back or vascular surgery was performed, patient needs to logroll (see Chapter 47) or requires assistance with turning.

Straight leg stabilizes patient's position. Flexed left leg shifts weight for easier turning.

(4) Have patient grab right side rail with left hand, pull toward right, and roll onto right side.

Pulling toward side rail reduces effort needed for turning.

(5) Instruct patient to turn every 2 hours while awake. Often patients require assistance with turning after surgery.

Reduces risk of vascular and pulmonary complications.

f. Leg exercises

(1) Have patient assume supine position in bed. Demonstrate leg exercises by performing passive range-of-motion exercises while simultaneously explaining exercise.

Provides normal anatomical position of lower extremities.

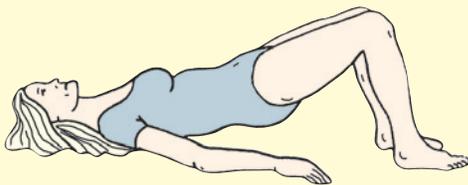
CLINICAL DECISION: *If patient's surgery involves one or both lower extremities, surgeon must order leg exercises in postoperative period. Leg unaffected by surgery can be exercised safely unless patient has preexisting thrombosis or thrombophlebitis.*

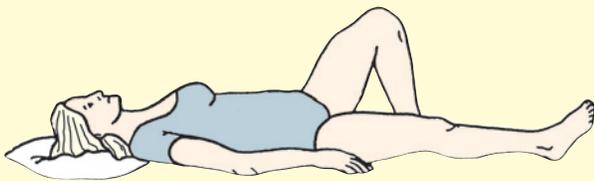
---

(2) Rotate each ankle in complete circle. Instruct patient to draw imaginary circles with big toe (see illustration). Repeat 5 times.

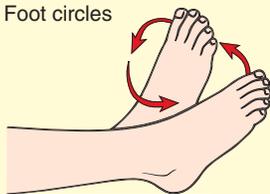
Maintains joint mobility and promotes venous return to prevent thrombi.

(3) Alternate dorsiflexion and plantar flexion of both feet. Direct patient to feel calf muscles contract and relax alternately (see illustrations *A* and *B*). Repeat 5 times.

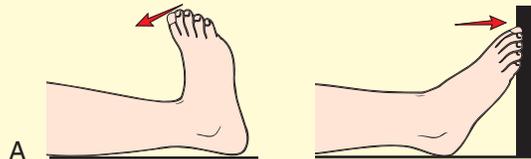
Stretches and contracts gastrocnemius muscles, improving venous return.


STEP 1e(1) Buttocks lift for moving to side of bed. (From Lowdermilk D, Perry SE: *Maternity and women's health care,* ed 9, St Louis, 2007, Mosby.)


STEP 1e(3) Leg position for turning. (From Lowdermilk D, Perry SE: *Maternity and women's health care,* ed 9, St Louis, 2007, Mosby.)

Desirable
Foot circles


STEP 1f(2) Foot circles. (From Lewis S et al: *Medical-surgical nursing: assessment and management of clinical problems,* ed 7, St Louis, 2007, Mosby.)

Essential
Alternate dorsiflexion and plantar flexion


STEP 1f(3) A, Alternate dorsiflexion and plantar flexion. **B,** Patient pushes feet to perform plantar flexion. (**A** From Lewis S et al: *Medical-surgical nursing: assessment and management of clinical problems,* ed 7, St Louis, 2007, Mosby.)

SKILL 50-1	DEMONSTRATING POSTOPERATIVE EXERCISES—cont'd

STEP	RATIONALE
(4) Perform quadriceps setting by tightening thigh and bringing knee down toward mattress, then relaxing (see illustration). Repeat 5 times.	Contracts muscles of upper legs, maintains knee mobility, and enhances venous return.
(5) Have patient alternately raise each leg straight up from bed surface, keeping knees flexed; have patient bend leg at hip and knee (see illustration). Repeat 5 times.	Promotes contraction and relaxation of quadriceps muscles and prevents venous pulling. Bending reduces strain on back.
2. Have patient continue to practice exercises before surgery at least every 2 hours while awake. Teach patient to coordinate turning and leg exercises with diaphragmatic breathing, IS, and coughing exercises.	Repetition of exercise sequence reinforces learning and establishes routine for exercises that develops habit for performance. Sequence of exercises is leg exercises, turning, breathing, and coughing.

EVALUATION

1. Observe patient perform all five exercises (only IS or PEP, not both) independently.	Provides opportunity for practice and return demonstration. Ensures that patient has learned correct technique.
2. Observe family member coach patient through steps of exercise.	Determines if family member can help in a positive, appropriate way.
3. After surgery measure patient's chest excursion and auscultate lungs	Determines extent of lung expansion and reveals presence of secretions or narrowed airways.
4. After surgery palpate calves gently for redness, warmth, and tenderness. Assess pedal pulses.	Absent signs and normal pulses indicate that no venous thrombosis is present.
5. Use **Teach Back.** State to patient, "I want to be sure that you understand why I want you to sit upright and take deep breaths every hour. Tell me how that helps you." Revise your instruction now or develop plan for revised patient teaching to be implemented at an appropriate time if patient is not able to teach back correctly.	Evaluates what patient is able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Patient is unable to perform exercises correctly before surgery.
- Assess for presence of anxiety, pain, and fatigue.
- Repeat teaching using more demonstration or redemonstration at time when family or friends are present.

2. Patient is unwilling to perform exercises after surgery because of incisional pain of thorax or abdomen (deep breathing, coughing, and turning) or because of surgery involving lower abdomen, groin, buttocks, or legs (leg exercises, turning).
- Instruct patient to ask for pain medication 30 minutes before performing postoperative exercise or to use patient-controlled analgesia (PCA) a few minutes before exercising.
- Report to surgeon or pain team inadequate pain relief and need to change analgesic or increase dose.

RECORDING AND REPORTING

- Record exercises demonstrated and whether patient is able to perform them independently.
- Report any problems patient has in completing exercises to nurse assigned to patient on next shift for follow-up.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- Incorporate teaching of family members to help patient implement postoperative exercises at home.

STEP 1f(4) Quadriceps (thigh) setting. (From Lewis S et al: *Medical-surgical nursing: assessment and management of clinical problems,* ed 7, St Louis, 2007, Mosby.)

STEP 1f(5) Hip and knee movements. (From Lewis S et al: *Medical-surgical nursing: assessment and management of clinical problems,* ed 7, St Louis, 2007, Mosby.)

KEY POINTS

- The preoperative period ranges from hours to days, with some patients assessed in the health care provider's office, preadmission clinic, anesthesia clinic, or by telephone.
- The goal of the preoperative assessment is to identify a patient's normal preoperative function and the presence of any risks to recognize, prevent, and minimize possible postoperative complications.
- Physical examination of a patient before surgery focuses on findings from the patient's medical history and on body systems that the surgery is likely to affect.
- Nursing diagnoses for a surgical patient apply to nursing care during one or all phases of surgery.
- All medications taken before surgery are discontinued automatically after surgery unless a health care provider reorders the drugs.
- Having a standardized checklist or protocol for hand-off communication between perioperative health care providers minimizes risks of injuries, missed care, and errors in translating information.
- Primary responsibility for informed consent rests with a patient's surgeon.
- Preoperative patient education increases patient satisfaction and knowledge and reduces patients' preoperative anxiety, which often leads to an increase in postoperative pain, poor outcomes, and prolonged hospital stays.
- Include family members in preoperative instruction when appropriate, since a family member often is the coach for postoperative exercises when a patient returns from surgery.
- Avoid inappropriate discussions about a surgical patient's condition and do not use social media to convey information.
- The circulating nurses' responsibilities within the OR focus on protecting a patient from potential harm.
- The information obtained from OR to PACU hand-off report allows a recovery nurse to anticipate how quickly to expect a patient to regain consciousness and what his or her analgesic needs will be.
- Postoperative nursing care aims to reduce the primary causes for postoperative complications, including impaired healing of the surgical wound, the effects of prolonged immobilization during surgery and convalescence, and the influence of anesthesia and analgesics.
- Pain relief is necessary for a patient to ambulate frequently and increase participation in care activities following surgery.

CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

Mrs. Campana has just been transported to your surgical nursing division from the PACU. She is 80 years old and had a right colectomy (right-sided large bowel resection) for removal of a tumor. Her vital signs were stable in the PACU, and her temperature was 36.8° C (98° F). She has an intravenous (IV) line in her right arm, a Foley catheter, a nasogastric (NG) tube, and oxygen at 4 L/min per nasal cannula. She received a total of 5 mg of morphine sulfate intravenously in the PACU and now has morphine patient-controlled analgesia (PCA) with a demand dose of 1 mg every 10 minutes connected to her IV line. When you assess her, she is slow to respond to your verbal questions.

1. Why may Mrs. Campana be slow to respond?

2. What are your priority assessments at this time considering Mrs. Campana's current decreased responsiveness? What do you need to do if you discover any unexpected or abnormal assessment findings?

3. Mrs. Campana's daughter enters the room and is very concerned about her mother's slowness to awaken. What do you tell her?

ⓔ*Answers to Clinical Application Questions can be found on the Evolve website.*

REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. Obesity places patients at an increased surgical risk because of which of the following factors? (Select all that apply.)
   1. Risk for bleeding is increased.
   2. Ventilatory capacity is reduced.
   3. Fatty tissue has a poor blood supply.
   4. Metabolic demands are increased.
   5. Physical mobility is often impaired.

2. The primary reason that you need to include family members when you teach a patient preoperative exercises is so they can:
   1. Coach and encourage the patient after surgery.
   2. Demonstrate to the patient at home.
   3. Relieve the nurse by getting the patient to do the exercises every 2 hours.
   4. Practice with the patient while he or she is waiting to be taken to the operating room.

3. In the postanesthesia care unit (PACU) a nurse notes that a patient is having difficulty breathing and suspects an upper-airway obstruction. The nurse's priority intervention at this time is:
   1. Suction the pharynx and bronchial tree.
   2. Give oxygen through a mask at 4 L/min.
   3. Ask the patient to use an incentive spirometer.
   4. Position the patient on one side with the face down and the neck slightly extended so the tongue falls forward.

4. Because an older adult is at increased risk for respiratory complications after surgery, the nurse needs to:
   1. Withhold pain medications and ambulate the patient every 2 hours.
   2. Monitor fluid and electrolyte status every shift and vital signs with temperature every 4 hours.
   3. Orient the patient to the surrounding environment frequently and ambulate him or her every 2 hours.
   4. Encourage the patient to turn, deep breathe, and cough frequently and ensure adequate pain control.

5. You are caring for a patient after surgery who had a liver resection. His prothrombin time (PT) is greater than normal. He has low blood pressure; tachycardia; thready pulse; and cool, clammy, pale skin, and he is restless. You assess his surgical wound, and the dressing is saturated with blood. Which immediate interventions do you perform? (Select all that apply.)
   1. Notify the surgeon.
   2. Maintain intravenous (IV) fluid infusion and prepare to give volume replacement.
   3. Monitor the patient's vital signs every 15 minutes or more frequently until his condition stabilizes.
   4. Wean oxygen therapy.
   5. Provide comfort through bathing.

6. You are a nurse in the postanesthesia care unit (PACU), and you note that your patient has a heart rate of 130 beats/min and a respiratory rate of 32 breaths/min; you also assess jaw muscle rigidity and rigidity of limbs, abdomen, and chest. What do you suspect, and which intervention is indicated?
   1. *Infection:* Notify surgeon and anticipate administration of antibiotics.

2. *Pneumonia:* Listen to breath sounds, notify surgeon, and anticipate order for chest radiography.
3. *Hypertension:* Check blood pressure, notify surgeon, and anticipate administration of antihypertensives.
4. *Malignant hyperthermia:* Notify surgeon/anesthesia provider immediately, prepare to administer dantrolene sodium (Dantrium), and monitor vital signs frequently.

7. After a patient has been given preoperative sedatives, which safety precaution do you take?
    1. Reinforce to patient to remain in bed or on the stretcher
    2. Raise the side rails and keep the bed or stretcher in the high position
    3. Determine if patient has any allergies to latex
    4. Obtain informed consent immediately after sedative administration

8. The operating room (OR) and postanesthesia care unit (PACU) are high-risk environments for patients with a latex allergy. Which safety measures do nurses in these areas implement to prevent a latex reaction? (Select all that apply.)
    1. Screen patients about food allergies known to have cross-reactivity to latex.
    2. Have a latex allergy cart available at all times.
    3. Communicate with the operating room (OR) team as soon as 24 to 48 hours in advance of the surgery when a patient with latex sensitivity is identified.
    4. Schedule the patient with a latex allergy for the last operative case of the day.
    5. Plan for the patient to be admitted to a private room after surgery.

9. A nurse is recovering a patient who received conscious sedation for cosmetic surgery. Which of the following is an advantage that conscious sedation has over general anesthesia? (Select all that apply.)
    1. Loss of sensation at the surgical site
    2. Reduction of fear and anxiety
    3. Amnesia about procedure
    4. Monitoring in phase I recovery
    5. Close monitoring for airway patency

10. You are assigned to care for the following patients on your surgical unit. On the basis of the information provided, which patient do you need to see first?
    1. A 75-year-old following hip replacement surgery who is complaining of moderate pain in the surgical site, with a heart rate of 92
    2. A 57-year-old following hip replacement 6 hours earlier who is receiving intravenous patient-controlled analgesia (PCA) with a history of obstructive sleep apnea (OSA) (The pulse oximeter has been alarming and reading 85%.)
    3. A 36-year-old following bladder neck suspension who is 30 minutes late to receive her postoperative dose of antibiotic
    4. A 48-year-old following total knee replacement who needs help repositioning in bed

11. Hand-off communications that occur between the postanesthesia care unit (PACU) nurse and the nurse on the postoperative nursing unit need to be done when a patient returns to the nursing unit. Which are appropriate components of a safe and effective hand-off? (Select all that apply.)
    1. Vital signs, type of anesthesia provided, blood loss, and level of consciousness
    2. Uninterrupted time to review the recent pertinent events and ask questions
    3. Verification of the patient using one identifier and the type of surgery performed

4. Review of pertinent events occurring in the operating room (OR) while at the nurses' station
5. Location of patient's family members

12. A nurse is working in the preoperative holding area and is assigned to care for a patient who is having a prosthetic aortic valve placed. The nurse inserts an intravenous (IV) line and obtains vital signs. The patient has a temperature of 39° C (102° F), heart rate of 120, blood pressure (BP) of 84/50, and an elevated white blood cell (WBC) count. The nurse immediately notifies the surgeon of the patient's vital signs because:
    1. He or she needs to get the patient into the operating room (OR) quickly to start the surgery because of the low BP.
    2. The surgery may need to be delayed to recheck the patient's WBC count and investigate the source of fever before surgery.
    3. The nurse anticipates the need for a fluid bolus to increase the patient's BP.
    4. The nurse anticipates an order for a sedative to help calm the patient and decrease the heart rate.

13. A nurse is preparing to provide a patient with instructions for how to perform incentive spirometry. The patient will likely have incisional pain after returning from an elective colon resection. Which of the following steps for incentive spirometry is the patient likely to have the most difficulty performing? (Select all that apply.)
    1. Assuming semi-Fowler's or high-Fowler's position
    2. Setting the incentive spirometer device scale at the volume level to be attained
    3. Placing the mouthpiece of the incentive spirometer so lips completely cover the mouthpiece
    4. Inhaling slowly while maintaining constant flow through unit until it reaches goal volume
    5. Breathing normally for a short period between each of the 10 breaths on incentive spirometry
    6. Ending with two coughs after the end of 10 incentive spirometry breaths hourly

14. A patient is admitted through the emergency department following a motorcycle crash with multiple orthopedic injuries. He goes to surgery for repair of fractures. He is postoperative day 3 from an open-reduction internal fixation of bilateral femur fractures and external fixator to his unstable pelvic fracture. Interventions that are necessary for prevention of venous thromboembolism in this patient include: (Select all that apply.)
    1. Intermittent pneumatic compression stockings.
    2. Vitamin K therapy.
    3. Passive range-of-motion exercises every 4 hours.
    4. Subcutaneous heparin or enoxaparin (Lovenox).
    5. Continuous heparin drip with a goal of an international normalized ratio (INR) 5 times higher than baseline.

15. You are caring for a 65-year-old patient 2 days after surgery and helping him ambulate down the hallway. The surgeon ordered exercise as tolerated. Your assessment indicates that the patient's heart rate at baseline is 88. After walking approximately 30 yards down the hallway, his heart rate is 110. What is your next action?
    1. Stop exercise immediately and have him sit in a nearby chair.
    2. Ask him how he feels; determine if there is any discomfort or shortness of breath; and, if not, continue exercise.
    3. Tell him that he needs to walk further to reach a heart rate of 120.
    4. Have him walk slower; he has reached his maximum.

Answers: 1. 2, 3, 5; **2.** 1; **3.** 4; **4.** 4; **5.** 1, 2, 3; **6.** 4; **7.** 1; **8.** 1, 2, 3; **9.** 2, 3; **10.** 2; **11.** 1, 2, 5; **12.** 2; **13.** 1, 4, 6; **14.** 1, 4; **15.** 2.

A

abduction Movement of a limb away from the body.

abrasion Scraping or rubbing away of epidermis; may result in localized bleeding and later weeping of serous fluid.

absorption Passage of drug molecules into the blood. Factors influencing drug absorption include route of administration, ability of the drug to dissolve, and conditions at the site of absorption.

acceptance Fifth stage of Kübler-Ross's stages of grief and dying. An individual comes to terms with a loss rather than submitting to resignation and hopelessness.

accessory muscles Muscles in the thoracic cage that assist with respiration.

accommodation Process of responding to the environment through new activity, thinking, and changing the existing schema or developing a new schema to deal with the new information. For example, a toddler whose parent consistently corrects him when he calls a horse a "doggie" accommodates and forms a new schema for horses.

accountability State of being answerable for one's actions—a nurse answers to himself or herself, the patient, the profession, the employing institution such as a hospital, and society for the effectiveness of nursing care performed.

accreditation Process whereby a professional association or nongovernmental agency grants recognition to a school or institution for demonstrated ability to meet predetermined criteria.

acculturation Process of adapting to and adopting a new culture.

acne Inflammatory, papulopustular skin eruption, usually occurring on the face, neck, shoulders, and upper back.

acromegaly Chronic metabolic condition caused by overproduction of growth hormone and characterized by gradual, marked enlargement and elongation of bones of the face, jaw, and extremities.

active listening Listening attentively with the whole person—mind, body, and spirit. It includes listening for main and supportive ideas; acknowledging and responding; giving appropriate feedback; and paying attention to the other person's total communication, including the content, intent, and feelings expressed.

active range-of-motion (ROM) exercise Exercise to the joint by the patient while doing activities of daily living or during joint assessment.

active strategies of health promotion Activities that depend on the patient's motivation to adopt a specific health program.

active transport Movement of materials across the cell membrane by means of chemical activity that allows the cell to admit larger molecules than would otherwise be possible.

activities of daily living (ADLs) Activities usually performed in the course of a normal day in the patient's life such as eating, dressing, bathing, brushing the teeth, or grooming.

activity tolerance Kind or amount of exercise or work that a person is able to perform.

actual loss Loss of an object, person, body part or function, or emotion that is overt and easily identifiable.

acuity recording Mechanism by which entries describing patient care activities are made over a 24-hour period. The activities are then translated into a rating score, or acuity score, that allows for a comparison of patients who vary by severity of illness.

acute care Pattern of health care in which a patient is treated for an acute episode of illness, for the sequelae of an accident or other trauma, or during recovery from surgery.

acute illness Illness characterized by symptoms that are of relatively short duration, are usually severe, and affect the functioning of the patient in all dimensions.

adduction Movement of a limb toward the body.

adolescence Period in development between the onset of puberty and adulthood. It usually begins between 11 and 13 years of age.

adult day care centers Facility for the supervised care of older adults; provides activities such as meals and socialization during specified day hours.

advanced practice registered nurse (APRN) Generally the most independently functioning nurse. An APRN has a master's degree in nursing, advanced education in pathophysiology, pharmacology, and physical assessment; and certification and expertise in a specialized area of practice.

advanced sleep phase syndrome Common in older adults; a disturbance in sleep manifested by early waking in the morning with an inability to get back to sleep. It is thought that this syndrome is caused by advancing of the circadian rhythm of the body.

adventitious sounds Abnormal lung sounds heard with auscultation.

adverse effect Harmful or unintended effect of a medication, diagnostic test, or therapeutic intervention.

adverse reaction Any harmful, unintended effect of a medication, diagnostic test, or therapeutic intervention.

advocacy Process whereby a nurse objectively provides patients with the information they need to make decisions and supports the patients in whatever decisions they make.

afebrile Without fever.

affective learning Acquisition of behaviors involved in expressing feelings about attitudes, appreciation, and values.

afterload Resistance to left ventricular ejection; the work the heart must overcome to fully eject blood from the left ventricle.

age-related macular degeneration Progressive disorder in which the macula (the specialized portion of the retina responsible for central vision) degenerates as a result of aging and loses its ability to function efficiently. First signs include blurring of reading matter, distortion or loss of central vision, sensitivity to glare, and distortion of objects.

agnostic Individual who believes that any ultimate reality is unknown or unknowable.

airborne precautions Safeguards designed to reduce the risk of transmission of infectious agents through the air that a person breathes.

alarm reaction Mobilization of the defense mechanisms of the body and mind to cope with a stressor; the initial stage of the general adaptation syndrome.

aldosterone Mineralocorticoid steroid hormone produced by the adrenal cortex with action in the renal tubule to regulate sodium and potassium balance in the blood.

allergic reactions Unfavorable physiological response to an allergen to which a person has previously been exposed and has developed antibodies.

alopecia Partial or complete loss of hair; baldness.

Alzheimer's disease Disease of the brain parenchyma that causes a gradual and progressive decline in cognitive functioning.

AMBULARM Device used for the patient who climbs out of bed unassisted and is in danger of falling. This device is worn on the leg and signals when the leg is in a dependent position such as over the side rail or on the floor.

amino acid Organic compound of one or more basic groups and one or more carboxyl groups. Amino acids are the building blocks that construct proteins and the end products of protein digestion.

anabolism Constructive metabolism characterized by conversion of simple substances into more complex compounds of living matter.

analgesic Relieving pain; drug that relieves pain.

analogies Resemblances made between things otherwise unlike.

anaphylactic reactions Hypersensitive condition induced by contact with certain antigens.

aneurysm Localized dilations of the wall of a blood vessel; usually caused by atherosclerosis, hypertension, or a congenital weakness in a vessel wall.

anger Second stage of Kübler-Ross's stages of grief and dying. During this stage an individual resists loss by expressing extreme displeasure, indignation, or hostility.

angiotensin Polypeptide occurring in the blood, causing vasoconstriction, increased blood pressure, and the release of aldosterone from the adrenal cortex.

anion gap Difference between the concentrations of serum cations and anions; determined by measuring the concentrations of sodium cations and chloride and bicarbonate anions.

anions Negatively charged electrolytes.

anthropometric measurements Body measures of height, weight, and skinfolds to evaluate muscle atrophy.

anthropometry Measurement of various body parts to determine nutritional and caloric status, muscular development, brain growth, and other parameters.

antibodies Immunoglobulins essential to the immune system that are produced by lymphoid tissue in response to bacteria, viruses, or other antigens.

anticipatory grief Grief response in which the person begins the grieving process before an actual loss.

antidiuretic hormone (ADH) Hormone that decreases the production of urine by increasing the resorption of water by the renal tubules. ADH is secreted by cells of the hypothalamus and stored in the posterior lobe of the pituitary gland.

antiembolic stockings Elasticized stockings that prevent formation of emboli and thrombi, especially after surgery or during bed rest.

antigen Substance, usually a protein, that causes the formation of an antibody and reacts specifically with that antibody.

antipyretic Substance or procedure that reduces fever.

anxiolytics Drugs used primarily to treat episodes of anxiety.

aphasia Abnormal neurological condition in which language function is defective or absent; related to injury to speech center in cerebral cortex, causing receptive or expressive aphasia.

apical pulse Heartbeat as listened to with the bell or diaphragm of a stethoscope placed on the apex of the heart.

apnea Absence of respirations for a period of time.

apothecary system System of measurement. The basic unit of weight is a grain. Weights derived from the grain are the gram, ounce, and pound. The basic measure for fluid is the minim. The fluidram, fluid ounce, pint, quart, and gallon are measures derived from the minim.

approximate To come close together, as in the edges of a wound.

arcus senilis Opaque ring, gray to white in color, that surrounds the periphery of the cornea. The condition is caused by deposits of fat granules in the cornea. Occurs primarily in older adults.

asepsis Absence of germs or microorganisms.

aseptic technique Any health care procedure in which added precautions are used to prevent contamination of a person, object, or area by microorganisms.

assault Unlawful threat to bring about harmful or offensive contact with another.

assertive communication Type of communication based on a philosophy of protecting individual rights and responsibilities. It includes the ability to be self-directive in acting to accomplish goals and advocate for others.

assessment First step of the nursing process. Activities required in the first step are data collection, validation, sorting, and documentation. The purpose is to gather information for health problem identification.

assimilation To become absorbed into another culture and adopt its characteristics.

assisted living Residential living facilities in which each resident has his or her own room and shares dining and social activity areas.

associative play Form of play in which a group of children participates in similar or identical activities without formal organization, direction, interaction, or goals.

atelectasis Collapse of alveoli, preventing the normal respiratory exchange of oxygen and carbon dioxide.

atheist Individual who does not believe in the existence of God.

atherosclerosis Common arterial disorder characterized by yellowish plaques of cholesterol, lipids, and cellular debris in the inner layers of the walls of the large- and medium-size arteries.

atrioventricular (AV) node Part of the cardiac conduction system located on the floor of the right atrium; receives electrical impulses from the atrium and transmits them to the bundle of His.

atrophied Wasted or reduced size or physiological activity of a part of the body caused by disease or other influences.

attachment Initial psychosocial relationship that develops between parents and the neonate.

attentional set Internal state of the learner that allows focusing and comprehension.

auditory Related to or experienced through hearing.

auscultation Method of physical examination; listening to the sounds produced by the body, usually with a stethoscope.

auscultatory gap Disappearance of sound when obtaining a blood pressure; typically occurs between the first and second Korotkoff sounds.

authority Right to act in areas in which an individual has been given and accepts responsibility.

autologous transfusion Procedure in which blood is removed from a donor and stored for a variable period before it is returned to the donor's own circulation.

autonomy Ability or tendency to function independently.

B

back-channeling Active listening technique that prompts a respondent to continue telling a story or describing a situation. Involves use of phrases such as "Go on," "Uh huh," and "Tell me more."

bacteriuria Presence of bacteria in the urine.

balance Position in which the person's center of gravity is correctly positioned so falling does not occur.

bandages Available in rolls of various widths and materials, including gauze, elasticized knit, elastic webbing, flannel, and muslin. Gauze bandages are lightweight and inexpensive, mold easily around contours of the body, and permit air circulation to underlying skin to prevent maceration. Elastic bandages conform well to body parts but can also be used to exert pressure over a body part.

bargaining Third stage of Kübler-Ross's stages of grief and dying. A person postpones the reality of a loss by attempting to make deals in a subtle or overt manner with others or with a higher being.

baridi Condition among the Bena people of Tanzania attributed to disrespectful behavior within the family or transgression of cultural taboos. The person experiences physical and psychological symptoms and is usually treated by a traditional healer, who has the person make a public admission or an apology or who treats the person with herbal remedies.

basal cell carcinoma Malignant epithelial cell tumor that begins as a papule and enlarges peripherally, developing a central crater that erodes, crusts, and bleeds. Metastasis is rare.

basal metabolic rate (BMR) Amount of energy used in a unit of time by a fasting, resting subject to maintain vital functions.

battery Legal term for touching another's body without consent.

bed boards Boards placed under the mattress of a bed that provide extra support to the mattress surface.

bed rest Placement of the patient in bed for therapeutic reasons for a prescribed period.

benchmarking Identifying best practices and comparing them to current organizational practices to improve performance. This process helps to support the claims of quality care delivery by the institution.

beneficence Doing good or actively promoting doing good; one of the four principles of the ethical theory of deontology.

benign breast disease (fibrocystic) Benign condition characterized by lumpy, painful breasts and sometimes nipple discharge. Symptoms are more apparent before the menstrual period. Known to be a risk factor for breast cancer.

bereavement Response to loss through death; a subjective experience that a person suffers after losing a person with whom there has been a significant relationship.

biases and prejudices Beliefs and attitudes associating negative permanent characteristics to people who are perceived as different from oneself.

bi-level positive airway pressure (BiPAP) Ventilatory support used to treat patients with obstructive sleep apnea, patients with congestive heart failure, and preterm infants with underdeveloped lungs.

bilineally Kinship that extends to both the mother's and father's sides of the family.

binders Bandages made of large pieces of material to fit specific body parts.

bioethics Branch of ethics within the field of health care.

biological clock Cyclical nature of body function. Functions controlled from within the body are synchronized with environmental factors; same meaning as biorhythm.

biological half-life Time it takes for the body to lower the amount of unchanged medication by half.

biotransformation Chemical changes that a substance undergoes in the body such as by the action of enzymes.

blanchable hyperemia Redness of the skin caused by dilation of the superficial capillaries. When pressure is applied to the skin, the area blanches, or turns a lighter color.

body image Peoples' subjective concept of their physical appearance.

body mechanics Coordinated efforts of the musculoskeletal and nervous systems to maintain proper balance, posture, and body alignment.

bone resorption Destruction of bone cells and release of calcium into the blood.

borborygmi Audible abdominal sounds produced by hyperactive intestinal peristalsis.

botanica Place that sells religious and herbal remedies.

bradycardia Slower-than-normal heart rate; heart contracts fewer than 60 times/min.

bradypnea Abnormally slow rate of breathing.

bronchospasm Excessive and prolonged contraction of the smooth muscle of the bronchi and bronchioles, resulting in an acute narrowing and obstruction of the respiratory airway.

bruit Abnormal sound or murmur heard while auscultating an organ, gland, or artery.

buccal Of or pertaining to the inside of the cheek or the gum next to the cheek.

buccal cavity Consists of the lips surrounding the opening of the mouth, the cheeks running along the side walls of the cavity, the tongue and its muscles, and the hard and soft palate.

buffer Substance or group of substances that can absorb or release hydrogen ions to correct an acid-base imbalance.

bundle of His Part of the cardiac conduction system that arises from the distal portion of the atrioventricular (AV) node and extends across the AV groove to the top of the intraventricular septum, where it divides into right and left bundle branches.

C

cachexia Malnutrition marked by weakness and emaciation, usually associated with severe illness.

capitation Payment mechanism in which a provider (e.g., health care network) receives a fixed amount of payment per enrollee.

capnography Also known as end titled CO_2 monitoring, it provides instant information about how effectively CO_2 is eliminated by the pulmonary system, how effectively it is transported through the vascular system, and how effectively CO_2 is produced by cellular metabolism. Capnography is measured near the end of exhalation.

carbohydrates Dietary classification of foods comprising sugars, starches, cellulose, and gum.

carbon monoxide Colorless, odorless, poisonous gas produced by the combustion of carbon or organic fuels.

cardiac index Adequacy of the cardiac output for an individual. It takes into account the body surface area (BSA) of the patient.

cardiac output (CO) Volume of blood expelled by the ventricles of the heart, equal to the amount of blood ejected at each beat multiplied by the number of beats in the period of time used for computation (usually 1 minute).

cardiopulmonary rehabilitation Actively assisting the patient with achieving and maintaining an optimal level of health through controlled physical exercise, nutrition counseling, relaxation and stress management techniques, prescribed medications and oxygen, and compliance.

cardiopulmonary resuscitation (CPR) Basic emergency procedures for life support consisting of artificial respiration and manual external cardiac massage.

care To feel concern for or interest in one who has sorrow or difficulties.

caring Universal phenomenon that influences the way we think, feel, and behave in relation to one another.

carriers People or animals who harbor and spread an organism that causes disease in others but do not become ill themselves.

case management Organized system for delivering health care to an individual patient or group of patients across an episode of illness and/or a continuum of care; includes assessment and development of a plan of care, coordination of all services, referral, and follow-up; usually assigned to one professional.

case management plan Multidisciplinary model for documenting patient care that usually includes plans for problems, key interventions, and expected outcomes for patients with a specific disease or condition.

catabolism Breakdown of body tissue into simpler substances.

cataplexy Condition characterized by sudden muscular weakness and loss of muscle tone.

cataracts Abnormal progressive condition of the lens of the eye characterized by loss of transparency.

cathartics Drugs that act to promote bowel evacuation.

catheterization Introduction of a catheter into a body cavity or organ to inject or remove fluid.

cations Positively charged electrolytes.

center of gravity Midpoint or center of the weight of a body or object.

centigrade Denotes temperature scale in which 0° is the freezing point of water and 100° is the boiling point of water at sea level; also called Celsius.

cerumen Yellowish or brownish waxy secretion produced by sweat glands in the external ear.

chancres Skin lesions or venereal sores (usually primary syphilis) that begin at the site of infection as papules and develop into red, bloodless, painless ulcers with a scooped-out appearance.

change-of-shift report Report that occurs between two scheduled nursing work shifts. Nurses communicate information about their assigned patients to nurses working on the next shift of duty.

channel Method used in the teaching-learning process to present content: visual, auditory, taste, smell. In the communication process a method used to transmit a message: visual, auditory, touch.

charting by exception (CBE) Charting methodology in which data are entered only when there is an exception from that which is normal or expected; reduces time spent documenting in charting. It is a shorthand method for documenting normal findings and routine care.

chest percussion Striking the chest wall with a cupped hand to promote mobilization and drainage of pulmonary secretions.

chest physiotherapy (CPT) Group of therapies used to mobilize pulmonary secretions for expectoration.

chest tube Catheter inserted through the thorax into the chest cavity for removing air or fluid; used after chest or heart surgery or pneumothorax.

Cheyne-Stokes respiration Occurs when there is decreased blood flow or injury to the brainstem.

chronic illness Illness that persists over a long time and affects physical, emotional, intellectual, social, and spiritual functioning.

circadian rhythm Repetition of certain physiological phenomena within a 24-hour cycle.

circular transactional communication process Communication model that enhances the linear communication by enabling the sender and receiver to view perceptions, attitudes, and potential reactions of others via a mental picture. This is a continuous and interactive activity.

circulating nurse Assistant to the scrub nurse and surgeon whose role is to provide necessary supplies; dispose of soiled instruments and supplies; and keep an accurate count of instruments, needles, and sponges used.

civil law Statutes concerned with protecting a person's rights.

climacteric Physiological, developmental change that occurs in the male reproductive system between the ages of 45 and 60.

clinical criteria Objective or subjective signs and symptoms, clusters of signs and symptoms, or risk factors.

clinical decision making Problem-solving approach that nurses use to define patient problems and select appropriate treatment.

clinical-decision support systems Computerized programs used within the health care setting to support decision-making.

Clinical Information System (CIS) A computer-based system that collects, stores, and manipulates data to allow health care providers to make informed decisions about patient care.

closed-ended question Form of question that limits a respondent's answer to one or two words.

clubbing Bulging of the tissues at the nail base caused by insufficient oxygenation at the periphery, resulting from conditions such as chronic emphysema and congenital heart disease.

code of ethics   Formal statement that delineates a profession's guidelines for ethical behavior. A code of ethics sets standards or expectations for the professional to achieve.

cognitive learning   Acquisition of intellectual skills that encompass behaviors such as thinking, understanding, and evaluating.

collaborative interventions   Therapies that require the knowledge, skill, and expertise of multiple health care professionals.

collaborative problem   Physiological complication that requires the nurse to use nursing- and health care provider–prescribed interventions to maximize patient outcomes.

colloid osmotic pressure   Abnormal condition of the kidney caused by the pressure of concentrations of large particles such as protein molecules that will pass through a membrane.

colon   Portion of the large intestine from the cecum to the rectum.

colonization   Presence and multiplication of microorganisms without tissue invasion or damage.

comforting   Acts toward another individual that display both an emotional and physical calm. The use of touch, establishing presence, the therapeutic use of silence, and the skillful and gentle performance of a procedure are examples of comforting nursing measures.

common law   One source for law that is created by judicial decisions as opposed to those created by legislative bodies (statutory law).

communicable disease   Any disease that can be transmitted from one person or animal to another by direct or indirect contact or by vectors.

communication   Ongoing, dynamic series of events that involves the transmission of meaning from sender to receiver.

community health nursing   Nursing approach that combines knowledge from the public health sciences with professional nursing theories to safeguard and improve the health of populations in the community.

community-based nursing   Acute and chronic care of individuals and families to strengthen their capacity for self-care and promote independence in decision making.

comorbidity   A chronic, long term condition existing simultaneously with and usually independently of another medical condition.

compassion   The feeling that arises when a person is confronted with another's suffering and feels motivated to relieve that suffering. Compassion shows kindness, caring, and a willingness to help others.

competence   Specific range of skills necessary to perform a task.

complete bed bath   Bath in which the entire body of a patient is washed in bed.

compress   Soft pad of gauze or cloth used to apply heat, cold, or medications to the surface of a body part.

computer-based patient record   Comprehensive computerized system used by all health care practitioners to permanently store information pertaining to a patient's health status, clinical problems, and functional abilities.

concentration   Relative content of a component within a substance or solution.

concentration gradient   Gradient that exists across a membrane, separating a high concentration of a particular ion from a low concentration of the same ion.

concept map   Care-planning tool that assists in critical thinking and forming associations between a patient's nursing diagnoses and interventions.

confianza   Trust.

confidentiality   Act of keeping information private or secret; in health care the nurse only shares information about a patient with other nurses or health care providers who need to know private information about a patient to provide care for him or her; information can only be shared with the patient's consent.

conjunctivitis   Highly contagious eye infection. The crusty drainage that collects on eyelid margins can easily spread from one eye to the other.

connectedness   Having close spiritual relationships with oneself, others, and God or another spiritual being.

connotative meaning   Shade or interpretation of the meaning of a word influenced by the thoughts, feelings, or ideas that people have about the word.

conscious sedation   Administration of central nervous system–depressant drugs and/or analgesics to provide analgesia, relieve anxiety, and/or provide amnesia during surgical, diagnostic, or interventional procedures.

constipation   Condition characterized by difficulty in passing stool or an infrequent passage of hard stool.

consultation   Process in which the help of a specialist is sought to identify ways to handle problems in patient management or in planning and implementing programs.

contact precautions   Safeguards designed to reduce the risk of transmission of epidemiologically important microorganisms by direct or indirect contact.

continent urinary diversion (CUR)   Surgical diversion of the drainage of urine from a diseased or dysfunctional bladder. Patient uses a catheter to drain the pouch.

continuous positive airway pressure (CPAP)   Ventilatory support used to treat patients with obstructive sleep apnea, patients with congestive heart failure, and preterm infants with under developed lungs.

convalescence   Period of recovery after an illness, injury, or surgery.

coping   Making an effort to manage psychological stress.

core temperature   Temperature of deep structures of the body.

cough   Sudden, audible expulsion of air from the lungs. The person breathes in, the glottis is partially closed, and the accessory muscles of expiration contract to expel the air forcibly.

counseling   Problem-solving method used to help patients recognize and manage stress and enhance interpersonal relationships. It helps patients examine alternatives and decide which choices are most helpful and appropriate.

crackles   Fine bubbling sounds heard on auscultation of the lung; produced by air entering distal airways and alveoli, which contain serous secretions.

crime   Act that violates a law and that may include criminal intent.

criminal law   Concerned with acts that threaten society but may involve only an individual.

crisis   Transition for better or worse in the course of a disease, usually indicated by a marked change in the intensity of signs and symptoms.

crisis intervention   Use of therapeutic techniques directed toward helping a patient resolve a particular and immediate problem.

critical pathways   Tools used in managed care that incorporate the treatment interventions of caregivers from all disciplines who normally care for a patient. Designed for a specific care type, a pathway is used to manage the care of a patient throughout a projected length of stay.

critical period of development   Specific phase or period when the presence of a function or reasoning has its greatest effect on a specific aspect of development.

critical thinking   Active, purposeful, organized, cognitive process used to carefully examine one's thinking and the thinking of other individuals.

crutch gait   Gait achieved by a person using crutches.

cue   Information that a nurse acquires through hearing, visual observations, touch, and smell.

cultural and linguistic competence   Set of congruent behaviors, attitudes, and policies that come together in a system or agency or among professionals that enables effective work in cross-cultural situations.

cultural assessment   Systematic and comprehensive examination of the cultural care values, beliefs, and practices of individuals, families, and communities.

cultural awareness   Gaining in-depth awareness of one's own background, stereotypes, biases, prejudices, and assumptions about other people.

cultural care accommodation or negotiation   Adapting or negotiating with the patient/families to achieve beneficial or satisfying health outcomes.

cultural care preservation or maintenance   Retaining and/or preserving relevant care values so patients are able to maintain their well-being, recover from illness, or face handicaps and/or death.

cultural care repatterning or restructuring   Reordering, changing, or greatly modifying a patient's/family's customs for a new, different, and beneficial health care pattern.

cultural competence   Process in which the health care professional continually strives to achieve the ability and availability to work effectively with individuals, families, and communities.

cultural encounters   Engaging in cross-cultural interactions; refining intercultural

communication skills; gaining in-depth understanding of others and avoiding stereotypes; and managing cultural conflict.

cultural imposition Using one's own values and customs as an absolute guide in interpreting behaviors.

cultural knowledge Obtaining knowledge of other cultures; gaining sensitivity to, respect for, and appreciation of differences.

cultural pain Feeling that a patient has after a health care worker disregards the patient's valued way of life.

cultural skills Communication, cultural assessment, and culturally competent care.

culturally congruent care Care that fits people's valued life patterns and sets of meanings generated from the people themselves. Sometimes this differs from the professionals' perspective on care.

culturally ignorant or blind Uneducated about other cultures.

culture Integrated patterns of human behavior that include the language, thoughts, communications, actions, customs, beliefs, values, and institutions of racial, ethnic, religious, or social groups.

culture care theory Leininger's theory that emphasizes culturally congruent care.

culture-bound syndromes Illnesses restricted to a particular culture or group because of its psychosocial characteristics.

culturological nursing assessment Systematic and comprehensive examination of the cultural care values, beliefs, and practices of individuals, families, and communities.

cutaneous stimulation Stimulation of a person's skin to prevent or reduce pain perception. A massage, warm bath, hot and cold therapies, and transcutaneous electrical nerve stimulation are some ways to reduce pain perception.

cyanosis Bluish discoloration of the skin and mucous membranes caused by an excess of deoxygenated hemoglobin in the blood or a structural defect in the hemoglobin molecule.

D

DAR (data, action, patient response) Format used in focus charting for recording patient information.

data analysis Logical examination of and professional judgment about patient assessment data; used in the diagnostic process to derive a nursing diagnosis.

data cluster Set of signs or symptoms that are grouped together in logical order.

database Store or bank of information, especially in a form that can be processed by computer.

debridement Removal of dead tissue from a wound.

decentralized management Organizational philosophy that brings decisions down to the level of the staff. Individuals best informed about a problem or issue participate in the decision-making process.

decision making Process involving critical appraisal of information that results from recognizing a problem and ends with generating,

testing, and evaluating a conclusion. Comes at the end of critical thinking.

deconditioning Physiological change following a period of inactivity, bed rest or sedentary lifestyle. It results in functional losses in such areas as mental status, degree of continence and ability to accomplish activities of daily living.

defecation Passage of feces from the digestive tract through the rectum.

defendant Individual or organization against whom legal charges are brought in a court of law.

defining characteristics The observable assessment cues that cluster as manifestations of a problem focused or health promotion nursing diagnosis.

dehiscence Separation of the edges of a wound, revealing underlying tissues.

dehydration Excessive loss of water from the body tissues accompanied by a disturbance of body electrolytes.

delegation Process of assigning another member of the health care team to be responsible for aspects of patient care (e.g., assigning nurse assistants to bathe a patient).

delirium Acute state of confusion that is potentially reversible and often has a physical cause.

dementia Generalized impairment of intellectual functioning that interferes with social and occupational functioning.

denial Unconscious refusal to admit an unacceptable idea.

denotative meaning Meaning of a word shared by individuals who use a common language. The word *baseball* has the same meaning for all individuals who speak English, but the word *code* primarily denotes cardiac arrest to health care providers.

dental caries Abnormal destructive condition in a tooth caused by a complex interaction of food, especially starches and sugars, with bacteria that form dental plaque.

deontology Traditional theory of ethics that proposes to define actions as right or wrong based on the characteristics of fidelity to promises, truthfulness, and justice. The conventional use of ethical terms such as *justice, autonomy, beneficence,* and *nonmaleficence* constitutes the practice of deontology.

depression (1) Reduction in happiness and well-being that contributes to physical and social limitations and complicates the treatment of concomitant medical conditions. It is usually reversible with treatment. (2) Fourth stage of Kübler-Ross's stages of grief and dying. In this stage the person realizes the full impact and significance of the loss.

dermis Sensitive vascular layer of the skin directly below the epidermis; composed of collagenous and elastic fibrous connective tissues that give the dermis strength and elasticity.

determinants of health Many variables that influence the health status of individuals or communities.

detoxify To remove the toxic quality of a substance. The liver acts to detoxify chemicals in drug compounds.

development Qualitative or observable aspects of the progressive changes that one makes in adapting to the environment.

developmental crises Crises associated with normal and expected phases of growth and development (e.g., the response to menopause); same as maturational crises.

diabetic retinopathy Disorder of retinal blood vessels. Pathological changes secondary to increased pressure in the blood vessels of the retina result in decreased vision or vision loss caused by hemorrhage and macular edema.

diagnosis-related group (DRG) Group of patients classified to establish a mechanism for health care reimbursement based on length of stay. Classification is based on the following variables: primary and secondary diagnosis, co-morbidities, primary and secondary procedures, and age.

diagnostic process Mental steps (data clustering and analysis, problem identification) that follow assessment and lead directly to the formulation of a diagnosis.

diagnostic reasoning Process that enables an observer to assign meaning to and classify phenomena in clinical situations by integrating observations and critical thinking.

diaphoresis Secretion of sweat, especially profuse secretion associated with an elevated body temperature, physical exertion, or emotional stress.

diaphragmatic breathing Respiration in which the abdomen moves out while the diaphragm descends on inspiration.

diarrhea Increase in the number of stools and the passage of liquid, unformed feces.

diastolic Pertaining to diastole, or the blood pressure at the instant of maximum cardiac relaxation.

dietary reference intake (DRI) Information on each vitamin or mineral to reflect a range of minimum-to-maximum amounts that avert deficiency or toxicity.

diffusion Movement of molecules from an area of high concentration to one of lower concentration.

digestion Breakdown of nutrients by chewing, churning, mixing with fluid, and chemical reactions.

direct care interventions Treatments performed through interaction with the patient. For example, a patient may require medication administration, insertion of an intravenous infusion, or counseling during a time of grief.

discharge planning Activities directed toward identifying future proposed therapy and the need for additional resources before and after returning home.

discrimination Prejudicial outlook, action, or treatment.

disease Malfunctioning or maladaptation of biological or psychological processes.

disinfection Process of destroying all pathogenic organisms except spores.

disorganization and despair One of Bowlby's four phases of mourning in which an individual endlessly examines how and why the loss occurred.

distress Damaging stress; one of the two types of stress identified by Selye.

disuse osteoporosis Reductions in skeletal mass routinely accompanying immobility or paralysis.

diuresis Increased rate of formation and excretion of urine.

documentation Written entry into the patient's medical record of all pertinent information about him or her. These entries validate the patient's problems and care and exist as a legal record.

dominant culture Customs, values, beliefs, traditions, and social and religious views held by a group of people that prevail over another secondary culture.

dorsiflexion Flexion toward the back.

drainage evacuators Convenient portable units that connect to tubular drains lying within a wound bed and exert a safe, constant, low-pressure vacuum to remove and collect drainage.

droplet precautions Safeguards designed to reduce the risk of droplet transmission of infectious agents.

dysmenorrhea Painful menstruation.

dysphagia Difficulty swallowing; commonly associated with obstructive or motor disorders of the esophagus.

dyspnea Sensation of shortness of breath.

dysrhythmia Deviation from the normal pattern of the heartbeat.

dysuria Painful urination resulting from bacterial infection of the bladder and obstructive conditions of the urethra.

E

ecchymosis Discoloration of the skin or bruise caused by leakage of blood into subcutaneous tissues as a result of trauma to underlying tissues.

ectropion Eversion of the eyelid that exposes the conjunctival membrane and part of the eyeball.

edema Abnormal accumulation of fluid in interstitial spaces of tissues.

egocentric Developmental characteristic wherein a toddler is only able to assume the view of his or her own activities and needs.

electrocardiogram (ECG) Graphic record of the electrical activity of the myocardium.

electrolyte Element or compound that, when melted or dissolved in water or other solvent, dissociates into ions and can carry an electrical current.

electronic health record An electronic record of patient health information generated whenever a patient accesses medical care in any health care delivery setting.

electronic infusion device Piece of medical equipment that delivers intravenous fluids at a prescribed rate through an intravenous catheter.

electronic medical record Part of the electronic health record that contains patient data gathered in a health care setting at a specific time and place.

embolism Abnormal condition in which a blood clot (embolus) travels through the bloodstream and becomes lodged in a blood vessel.

emerging adulthood The time from adolescence to the young adult when responsibilities of a stable job, marriage and parenthood begin. It includes five features: the age of identity exploration; the age of instability, the age of self-focus, the age of feeling in between and the age of possibilities.

emotional intelligence Assessment and communication technique used to better understand and perceive emotions of themselves. This assists in building a therapeutic relationship.

empathy Understanding and acceptance of a person's feelings and the ability to sense the person's private world.

empowered Gave legal authority to or enabled an individual or group; promoted self-actualization of an individual or group.

endogenous infections Infections produced within a cell or organism.

endorphins Hormones that act on the mind such as morphine and opiates and produce a sense of well-being and reducing pain.

endotracheal tube Short-term artificial airways to administer mechanical ventilation, relieve upper airway obstruction, protect against aspiration, or clear secretions.

enema Procedure involving introduction of a solution into the rectum for cleansing or therapeutic purposes.

enteral nutrition (EN) Provision of nutrients through the gastrointestinal tract when the patient cannot ingest, chew, or swallow food but can digest and absorb nutrients.

entropion Condition in which the eyelid turns inward toward the eye.

environment All of the many factors (e.g., physical and psychological) that influence or affect the life and survival of a person.

epidermis Outer layer of the skin that has several thin layers in different stages of maturation; shields and protects the underlying tissues from water loss, mechanical or chemical injury, and penetration by disease-causing microorganisms.

epidural infusion Type of nerve block anesthesia in which an anesthetic is intermittently or continuously injected into the lumbosacral region of the spinal cord.

erythema Redness or inflammation of the skin or mucous membranes that is a result of dilation and congestion of superficial capillaries; sunburn is an example.

eschar Thick layer of dead, dry tissue that covers a pressure ulcer or thermal burn. It may be allowed to be sloughed off naturally, or it may need to be surgically removed.

ethical dilemma Dilemma existing when the right thing to do is not clear. Resolution requires the negotiation of differing values among those involved in the dilemma.

ethical principles Set of guidelines for the expectations a profession and the standards of behavior for its members.

ethics Principles or standards that govern proper conduct.

ethics of care Delivery of health care based on ethical principles and standards of care.

ethnicity Shared identity related to social and cultural heritage such as values, language, geographical space, and racial characteristics.

ethnocentrism Tendency to hold one's own way of life as superior to that of others.

ethnohistory Significant historical experiences of a particular group.

etiology Study of all factors that may be involved in the development of a disease.

eupnea Normal respirations that are quiet, effortless, and rhythmical.

eustress Stress that protects health; one of the two types of stress identified by Selye.

evaluation Determination of the extent to which established patient goals have been achieved.

evidence-based knowledge Knowledge that is derived from the integration of best research, clinical expertise, and patient values.

evidence-based practice Use of current best evidence from nursing research, clinical expertise, practice trends, and patient preferences to guide nursing decisions about care provided to patients.

evisceration Protrusion of visceral organs through a surgical wound.

exacerbations Increases in the gravity of a disease or disorder as marked by greater intensity in signs or symptoms.

excessive daytime sleepiness Extreme fatigue felt during the day. Signs of this include falling asleep at inappropriate times such as while eating, talking, or driving. May indicate a sleep disorder.

excoriation Injury to the surface of the skin caused by abrasion.

exhaustion stage Phase that occurs when the body can no longer resist the stress (i.e., when the energy necessary to maintain adaptation is depleted).

exogenous infection Infection originating outside an organ or part.

exostosis Abnormal benign growth on the surface of a bone.

expected outcomes Expected conditions of a patient at the end of therapy or a disease process, including the degree of wellness and the need for continuing care, medications, support, counseling, or education.

extended care facility Institution devoted to providing medical, nursing, or custodial care for an individual over a prolonged period such as during the course of a chronic disease or the rehabilitation phase after an acute illness.

extension Movement by certain joints that increases the angle between two adjoining bones.

extracellular fluid (ECF) Portion of body fluids composed of the interstitial fluid and blood plasma.

exudate Fluid, cells, or other substances that have been discharged from cells or blood vessels slowly through small pores or breaks in cell membranes.

F

face-saving   Way of speaking or acting that preserves dignity.

Fahrenheit   Denotes temperature scale in which 32° is the freezing point of water and 212° is the boiling point of water at sea level.

faith   Set of beliefs and a way of relating to self, others, and a Supreme Being.

fajita   Cotton binder used on a newborn's abdomen among Hispanics and Filipinos to prevent gas and umbilical hernia.

family   Group of interacting individuals composing a basic unit of society.

family as context   Nursing perspective in which the family is viewed as a unit of interacting members having attributes, functions, and goals separate from those of the individual family members.

family caregiving   A family process that occurs in response to an illness and encompasses multiple cognitive, behavioral, and interpersonal processes.

family diversity   Unique needs and characteristics of each member in a family.

family durability   System of support for a family that includes immediate and extended family members.

family forms   Patterns of people considered by family members to be included in the family.

family functioning   Processes families use to achieve their goals.

family hardiness   Internal strengths and durability of the family unit; characterized by a sense of control over the outcome of life events and hardships, a view of change as beneficial and growth-producing, and an active rather than passive orientation in responding to stressful life events.

family health   Determined by the effectiveness of the family's structure, the processes that the family uses to meet its goals, and internal and external forces.

family as patient   Nursing approach that takes into consideration the effect of one intervention on all members of a family.

family resiliency   Family's ability to cope with expected and unexpected stressors.

family structure   Based on organization (i.e., ongoing membership) of the family and the pattern of relationships.

farmacia   Place to obtain prescribed medications.

febrile   Pertaining to or characterized by an elevated body temperature.

fecal impaction   Accumulation of hardened fecal material in the rectum or sigmoid colon.

fecal incontinence   Inability to control passage of feces and gas from the anus.

fecal occult blood test (FOBT)   Measures microscopic amounts of blood in the feces.

feces   Waste or excrement from the gastrointestinal tract.

feedback   Process in which the output of a given system is returned to the system.

felony   Crime of a serious nature that carries a penalty of imprisonment or death.

feminist ethics   Ethical approach that focuses on the nature of relationships to guide participants in making difficult decisions, especially relationships in which power is unequal or in which a point of view has become ignored or invisible.

fever   Elevation in the hypothalamic set point so body temperature is regulated at a higher level.

fictive   Nonblood kin; considered family in some collective cultures.

fidelity   Agreement to keep a promise.

fight-or-flight response   Total physiological response to stress that occurs during the alarm reaction stage of the general adaptation syndrome. Massive changes in all body systems prepare a human being to choose to flee or remain and fight the stressor.

filtration   Straining of fluid through a membrane.

fistula   Abnormal passage from an internal organ to the surface of the body or between two internal organs.

flashback   Recollection so strong that the individual thinks that he or she is actually experiencing the trauma again or seeing it unfold before his or her eyes.

flatus   Intestinal gas.

flora   Microorganisms that live on or within a body to compete with disease-producing microorganisms and provide a natural immunity against certain infections.

flow sheets   Documents on which frequent observations or specific measurements are recorded.

fluctuance   Soft, boggy feeling when tissue is palpated; usually a sign of tissue infection.

fluid volume deficit (FVD)   Fluid and electrolyte disorder caused by failure of bodily homeostatic mechanisms to regulate the retention and excretion of body fluids. The condition is characterized by decreased output of urine, high specific gravity of urine, output of urine that is greater than the intake of fluid in the body, hemoconcentration, and increased serum levels of sodium.

fluid volume excess (FVE)   Fluid and electrolyte disorder characterized by an increase in fluid retention and edema, resulting from failure of bodily homeostatic mechanisms to regulate the retention and excretion of body fluids.

focus charting   Charting methodology for structuring progress notes according to the focus of the note (e.g., symptoms and nursing diagnosis). Each note includes data, actions, and patient response.

focused cultural assessment   Method of evaluating a patient's ethnohistory, biocultural history, social organization, and religious and spiritual beliefs to find issues that are most relevant to the problem at hand.

food poisoning   Toxic processes resulting from the ingestion of a food contaminated by toxic substances or bacteria-containing toxins.

food security   All members of a household have access to sufficient, safe, nutritious food to maintain a healthy lifestyle.

foot boots   Soft, foot-shaped devices designed to reduce the risk of footdrop by maintaining the foot in dorsiflexion.

footdrop   Abnormal neuromuscular condition of the lower leg and foot characterized by an inability to dorsiflex, or evert, the foot.

friction   Effects of rubbing or the resistance that a moving body meets from the surface on which it moves; a force that occurs in a direction to oppose movement.

functional health illiteracy   Inability of an individual to obtain, interpret, and understand basic information about health.

functional health patterns   Method for organizing assessment data based on the level of patient function in specific areas (e.g., mobility).

functional nursing   Method of patient care delivery in which each staff member is assigned a task that is completed for all patients on the unit.

future orientation   Time dimension emphasized by dominant American culture. It is characterized by direct communication and is focused on task achievement, whereas past orientation communication is circular and indirect and is focused on group harmony.

G

gait   Manner or style of walking, including rhythm, cadence, and speed.

gastrostomy feeding tube   Insertion of a feeding tube through a stoma into the stomach to provide enteral nutrition.

general adaptation syndrome (GAS)   Generalized defense response of the body to stress; consists of three stages: alarm, resistance, and exhaustion.

general anesthesia   Intravenous or inhaled medications that cause the patient to lose all sensation and consciousness.

genomics   Describes the study of all the genes in a person and interactions of those genes with one another and with that person's environment.

geriatrics   Branch of health care dealing with the physiology and psychology of aging and the diagnosis and treatment of diseases affecting older adults.

gerontology   Study of all aspects of the aging process and its consequences.

gingivae   Gums of the mouth; mucous membrane with supporting fibrous tissue that overlies the crowns of unerupted teeth and encircles the necks of teeth that have erupted.

glaucoma   Abnormal condition of elevated pressure within an eye caused by obstruction of the outflow of aqueous humor. If untreated, it often results in peripheral visual loss, decreased visual acuity with difficulty adapting to darkness, and a halo effect around lights.

globalization   Worldwide scope or application.

glomerulus   Cluster or collection of capillary vessels within the kidney involved in the initial formation of urine.

gluconeogenesis   Formation of glucose or glycogen from substances that are not carbohydrates such as protein or lipid.

glucose   Primary fuel for the body; needed to carry out major physiological functions.

glycogen   Polysaccharide that is the major carbohydrate stored in animal cells.

glycogenesis   Process for storing glucose in the form of glycogen in the liver.

goals   Desired results of nursing actions set realistically by the nurse and patient as part of the planning stage of the nursing process.

Good Samaritan laws   Legislation enacted in some states to protect health care professionals from liability in rendering emergency aid unless there is proven willful wrong or gross negligence.

graduated measuring container   Receptacle for volume measurement.

granny midwives   Amateur health practitioners that assist in labor and delivery.

granulation tissue   Soft, pink, fleshy projections of tissue that form during the healing process in a wound not healing by primary intention.

graphic record   Charting mechanism that allows for the recording of vital signs and weight in such a manner that caregivers can quickly note changes in the patient's status.

grief   Form of sorrow involving the person's thoughts, feelings, and behaviors that occurs as a response to an actual or perceived loss.

grieving process   Sequence of affective, cognitive, and physiological states through which the person responds to and finally accepts an irretrievable loss.

grounded   Connection between the electric circuit and the ground, which becomes part of the circuit.

growth   Measurable or quantitative aspect of an individual's increase in physical dimensions as a result of an increase in number of cells. Indicators of growth include changes in height, weight, and sexual characteristics.

guided imagery   Method of pain control in which the patient creates a mental image, concentrates on that image, and gradually becomes less aware of pain.

gustatory   Pertaining to the sense of taste.

H

halal   Foods permissible for Muslims to eat.

hand rolls   Rolls of cloth that keep the thumb slightly adducted and in opposition to the fingers.

hand-wrist splints   Splints individually molded for the patient to maintain proper alignment of the thumb, slight adduction of the wrist, and slight dorsiflexion.

haram   Foods prohibited by Muslim religious standards.

health   Dynamic state in which individuals adapt to their internal and external environments so there is a state of physical, emotional, intellectual, social, and spiritual well-being.

health belief model   Conceptual framework that describes a person's health behavior as an expression of his or her health beliefs.

health beliefs   Patient's personal beliefs about levels of wellness that can motivate or impede participation in changing risk factors, participating in care, and selecting care options.

health care–acquired infection   Infection that was not present or incubating at the time of admission to a health care setting.

health care problems   Any conditions or dysfunctions that the patient experiences as a result of illness or treatment of an illness.

health disparities   Preventable differences in the burden of disease, injury, violence, or opportunities to achieve optimal health that are experienced by socially and economically disadvantaged populations.

health informatics   Application of computer and information science in all basic and applied biomedical sciences to facilitate the acquisition, processing, interpretation, optimal use, and communication of health-related data.

health literacy   Patients' reading and mathematics skills, comprehension, ability to make health-related decisions, and successful functioning as a consumer of health care.

health promotion   Activities such as routine exercise and good nutrition that help patients maintain or enhance their present level of health and reduce their risk of developing certain diseases.

health promotion model   Defines health as a positive, dynamic state, not merely the absence of disease. The health promotion model emphasizes well-being, personal fulfillment, and self-actualization rather than reaction to the threat of illness.

health status   Description of health of an individual or community.

heat exhaustion   Abnormal condition caused by depletion of body fluid and electrolytes resulting from exposure to intense heat or the inability to acclimatize to heat.

heat stroke   Continued exposure to extreme heat that raises the core body temperature to 40.5° C (105° F) or higher.

hematemesis   Vomiting of blood, indicating upper gastrointestinal bleeding.

hematoma   Collection of blood trapped in the tissues of the skin or an organ.

hematuria   Abnormal presence of blood in the urine.

hemolysis   Breakdown of red blood cells and release of hemoglobin that may occur after administration of hypotonic intravenous solutions, causing swelling and rupture of erythrocytes.

hemoptysis   Coughing up blood from the respiratory tract.

hemorrhoids   Permanent dilation and engorgement of veins within the lining of the rectum.

hemostasis   Termination of bleeding by mechanical or chemical means or the coagulation process of the body.

hemothorax   Accumulation of blood and fluid in the pleural cavity between the parietal and visceral pleurae.

hernia   Protrusion of an organ through an abnormal opening in the muscle wall of the cavity that surrounds it.

hilots   Amateur health practitioners that assist in labor and delivery among Filipinos.

holistic   Of or pertaining to the whole; considering all factors.

holistic health   Comprehensive view of the person as a biopsychosocial and spiritual being.

home care   Health service provided in the patient's place of residence to promote, maintain, or restore health or minimize the effects of illness and disability.

homeostasis   State of relative constancy in the internal environment of the body; maintained naturally by physiological adaptive mechanisms.

hope   Confident but uncertain expectation of achieving a future goal.

hospice   System of family-centered care designed to help terminally ill people be comfortable and maintain a satisfactory lifestyle throughout the terminal phase of their illness.

Hoyer lift   Mechanical device that uses a canvas sling to easily lift dependent patients for transfer.

humidification   Process of adding water to gas.

humor   Coping strategy based on an individual's cognitive appraisal of a stimulus that results in behavior such as smiling, laughing, or feelings of amusement that lessen emotional distress.

hydrocephalus   Abnormal accumulation of cerebrospinal fluid in the ventricles of the brain.

hydrostatic pressure   Pressure caused by a liquid.

hyperactive/overactive bladder   Common bladder complaint that occurs more frequently with aging and includes the symptoms of urgency, frequency, nocturia, and urge incontinence.

hypercalcemia   Greater-than-normal amount of calcium in the blood.

hypercapnia   Greater-than-normal amounts of carbon dioxide in the blood; also called hypercarbia.

hyperextension   Position of maximal extension of a joint.

hyperglycemia   Elevated serum glucose levels.

hypertension   Disorder characterized by an elevated blood pressure persistently exceeding 120/80 mm Hg.

hyperthermia   Situation in which body temperature exceeds the set point.

hypertonic   Situation in which one solution has a greater concentration of solute than another; therefore the first solution exerts greater osmotic pressure.

hypertonicity   Excessive tension of the arterial walls or muscles.

hyperventilation   Respiratory rate in excess of that required to maintain normal carbon dioxide levels in the body tissues.

hypnotics   Class of drug that causes insensibility to pain and induces sleep.

hypostatic pneumonia   Pneumonia that results from fluid accumulation as a result of inactivity.

hypotension   Abnormal lowering of blood pressure that is inadequate for normal perfusion and oxygenation of tissues.

hypothermia   Abnormal lowering of body temperature below 35° C, or 95° F, usually caused by prolonged exposure to cold.

hypotonic Situation in which one solution has a smaller concentration of solute than another; therefore the first solution exerts less osmotic pressure.

hypotonicity Reduced tension of the arterial walls or muscles.

hypoventilation Respiratory rate insufficient to prevent carbon dioxide retention.

hypovolemia Abnormally low circulating blood volume.

hypoxemia Arterial blood oxygen level less than 60 mm Hg; low oxygen level in the blood.

hypoxia Inadequate cellular oxygenation that may result from a deficiency in the delivery or use of oxygen at the cellular level.

I

identity Component of self-concept characterized by one's persisting consciousness of being oneself, separate and distinct from others.

idiosyncratic reaction Individual sensitivity to effects of a drug caused by inherited or other bodily constitution factors.

illness (1) Abnormal process in which any aspect of a person's functioning is diminished or impaired compared with his or her previous condition. (2) The personal, interpersonal, and cultural reaction to disease.

illness behavior Ways in which people monitor their bodies, define and interpret their symptoms, take remedial actions, and use the health care system.

illness prevention Health education programs or activities directed toward protecting patients from threats or potential threats to health and minimizing risk factors.

immobility Inability to move about freely; caused by any condition in which movement is impaired or therapeutically restricted.

immunity Quality of being insusceptible to or unaffected by a particular disease or condition.

immunization Process by which resistance to an infectious disease is induced or augmented.

implementation Initiation and completion of the nursing actions necessary to help the patient achieve health care goals.

impression management Ability to interpret others' behavior within their own context of meanings and behave in a culturally congruent way to achieve desired outcomes of communication.

incentive spirometry Method of encouraging voluntary deep breathing by providing visual feedback to patients of the inspiratory volume they have achieved.

incident rates Rate of new cases of a disease in a specified population over a defined period of time.

incident report Confidential document that describes any patient accident while the person is on the premises of a health care agency. (See occurrence report.)

independent practice association (IPA) Managed care organization that contracts with physicians or health care providers who usually are members of groups and whose practices include fee-for-service and capitated patients.

indirect care interventions Treatments performed away from the patient but on behalf of the patient or group of patients.

induration Hardening of a tissue, particularly the skin, because of edema or inflammation.

infection Invasion of the body by pathogenic microorganisms that reproduce and multiply.

inference (1) Judgment or interpretation of informational cues. (2) Taking one proposition as a given and guessing that another proposition follows.

infiltration Dislodging an intravenous catheter or needle from a vein into the subcutaneous space.

inflammation Protective response of body tissues to irritation or injury.

informed consent Process of obtaining permission from a patient to perform a specific test or procedure after describing all risks, side effects, and benefits.

infusion pump Device that delivers a measured amount of fluid over a period of time.

infusions Introduction of fluid into the vein, giving intravenous fluid over time.

inhalation Method of medication delivery through the patient's respiratory tract. The respiratory tract provides a large surface area for drug absorption. Inhalation can be through the nasal or oral route.

injections Parenteral administration of medication; four major sites of injection: subcutaneous, intramuscular, intravenous, and intradermal.

insensible water loss Water loss that is continuous and not perceived by the person.

insomnia Condition characterized by chronic inability to sleep or remain asleep through the night.

inspection Method of physical examination by which the patient is visually systematically examined for appearance, structure, function, and behavior.

instillation To cause to enter drop by drop or very slowly.

institutional ethics committee Interdisciplinary committee that discusses and processes ethical dilemmas that arise within a health care institution.

instrumental activities of daily living (IADLs) Activities necessary for independence in society beyond eating, grooming, transferring, and toileting; include such skills as shopping, preparing meals, banking, and taking medications.

integrated delivery network (IDN) Set of providers and services organized to deliver a coordinated continuum of care to the population of patients served at a capitated cost.

interpersonal communication Exchange of information between two persons or among persons in a small group.

interstitial fluid Fluid that fills the spaces between most of the cells of the body and provides a substantial portion of the liquid environment of the body.

interview Organized, systematic conversation with the patient designed to obtain pertinent health-related subjective information.

intracellular fluid Liquid within the cell membrane.

intradermal (ID) Injection given between layers of the skin into the dermis. Injections are given at a 5- to 15-degree angle.

intramuscular (IM) Injections given into muscle tissue. The intramuscular route provides a fast rate of absorption that is related to the greater vascularity of the muscle. Injections are given at a 90-degree angle.

intraocular Method of medication delivery that involves inserting a medication disk similar to a contact lens into the patient's eye.

intrapersonal communication Communication that occurs within an individual (i.e., people "talk with themselves" silently or form an idea in their own mind).

intravascular fluid Fluid circulating within blood vessels of the body.

intravenous Injection directly into the bloodstream. Action of the drug begins immediately when given intravenously.

intravenous fat emulsions Soybean- or safflower oil–based solutions that are isotonic and may be infused with amino acid and dextrose solution through a central or peripheral line.

intubation Insertion of a breathing tube through the mouth or nose into the trachea to ensure a patent airway.

intuition Inner sensing that something is so.

irrigation Process of washing out a body cavity or wounded area with a stream of fluid.

ischemia Decreased blood supply to a body part such as skin tissue or to an organ such as the heart.

isolation Separation of a seriously ill patient from others to prevent the spread of an infection or protect the patient from irritating environmental factors.

isometric exercises Activities that involve muscle tension without muscle shortening, do not have any beneficial effect on preventing orthostatic hypotension, but may improve activity tolerance.

isotonic Situation in which two solutions have the same concentration of solute; therefore both solutions exert the same osmotic pressure.

J

jaundice Yellow discoloration of the skin, mucous membranes, and sclera caused by greater-than-normal amounts of bilirubin in the blood.

jejunostomy tube Hollow tube inserted into the jejunum through the abdominal wall for administration of liquefied foods to patients who have a high risk of aspiration.

joint contracture Abnormality that may result in permanent condition of a joint; is characterized by flexion and fixation; and is caused by disuse, atrophy, and shortening of muscle fibers and surrounding joint tissues.

joints Connections between bones; classified according to structure and degree of mobility.

judgment Ability to form an opinion or draw sound conclusions.

justice Ethical standard of fairness.

K

Kardex   Trade name for card-filing system that allows quick reference to the particular need of the patient for certain aspects of nursing care.

karma   Asian Indian belief that attributes mental illness to past deeds in one's previous life.

knowing the patient   An in-depth knowledge of the patient's patterns of responses; fosters skilled clinical decision making.

Korotkoff sound   Sound heard during the taking of blood pressure using a sphygmomanometer and stethoscope.

Kussmaul respiration   Increase in both rate and depth of respirations.

kyphosis   Exaggeration of the posterior curvature of the thoracic spine.

L

la cuarantena   Period of rest and restricted physical activity after childbirth that usually lasts 40 days.

laceration   Torn, jagged wound.

language   Code that conveys specific meaning as words are combined.

laryngospasm   Sudden uncontrolled contraction of the laryngeal muscles, which in turn decreases airway size.

lateral violence   Hostile, aggressive, and harmful verbal and nonverbal behavior by a nurse to another nurse via attitudes, actions, words, or behaviors. This behavior includes criticizing, intimidations, blaming, fighting, public humiliation, isolating, withholding assistance, or undermining efforts in completing assignments. This leaves the nurse feeling bullied, inadequate and powerless.

law   Rule, standard, or principle that states a fact or relationship between factors.

laxatives   Drugs that act to promote bowel evacuation.

learning   Acquisition of new knowledge and skills as a result of reinforcement, practice, and experience.

learning objective   Written statement that describes the behavior that a teacher expects from an individual after a learning activity.

left-sided heart failure   Abnormal condition characterized by impaired functioning of the left ventricle caused by elevated pressures and pulmonary congestion.

leukoplakia   Thick, white patches observed on oral mucous membranes.

licensed practical nurse (LPN)   Also known as the licensed vocational nurse (LVN) or in Canada, registered nurse's assistant (RNA); trained in basic nursing skills and the provision of direct patient care.

licensed vocational nurse (LVN)   The LVN is the same as a licensed practical nurse (LPN), an individual trained in the United States in basic nursing techniques and direct patient care who practices under the supervision of a registered nurse. The LVN is licensed by a board after completing what is usually a 12-month educational program and passing a licensure examination. In Canada an LVN is called a certified nursing assistant.

lipids   Compounds that are insoluble in water but soluble in organic solvents.

lipogenesis   Process during which fatty acids are synthesized.

living wills   Instruments by which a dying person makes wishes known.

local anesthesia   Loss of sensation at the desired site of action.

logroll   Maneuver used to turn a reclining patient from one side to the other or completely over without moving the spinal column out of alignment.

lordosis   Increased lumbar curvature.

M

maceration   Softening and breaking down of skin from prolonged exposure to moisture.

mal de ojo   Evil eye.

malignant hyperthermia   Autosomal-dominant trait characterized by often fatal hyperthermia in affected people exposed to certain anesthetic agents.

malpractice   Injurious or unprofessional actions that harm another.

malpractice insurance   Type of insurance to protect the health care professional. In case of a malpractice claim, the insurance pays the award to the plaintiff.

managed care   Health care system in which there is administrative control over primary health care services. Redundant facilities and services are eliminated, and costs are reduced. Preventive care and health education are emphasized.

Maslow's hierarchy of needs   Model developed by Abram Maslow that is used to explain human motivation.

matrilineal   Kinship that is limited to only the mother's side.

maturation   Genetically determined biological plan for growth and development. Physical growth and motor development are a function of maturation.

maturational loss   Loss, usually of an aspect of self, resulting from the normal changes of growth and development.

Medicaid   State medical assistance to people with low incomes, based on Title XIX of the Social Security Act. States receive matching federal funds to provide medical care and services to people meeting categorical and income requirements.

medical asepsis   Procedures used to reduce the number of microorganisms and prevent their spread.

medical diagnosis   Formal statement of the disease entity or illness made by the physician or health care provider.

medical record   Patient's chart; a legal document.

Medicare   Federally funded national health insurance program in the United States for people over 65 years of age. The program is administered in two parts. Part A provides basic protection against costs of medical, surgical, and psychiatric hospital care. Part B is a voluntary medical insurance program financed in part from federal funds and in part from premiums contributed by people enrolled in the program.

medication abuse   Maladaptive pattern of recurrent medication use.

medication allergy   Adverse reaction such as rash, chills, or gastrointestinal disturbances to a medication. Once a drug allergy occurs, the patient can no longer receive that particular medication.

medication dependence   Maladaptive pattern of medication use in the following patterns: using excessive amounts of the medication, increased activities directed toward obtaining the medication, or withdrawal from professional or recreational activities.

medication error   Any event that could cause or lead to a patient's receiving inappropriate drug therapy or failing to receive appropriate drug therapy.

medication interaction   Response that occurs when one drug modifies the action of another drug. The interaction can potentiate or diminish the actions of another drug; or it may alter the way a drug is metabolized, absorbed, or excreted.

melanoma   Group of malignant neoplasms, primarily of the skin, that are composed of melanocytes. Common in fair-skinned people having light-colored eyes and those who have been sunburned.

melena   Abnormal black, sticky stool containing digested blood that is indicative of gastrointestinal bleeding.

menarche   Onset of a girl's first menstruation.

Ménière's disease   Chronic disease of the inner ear characterized by recurrent episodes of vertigo; progressive sensorineural hearing loss, which may be bilateral; and tinnitus.

menopause   Physiological cessation of ovulation and menstruation that typically occurs during middle adulthood in women.

message   Information sent or expressed by sender in the communication process.

metabolic acidosis   Abnormal condition of high hydrogen ion concentration in the extracellular fluid caused by either a primary increase in hydrogen ions or a decrease in bicarbonate.

metabolic alkalosis   Abnormal condition characterized by the significant loss of acid from the body or increased levels of bicarbonate.

metabolism   Aggregate of all chemical processes that take place in living organisms and result in growth, generation of energy, elimination of wastes, and other functions concerned with the distribution of nutrients in the blood after digestion.

metacommunication   Dependent not only on what is said but also on the relationship to the other person involved in the interaction. It is a message that conveys the sender's attitude toward self and the message and the attitudes, feelings, and intentions toward the listener.

metastasize   Spread of tumor cells to distant parts of the body from a primary site (e.g., lung, breast, or bowel).

metered-dose inhaler (MDI)   Device designed to deliver a measured dose of an inhalation drug.

metric system Logically organized decimal system of measurement; metric units can easily be converted and computed through simple multiplication and division. Each basic unit of measurement is organized into units of 10.

microorganisms Microscopic entities such as bacteria, viruses, and fungi that are capable of carrying on living processes.

micturition Urination; act of passing or expelling urine voluntarily through the urethra.

milliequivalent per liter (mEq/L) Number of grams of a specific electrolyte dissolved in 1 L of plasma.

mind mapping Graphic approach to represent the connections between concepts and ideas (e.g., nursing diagnoses) that are related to a central subject (e.g., the patient's health problems).

mindfulness A moment-to-moment present awareness with an attitude on non-judgment, acceptance, and openness. Mindfulness meditative practices are effective in reducing psychological and physical symptoms or perceptions of stress.

minerals Inorganic elements essential to the body because of their role as catalysts in biochemical reactions.

minimum data set (MDS) Required by the Omnibus Budget Reconciliation Act of 1987, the MDS is a uniform data set established by the Department of Health and Human Services. It serves as the framework for any state-specified assessment instruments used to develop a written and comprehensive plan of care for newly admitted residents of nursing facilities.

misdemeanor Lesser crime than a felony; the penalty is usually a fine or imprisonment for less than 1 year.

mobility Person's ability to move about freely.

moderate sedation/analgesia/conscious sedation Administration of central nervous system depressant drugs and/or analgesics to provide analgesia, relieve anxiety, and/or provide amnesia during surgical, diagnostic, or interventional procedures. Routinely used for diagnostic or therapeutic procedures that do not require complete anesthesia but simply a decreased level of consciousness.

monosaturated fatty acid Fatty acid in which some of the carbon atoms in the hydrocarbon chain are joined by double or triple bonds. Monounsaturated fatty acids have only one double or triple bond per molecule and are found as components of fats in such foods as fowls, almonds, pecans, cashew nuts, peanuts, and olive oil.

morals Personal conviction that something is absolutely right or wrong in all situations.

motivation Internal impulse that causes a person to take action.

motivational interviewing Interview technique used to identify patient's thoughts, beliefs, fears and current health care behavior with the aim of helping them to identify improved self-care behaviors.

mourning Process of grieving.

murmurs Blowing or whooshing sounds created by changes in blood flow through the heart or abnormalities in valve closure.

muscle tone Normal state of balanced muscle tension.

myocardial contractility Measure of stretch of the cardiac muscle fiber. It can also affect stroke volume and cardiac output. Poor contraction decreases the amount of blood ejected by the ventricles during each contraction.

myocardial infarction Necrosis of a portion of cardiac muscle caused by obstruction in a coronary artery.

myocardial ischemia Condition that results when the supply of blood to the myocardium from the coronary arteries is insufficient to meet the oxygen demands of the organ.

N

NANDA International North American Nursing Diagnosis Association organized in 1973. It formally identifies, develops, and classifies nursing diagnoses.

narcolepsy Syndrome involving sudden sleep attacks that a person cannot inhibit. Uncontrollable desire to sleep may occur several times during a day.

nasogastric (NG) tube Tube passed into the stomach through the nose to empty the stomach of its contents or deliver medication and/or nourishment.

nebulization Process of adding moisture to inspired air by the adding water droplets.

necessary losses Losses that every person experiences.

necrotic Of or pertaining to the death of tissue in response to disease or injury.

negative health behaviors Practices actually or potentially harmful to health such as smoking, drug or alcohol abuse, poor diet, and refusal to take necessary medications.

negative nitrogen balance Condition occurring when the body excretes more nitrogen than it takes in.

negligence Careless act of omission or commission that results in injury to another.

neonate Stage of life from birth to 1 month of age.

nephrons Structural and functional units of the kidney containing renal glomeruli and tubules.

neurotransmitter Chemical that transfers the electrical impulse from the nerve fiber to the muscle fiber.

nociceptors Somatic and visceral free nerve endings of thinly myelinated and unmyelinated fibers. They usually react to tissue injury but may also be excited by endogenous chemical substances.

nocturia Urination at night; can be a symptom of renal disease or may occur in persons who drink excessive amounts of fluids before bedtime.

nonblanchable hyperemia Redness of the skin caused by dilation of the superficial capillaries. The redness persists when pressure is applied to the area, indicating tissue damage.

noninvasive positive-pressure ventilation (NPPV) Used to prevent using invasive artificial airways (endotracheal [ET] tube or tracheostomy) in patients with acute respiratory failure, cardiogenic pulmonary edema, or exacerbation of chronic obstructive pulmonary disease. It has also been used following extubation of an ET tube.

nonmaleficence Fundamental ethical agreement to do no harm. Closely related to the ethical standard of beneficence.

nonrapid eye movement (NREM) sleep Sleep that occurs during the first four stages of normal sleep.

nonshivering thermogenesis Occurs primarily in neonates. Because neonates cannot shiver, a limited amount of vascular brown adipose tissue present at birth can be metabolized for heat production.

nonverbal communication Communication using expressions, gestures, body posture, and positioning rather than words.

normal sinus rhythm (NSR) The wave pattern on an electrocardiogram that indicates normal conduction of an electrical impulse through the myocardium.

numbing One of Bowlby's four phases of mourning. It is characterized by the lack of feeling or feeling stunned by the loss; may last a few days or many weeks.

Nurse Practice Acts Statutes enacted by the legislature of any of the states or the appropriate officers of the districts or possessions that describe and define the scope of nursing practice.

nurse-initiated interventions Response of the nurse to the patient's health care needs and nursing diagnoses. This type of intervention is an autonomous action based on scientific rationale that is executed to benefit the patient in a predicted way related to the nursing diagnosis and patient-centered goals.

Nursing Clinical Information System (NCIS) A system that incorporates the principles of nursing informatics to support the work that nurses do by facilitating documentation of nursing process activities and offering resources for managing nursing care delivery.

nursing diagnosis Formal statement of an actual or potential health problem that nurses can legally and independently treat; the second step of the nursing process, during which the patient's actual and potential unhealthy responses to an illness or condition are identified.

nursing health history Data collected about a patient's present level of wellness, changes in life patterns, sociocultural role, and mental and emotional reactions to illness.

nursing intervention Any treatment based on clinical judgment and knowledge that a nurse performs to enhance patient outcomes.

Nursing Outcomes Classification A systematic organization of nurse sensitive outcomes into groups or categories based upon similarities, dissimilarities, and relationships among the outcomes.

nursing process Systematic problem-solving method by which nurses individualize care for each patient. The five steps of the nursing

process are assessment, diagnosis, planning, implementation, and evaluation.

nursing-sensitive outcomes   Outcomes that are within the scope of nursing practice; consequences or effects of nursing interventions that result in changes in the patient's symptoms, functional status, safety, psychological distress, or costs.

nurturant   Behavior that involves caring for or fostering the well-being of another individual.

nutrients   Foods that contain elements necessary for body function, including water, carbohydrates, proteins, fats, vitamins, and minerals.

O

obesity   Abnormal increase in the proportion of fat cells, mainly in the viscera and subcutaneous tissues of the body.

objective data   Information that can be observed by others; free of feelings, perceptions, prejudices.

occurrence report   Confidential document that describes any patient accident while the person is on the premises of a health care agency. (See incident report.)

olfactory   Pertaining to the sense of smell.

oncotic pressure   Total influence of the protein on the osmotic activity of plasma fluid.

Open-ended question   Form of question that prompts a respondent to answer in more than one or two words.

operating bed   Table for surgery.

operating room   (1) Room in a health care facility in which surgical procedures requiring anesthesia are performed. (2) Informal: a suite of rooms or an area in a health care facility in which patients are prepared for surgery, undergo surgical procedures, and recover from the anesthetic procedures required for the surgery.

ophthalmic   Drugs given into the eye in the form of either eye drops or ointments.

ophthalmoscope   Instrument used to illuminate the structures of the eye to examine the fundus, which includes the retina, choroid, optic nerve disc, macula, fovea centralis, and retinal vessels.

opioid   Drug substance derived from opium or produced synthetically that alters perception of pain and that, with repeated use, may result in physical and psychological dependence (narcotic).

oral hygiene   Condition or practice of maintaining the tissues and structures of the mouth.

orthopnea   Abnormal condition in which a person must sit or stand to breathe comfortably.

orthostatic hypotension   Abnormally low blood pressure occurring when a person stands.

osmolality   Concentration or osmotic pressure of a solution expressed in osmoles or milliosmoles per kilogram of water.

osmolarity   Osmotic pressure of a solution expressed in osmoles or milliosmoles per kilogram of the solution.

osmoreceptors   Neurons in the hypothalamus that are sensitive to the fluid concentration in the blood plasma and regulate the secretion of antidiuretic hormone.

osmosis   Movement of a pure solvent through a semipermeable membrane from a solution with a lower solute concentration to one with a higher solute concentration.

osmotic pressure   Drawing power for water, which depends on the number of molecules in the solution.

osteoporosis   Disorder characterized by abnormal rarefaction of bone, occurring most frequently in postmenopausal women, sedentary or immobilized individuals, and patients on long-term steroid therapy.

ostomy   Surgical procedure in which an opening is made into the abdominal wall to allow the passage of intestinal contents from the bowel (colostomy) or urine from the bladder (urostomy).

otoscope   Instrument with a special ear speculum used to examine the deeper structures of the external and middle ear.

ototoxic   Having a harmful effect on the eighth cranial (auditory) nerve or the organs of hearing and balance.

outcome   Condition of a patient at the end of treatment, including the degree of wellness and the need for continuing care, medication, support, counseling, or education.

outliers   Patients with extended lengths of stay beyond allowable inpatient days or costs.

outpatient   Patient who has not been admitted to a hospital but receives treatments in a clinic or facility associated with the hospital.

oxygen desaturation   A decrease in oxygen concentration in the blood resulting from any condition that affects the exchange of carbon dioxide and oxygen.

oxygen saturation   Amount of hemoglobin fully saturated with oxygen, given as a percent value.

oxygen therapy   Procedure in which oxygen is administered to a patient to relieve or prevent hypoxia.

P

pain   Subjective, unpleasant sensation caused by noxious stimulation of sensory nerve endings.

palliative care   Level of care that is designed to relieve or reduce intensity of uncomfortable symptoms but not to produce a cure. Palliative care relies on comfort measures and use of alternative therapies to help individuals become more at peace during end of life.

pallor   Unnatural paleness or absence of color in the skin.

palpation   Method of physical examination whereby the fingers or hands of the examiner are applied to the patient's body to feel body parts underlying the skin.

palpitations   Bounding or racing of the heart associated with normal emotions or a heart disorder.

Papanicolaou (Pap) smear   Painless screening test for cervical cancer. Specimens are taken of squamous and columnar cells of the cervix.

parallel play   Form of play among a group of children, primarily toddlers, in which each one engages in an independent activity that is similar to but not influenced by or shared with the others.

paralytic ileus   Usually temporary paralysis of intestinal wall that may occur after abdominal surgery or peritoneal injury and that causes cessation of peristalsis; leads to abdominal distention and symptoms of obstruction.

parenteral administration   Giving medication by a route other than the gastrointestinal tract.

parenteral nutrition (PN)   Administration of a nutritional solution into the vascular system.

parteras   Lay midwives.

partial bed bath   Bath in which body parts that might cause the patient discomfort if left unbathed (i.e., face, hands, axillary areas, back, and perineum) are washed in bed.

passive range-of-motion (PROM) exercises   Range of movement through which a joint is moved with assistance.

passive strategies of health promotion   Activities that involve the patient as the recipient of actions by health care professionals.

pathogenicity   Ability of a pathogenic agent to produce a disease.

pathogens   Microorganisms capable of producing disease.

pathological fractures   Fractures resulting from weakened bone tissue; frequently caused by osteoporosis or neoplasms.

patient-centered care   Concept to improve work efficiency by changing the way that patient care is delivered.

patient-and-family-centered care   Model of nursing care in which mutual partnerships between the patient, family and health care team are formed to plan, implement and evaluate the nursing and health care delivered.

patient-controlled analgesia (PCA)   Drug delivery system that allows patients to self-administer analgesic medications on demand.

patrilineal, patrilineally   Kinship that is limited to only the father's side.

pay for performance   Quality improvement program that rewards excellence through financial incentives to motivate change to achieve measurable improvements and improve patient care quality and safety.

perceived loss   Loss that is less obvious to the individual experiencing it. Although easily overlooked or misunderstood, a perceived loss results in the same grief process as an actual loss.

perception   Peoples' mental image or concept of elements in their environment, including information gained through the senses.

percussion   Method of physical examination whereby the location, size, and density of a body part is determined by the tone obtained from the striking of short, sharp taps of the fingers.

perfusion   (1) Passage of a fluid through a specific organ or an area of the body. (2) Therapeutic measure whereby a drug intended for an isolated part of the body is introduced via the bloodstream. (3) Relates to the ability of the cardiovascular system to pump oxygenated blood to the tissues and return deoxygenated blood to the lungs.

perineal care Procedure prescribed for cleaning the genital and anal areas as part of the daily bath or after various obstetrical and gynecological procedures.

perioperative nursing Refers to the role of the operating room nurse during the preoperative, intraoperative, and postoperative phases of surgery.

peripherally inserted central catheter (PICC) Alternative intravenous access when the patient requires intermediate-length venous access greater than 7 days to 3 months. Intravenous access is achieved by inserting a catheter into a central vein by way of a peripheral vein.

peristalsis Rhythmical contractions of the intestine that propel gastric contents through the length of the gastrointestinal tract.

peritonitis Inflammation of the peritoneum produced by bacteria or irritating substances introduced into the abdominal cavity by a penetrating wound or perforation of an organ in the gastrointestinal or reproductive tract.

PERRLA Acronym for "pupils equal, round, reactive to light, accommodation"; the acronym is recorded in the physical examination if eye and pupil assessments are normal.

personalismo Personalistic.

petechiae Tiny purple or red spots that appear on skin as minute hemorrhages within dermal layers.

pharmacokinetics Study of how drugs enter the body, reach their site of action, are metabolized, and exit from the body.

phlebitis Inflammation of a vein.

physician-initiated interventions Based on the physician's response to a medical diagnosis, the nurse responds to his or her written orders.

PIE note Problem-oriented medical record; the four interdisciplinary sections are the database, problem list, care plan, and progress notes.

placebos Dosage form that contains no pharmacologically active ingredients but may relieve pain through psychological effects.

plaintiff Individual who files formal charges against an individual or organization for a legal offense.

planning Process of designing interventions to achieve the goals and outcomes of health care delivery.

plantar flexion Toe-down motion of the foot at the ankle.

pleural friction rub Adventitious lung sound caused by inflamed parietal and visceral pleura rubbing together on inspiration.

pneumothorax Collection of air or gas in the pleural space.

point of maximal impulse (PMI) Point where the heartbeat can most easily be palpated through the chest wall. This is usually the fourth intercostal space at the midclavicular line.

point of view Way of looking at issues that reflects an individual's culture and societal influences.

poison Any substance that impairs health or destroys life when ingested, inhaled, or absorbed by the body in relatively small amounts.

poison control center One of a network of facilities that provides information regarding all aspects of poisoning or intoxication, maintains records of their occurrence, and refers patients to treatment centers.

polypharmacy Use of a number of different drugs by a patient who may have one or several health problems.

polyunsaturated fatty acid Fatty acid that has two or more carbon double bonds.

population Collection of individuals who have in common one or more personal or environmental characteristics.

positive health behaviors Activities related to maintaining, attaining, or regaining good health and preventing illness. Common positive health behaviors include immunizations, proper sleep patterns, adequate exercise, and nutrition.

postanesthesia care unit (PACU) Area adjoining the operating room to which surgical patients are taken while still under anesthesia.

postmortem care Care of a patient's body after death.

postural drainage Use of positioning along with percussion and vibration to drain secretions from specific segments of the lungs and bronchi into the trachea.

postural hypotension Abnormally low blood pressure occurring when an individual assumes the standing posture; also called orthostatic hypotension.

posture Position of the body in relation to the surrounding space.

power of attorney for health care Person designated by the patient to make health care decisions for the patient if the patient becomes unable to make his or her own decisions.

preadolescence Transitional developmental stage that occurs between childhood and adolescence.

preanesthesia care unit Area outside the operating room where preoperative preparations are completed.

preload Volume of blood in the ventricles at the end of diastole, immediately before ventricular contraction.

preoperative teaching Instruction regarding a patient's anticipated surgery and recovery that is given before surgery. Instruction includes, but is not limited to, dietary and activity restrictions, anticipated assessment activities, postoperative procedures, and pain-relief measures.

presbycusis Hearing loss associated with aging. It usually involves both a loss of hearing sensitivity and a reduction in the clarity of speech.

presbyopia Gradual decline in ability of the lens to accommodate or focus on close objects; reduces ability to see near objects clearly. This condition commonly develops with advancing age.

prescriptions Written directions for a therapeutic agent (e.g., medication, drugs).

presence Deep physical, psychological, and spiritual connection or engagement between a nurse and patient.

present time orientation Time dimension that focuses on what is happening here and now. Communication patterns are circular, and this time orientation is in conflict with the dominant organizational norm in health care that emphasizes punctuality and adherence to appointments.

pressure ulcer Inflammation, sore, or ulcer in the skin over a bony prominence.

presurgical care unit (PSCU) Area outside the operating room where preoperative preparations are completed.

preventive nursing actions Nursing actions directed toward preventing illness and promoting health to avoid the need for primary, secondary, or tertiary health care.

primary appraisal Evaluating an event for its personal meaning related to stress.

primary care First contact in a given episode of illness that leads to a decision regarding a course of action to resolve the health problem.

primary health care Combination of primary and public health care that is accessible to individuals and families in a community and provided at an affordable cost.

primary intention Primary union of the edges of a wound, progressing to complete scar formation without granulation.

primary nursing Method of nursing practice in which the patient's care is managed for the duration by one nurse who directs and coordinates other nurses and health care personnel. When on duty, the primary nurse cares for the patient directly.

primary prevention First contact in a given episode of illness that leads to a decision regarding a course of action to prevent worsening of the health problem.

problem focused diagnosis A clinical judgment concerning an undesirable human response to a health condition/life process that exists in an individual, family, or community.

problem identification One of the steps of the diagnostic process in which the patient's health care problem is recognized as a result of data analysis based on professional knowledge and experience.

problem solving Methodical, systematic approach to explore conditions and develop solutions, including analysis of data, determination of causative factors, and selection of appropriate actions to reverse or eliminate the problem.

problem-oriented medical record (POMR) Method of recording data about the health status of a patient that fosters a collaborative problem-solving approach by all members of the health care team.

productive cough Sudden expulsion of air from the lungs that effectively removes sputum from the respiratory tract and helps clear the airways.

professional standards review organization (PSRO) Focuses on evaluation of nursing care provided in a health care setting. The quality, effectiveness, and appropriateness of nursing care for the patient are the focus of evaluation.

prone Position of the patient lying face down.

proprioception Ability of the body to sense its position and movement in space.

prospective payment system (PPS) Payment mechanism for reimbursing hospitals for

inpatient health care services in which a pre-determined rate is set for treatment of specific illnesses.

prostaglandins   Potent hormonelike substances that act in exceedingly low doses on target organs. They can be used to treat asthma and gastric hyperacidity.

proteins   Any of a large group of naturally occurring, complex, organic nitrogenous compounds. Each is composed of large combinations of amino acids containing the elements carbon; hydrogen; nitrogen; oxygen; usually sulfur; and occasionally phosphorus, iron, iodine, or other essential constituents of living cells. Protein is the major source of building material for muscles, blood, skin, hair, nails, and the internal organs.

proteinuria   Presence in the urine of abnormally large quantities of protein, usually albumin. Persistent proteinuria is usually a sign of renal disease or renal complications of another disease, hypertension, or heart failure.

protocol   Written and approved plan specifying the procedures to be followed during an assessment or in providing treatment.

pruritus   Symptom of itching; an uncomfortable sensation leading to the urge to scratch.

psychomotor learning   Acquisition of ability to perform motor skills.

ptosis   Abnormal condition of one or both upper eyelids in which the eyelid droops; caused by weakness of the levator muscle or paralysis of the third cranial nerve.

puberty   Developmental period of emotional and physical changes, including the development of secondary sex characteristics and the onset of menstruation and ejaculation.

public health nursing   Nursing specialty that requires the nurse to care for the needs of populations or groups.

public communication   Interaction of one individual with large groups of people.

pulmonary hygiene   More frequent turning, deep breathing, coughing, use of incentive spirometry, and chest physical therapy (PT) if ordered.

pulse deficit   Condition that exists when the radial pulse is less than the ventricular rate as auscultated at the apex or seen on an electrocardiogram. The condition indicates a lack of peripheral perfusion for some of the heart contractions.

pulse pressure   Difference between the systolic and diastolic pressures, normally 30 to 40 mm Hg.

Purkinje network   Complex network of muscle fibers that spread through the right and left ventricles of the heart and carry the impulses that contract those chambers almost simultaneously.

pursed-lip breathing   Deep inspiration followed by prolonged expiration through pursed lips.

pyrexia   Abnormal elevation of the temperature of the body above 37° C (98.6° F) because of disease; same as fever.

pyrogens   Substances that cause a rise in body temperature, as in the case of bacterial toxins.

Q

QSEN   The Quality and Safety in the Education of Nurses (QSEN) initiative is the commitment of nursing to the competencies outlined in the Institute of Medicine report related to nursing education. QSEN encompasses six competencies: patient-centered care, teamwork, collaboration, evidence-based practice, quality improvement, and safety.

quality improvement   Monitoring and evaluation of processes and outcomes in health care or any other business to identify opportunities for improvement.

quality indicator   Quantitative measure of an important aspect of care that determines whether quality of service conforms to requirements or standards of care.

R

race   Common biological characteristics shared by a group of people.

Ramadan   Religious observance held during the ninth month of the Islamic calendar year. It involves fasting from sunrise to sunset.

range of motion (ROM)   Range of movement of a joint from maximum extension to maximum flexion as measured in degrees of a circle.

rapid eye movement (REM) sleep   Stage of sleep in which dreaming and rapid eye movements are prominent; important for mental restoration.

reaction   Component of the pain experience that may include both physiological responses such as in the general adaptation syndrome and behavioral responses.

reality orientation   Therapeutic modality for restoring an individual's sense of the present.

receiver   Person to whom message is sent during the communication process.

reception   Neurophysiological components of the pain experience in which nervous system receptors receive painful stimuli and transmit them through peripheral nerves to the spinal cord and brain.

record   Written form of communication that permanently documents information relevant to health care management.

recovery   Period of time immediately following surgery when the patient is closely observed for effects of anesthesia, changes in vital signs, and bleeding. The area is usually in the postanesthesia care unit.

referent   Factor that motivates a person to communicate with another individual.

reflection   Process of thinking back or recalling an event to discover the meaning and purpose of that event. Useful in critical thinking.

refractive error   Defect in the ability of the lens of the eye to focus light such as occurs in nearsightedness and farsightedness.

regional anesthesia   Loss of sensation in an area of the body supplied by sensory nerve pathways.

registered nurse (RN)   In the United States a nurse who has completed a course of study at a state-approved, accredited school of nursing

and has passed the National Council Licensure Examination (NCLEX-RN).

regression   Return to an earlier developmental stage or behavior.

regulatory agencies   Local, state, provincial, or national agencies that inspect and certify health care agencies as meeting specified standards. These agencies can also determine the amount of reimbursement for health care delivered.

rehabilitation   Restoration of an individual to normal or near-normal function after a physical or mental illness, injury, or chemical addiction.

reinforcement   Provision of a contingent response to a learner's behavior that increases the probability of recurrence of the behavior.

related factor   Any condition or event that accompanies or is linked with the patient's health care problem.

relaxation   Act of being relaxed or less tense.

reminiscence   Recalling the past to assign new meaning to past experiences.

remissions   Partial or complete disappearances of the clinical and subjective characteristics of chronic or malignant disease; remission may be spontaneous or the result of therapy.

renal calculi   Calcium stones in the renal pelvis.

renin   Proteolytic enzyme produced by and stored in the juxtaglomerular apparatus that surrounds each arteriole as it enters a glomerulus. The enzyme affects the blood pressure by catalyzing the change of angiotensinogen to angiotensin, a strong repressor.

reorganization   Last phase of Bowlby's phases of mourning. During this phase, which sometimes requires a year or more, the person begins to accept unaccustomed roles, acquire new skills, and build new relationships.

reports   Transfer of information from the nurses on one shift to the nurses on the following shift. Report may also be given by one of the members of the nursing team to another health care provider (e.g., a physician or therapist).

reservoir   Place where microorganisms survive, multiply, and await transfer to a susceptible host.

residual urine   Volume of urine remaining in the bladder after a normal voiding; the bladder normally is almost completely empty after micturition.

resistance stage   Third stage of the stress response, when the person attempts to adapt to the stressor. The body stabilizes; hormone levels stabilize; and heart rate, blood pressure, and cardiac output return to normal.

resource utilization group (RUG)   Method of classification for health care reimbursement for long-term care facilities.

respeto   Respectful.

respiration   Exchange of oxygen and carbon dioxide during cellular metabolism.

respiratory acidosis   Abnormal condition characterized by increased arterial carbon dioxide concentration, excess carbonic acid, and increased hydrogen ion concentration.

respiratory alkalosis   Abnormal condition characterized by decreased arterial carbon dioxide concentration and hydrogen ion concentration.

respite care Short-term health services to dependent older adults either in their home or in an institutional setting.

responsibility Carrying out duties associated with a particular role.

restorative care Health care settings and services in which patients who are recovering from illness or disability receive rehabilitation and supportive care.

restraint Device to aid in the immobilization of a patient or patient's extremity.

return demonstration Demonstration after the patient has first observed the teacher and then practiced the skill in mock or real situations.

rhonchi Abnormal lung sound auscultated when the patient's airways are obstructed with thick secretions.

right-sided heart failure Abnormal condition that results from impaired functioning of the right ventricle; characterized by venous congestion in the systemic circulation.

risk factor Any internal or external variable that makes a person or group more vulnerable to illness or an unhealthy event.

risk management Function of hospital or other health facility administration that is directed toward identification, evaluation, and correction of potential risks that could lead to injury of patients, staff members, or visitors and result in property loss or damage.

risk nursing diagnosis A clinical judgment concerning the vulnerability of an individual, family, group or community for developing an undesirable human response to health conditions/life processes.

role performance Way in which a person views his or her ability to carry out significant roles.

root cause analysis Process of data collection and analysis that aids in finding the real cause of the problem and working on dealing with it rather than just dealing with its effects.

S

Sabbath From sundown on Friday to sundown on Saturday, this religious observance is a day of rest and worship for Jews and some Christian sects.

sandbags Sand-filled plastic tubes that can be shaped to body contours. They can immobilize an extremity or maintain body alignment.

saturated fatty acid Fatty acid in which each carbon in the chain has an attached hydrogen atom.

scientific method Codified sequence of steps used in the formulation, testing, evaluation, and reporting of scientific ideas.

scientific rationale Reason why a specific nursing action was chosen based on supporting literature.

scoliosis Lateral spinal curvature.

scrub nurse Registered nurse or operating room technician who assists surgeons during operations.

secondary appraisal Evaluating one's possible coping strategies when confronted with a stressor.

secondary intention Wound closure in which the edges are separated; granulation tissue develops to fill the gap; and, finally, epithelium grows in over the granulation, producing a larger scar than results with primary intention.

secondary prevention Level of preventive medicine that focuses on early diagnosis, use of referral services, and rapid initiation of treatment to stop the progress of disease processes.

sedatives Medications that produce a calming effect by decreasing functional activity, diminishing irritability, and allaying excitement.

segmentation Alternating contraction and relaxation of gastrointestinal mucosa.

self-concept Complex, dynamic integration of conscious and unconscious feelings, attitudes, and perceptions about one's identity, physical being, worth, and roles; how a person perceives and defines self.

self-esteem Feeling of self-worth characterized by feelings of achievement, adequacy, self-confidence, and usefulness.

self-transcendence Sense of authentically connecting to one's inner self.

sender Person who initiates interpersonal communication by conveying a message.

sensible water loss Loss of fluid from the body through the secretory activity of the sweat glands and the exhalation of humidified air from the lungs.

sensory deficits Defects in the function of one or more of the senses, resulting in visual, auditory, or olfactory impairments.

sensory deprivation State in which stimulation to one or more of the senses is lacking, resulting in impaired sensory perception.

sensory overload State in which stimulation to one or more of the senses is so excessive that the brain disregards or does not meaningfully respond to stimuli.

sequential compression stockings Plastic stockings attached to an air pump that inflates and deflates the stockings, applying intermittent pressure sequentially from the ankle to the knee.

serum half-life Time needed for excretion processes to lower the serum drug concentration by half.

sexual dysfunction Inability or difficulty in sexual functioning caused by physiological or psychological factors or both.

sexual orientation Clear, persistent erotic preference for a person of one sex or the other.

sexuality "A function of the total personality … concerned with the biological, psychological, sociological, spiritual and culture variables of life …" (Sex Information and Education Council of the United States, 1980).

sexually transmitted infection Infectious process spread through sexual contact, including oral, genital, or anal sexual activity.

shear Force exerted against the skin while the skin remains stationary and the bony structures move.

side effect Any reaction or consequence that results from medication or therapy.

side rails Bars positioned along the sides of the length of the bed or stretcher to reduce the patient's risk of falling.

simpatia Friendly.

sinoatrial (SA) node Called the *pacemaker of the heart* because the origin of the normal heartbeat begins at the SA node. The SA node is in the right atrium next to the entrance of the superior vena cava.

situational crisis Unexpected crisis that arises suddenly in response to an external event or a conflict concerning a specific circumstance.

situational loss Loss of a person, thing, or quality resulting from a change in a life situation, including changes related to illness, body image, environment, and death.

sitz bath Bath in which only the hips or buttocks are immersed in fluid.

skilled nursing facility Institution or part of an institution that meets criteria for accreditation established by the sections of the Social Security Act that determine the basis for Medicaid and Medicare reimbursement for skilled nursing care, including rehabilitation and various medical and nursing procedures.

sleep State marked by reduced consciousness, diminished activity of the skeletal muscles, and depressed metabolism.

sleep apnea Cessation of breathing for a time during sleep.

sleep deprivation Condition resulting from a decrease in the amount, quality, and consistency of sleep.

SOAP note Progress note that focuses on a single patient problem and includes subjective and objective data, analysis, and planning; most often used in the problem-oriented medical record (POMR).

social determinants of health Factors that contribute to a person's current state of health. These factors may be biological, socioeconomic, psychosocial, behavioral, or social in nature.

socializing Interacting with friends or other people; communicating with others to form relationships and help people feel relaxed.

solute Substance dissolved in a solution.

solution Mixture of one or more substances dissolved in another substance. The molecules of each of the substances disperse homogeneously and do not change chemically. A solution may be a liquid, gas, or solid.

solvent Any liquid in which another substance can be dissolved.

source record Organization of a patient's chart so each discipline (e.g., nursing, medicine, social work, or respiratory therapy) has a separate section in which to record data. Unlike POMR, the information is not organized by patient problems. The advantage of a source record is that caregivers can easily locate the proper section of the record in which to make entries.

sphygmomanometer Device for measuring the arterial blood pressure that consists of an arm or leg cuff with an air bladder connected to a tube, a bulb for pumping air into the bladder, and a gauge for indicating the amount of air pressure being exerted against the artery.

spiritual distress   State of being out of harmony with a system of beliefs, a Supreme Being, or God.

spiritual well-being   Individual's spirituality that enables a person to love, have faith and hope, seek meaning in life, and nurture relationships with others.

spirituality   Spiritual dimension of a person, including the relationship with humanity, nature, and a supreme being.

standard of care   Minimum level of care accepted to ensure high-quality care to patients. Standards of care define the types of therapies typically administered to patients with defined problems or needs.

standard precautions   Guidelines recommended by the Centers for Disease Control and Prevention (CDC) to reduce risk of transmission of bloodborne and other pathogens in hospitals.

standardized care plans   Written care plans used for groups of patients who have similar health care problems.

standing order   Written and approved documents containing rules, policies, procedures, regulations, and orders for the conduct of patient care in various stipulated clinical settings.

statutory law   Of or related to laws enacted by a legislative branch of the government.

stenosis   Abnormal condition characterized by the constriction or narrowing of an opening or passageway in a body structure.

stereotypes   Generalizations that are made about individuals without further assessment.

sterilization   (1) Rendering a person unable to produce children; accomplished by surgical, chemical, or other means. (2) A technique for destroying microorganisms using heat, water, chemicals, or gases.

stoma   Artificially created opening between a body cavity and the surface of the body (e.g., a colostomy formed from a portion of the colon pulled through the abdominal wall).

stress   Physiological or psychological tension that threatens homeostasis or a person's psychological equilibrium.

stressor   Any event, situation, or other stimulus encountered in a person's external or internal environment that necessitates change or adaptation by the person.

striae   Streaks or linear scars that result from rapid development of tension in the skin.

stroke volume (SV)   Amount of blood ejected by the ventricles with each contraction. It can be affected by the amount of blood in the left ventricle at the end of diastole (preload), the resistance to left ventricular ejection (afterload), and myocardial contractility.

subacute care   Level of medical specialty care provided to patients who need a greater intensity of care than that provided in a skilled nursing facility but who do not require acute care.

subcultures   Various ethnic, religious, and other groups with distinct characteristics from the dominant culture.

subcutaneous (sub-Q)   Injection given into the connective tissue under the dermis. The subcutaneous tissue absorbs drugs more slowly than those injected into muscle. Injections are usually given at a 45-degree angle.

subjective data   Information gathered from patient statements; the patient's feelings and perceptions. Not verifiable by another except by inference.

sublingual   Route of medication administration in which the medication is placed underneath the patient's tongue.

Sunrise Model   A model developed by Leininger that aids the health care practitioner in designing care decisions and actions in a culturally congruent fashion.

supine   Position of the patient in which the patient is resting on his or her back.

suprainfection   Secondary infection usually caused by an opportunistic pathogen.

suprapubic catheter   Catheter surgically inserted through abdomen into bladder.

surfactant   Chemical produced in the lungs to maintain the surface tension of the alveoli and keep them from collapsing.

surgical asepsis   Procedures used to eliminate any microorganisms from an area. Also called *sterile technique*.

sympathy   Concern, sorrow, or pity felt by the nurse for the patient. Sympathy is a subjective look at another person's world that prevents a clear perspective of all sides of the issues confronting that person.

synapse   Region surrounding the point of contact between two neurons or between a neuron and an effector organ.

syncope   Brief lapse in consciousness caused by transient cerebral hypoxia.

synergistic effect   Effect resulting from two drugs acting synergistically. The effect of the two drugs combined is greater than the effect that would be expected if the individual effects of the two drugs acting alone were added together.

systolic   Pertaining to or resulting from ventricular contraction.

T

tachycardia   Rapid regular heart rate ranging between 100 and 150 beats/min.

tachypnea   Abnormally rapid rate of breathing.

tactile   Relating to the sense of touch.

tactile fremitus   Tremulous vibration of the chest wall during breathing that is palpable on physical examination.

teaching   Implementation method used to present correct principles, procedures, and techniques of health care; to inform patients about their health status; and to refer patients and family to appropriate health or social resources in the community.

team nursing   Decentralized system in which the care of a patient is distributed among the members of a team. The charge nurse delegates authority to a team leader, who must be a professional nurse.

teratogens   Chemical or physiological agents that may produce adverse effects in the embryo or fetus.

tertiary prevention   Activities directed toward rehabilitation rather than diagnosis and treatment.

therapeutic communication   Process in which the nurse consciously influences a patient or helps the patient to a better understanding through verbal and/or nonverbal communication.

therapeutic effect   Desired benefit of a medication, treatment, or procedure.

thermoregulation   Internal control of body temperature.

threshold   Point at which a person first perceives a painful stimulus as being painful.

thrill   Continuous palpable sensation like the purring of a cat.

thrombus   Accumulation of platelets, fibrin, clotting factors, and the cellular elements of the blood attached to the interior wall of a vein or artery, sometimes occluding the lumen of the vessel.

tinnitus   Ringing heard in one or both ears.

tissue ischemia   Point at which tissues receive insufficient oxygen and perfusion.

tolerance   Point at which a person is not willing to accept pain of greater severity or duration.

tort   Act that causes injury for which the injured party can bring civil action.

total patient care   Nursing delivery of care model originally developed during Florence Nightingale's time. In the model a registered nurse (RN) is responsible for all aspects of care for one or more patients. The RN works directly with the patient, family, physician or health care provider, and health care team members. The model typically has a shift-based focus.

touch   To come in contact with another person, often conveying caring, emotional support, encouragement, or tenderness.

toxic effect   Effect of a medication that results in an adverse response.

tracheostomy   Procedure whereby a surgical incision is made into the trachea and a short artificial airway (a tracheostomy tube) is inserted.

transcendence   The belief that there is a force outside of and greater than the person that exists beyond the material world.

transcultural   Concept of care extending across cultures that distinguishes nursing from other health disciplines.

transcultural nursing   Distinct discipline developed by Leininger that focuses on the comparative study of cultures to understand similarities and differences among groups of people.

transcutaneous electrical nerve stimulation (TENS)   Technique in which a battery-powered device blocks pain impulses from reaching the spinal cord by delivering weak electrical impulses directly to the surface of the skin.

transdermal disk   Medication delivery device in which the medication is saturated on a wafer-like disk, which is affixed to the patient's skin. This method ensures that the patient receives a continuous level of medication.

transfer report Verbal exchange of information between caregivers when a patient is moved from one nursing unit or health care setting to another. The report includes information necessary to maintain a consistent level of care from one setting to another.

transformational leadership A leadership style that focuses on change and innovation through effective communication and team building. Engagement, empowerment, and accountability are critical to team effectiveness.

transfusion reaction Systemic response by the body to the administration of blood incompatible with that of the recipient.

trapeze bar Metal triangular-shaped bar that can be suspended over a patient's bed from an overhanging frame; permits patients to move up and down in bed while in traction or some other encumbrance.

trimester Referring to one of the three phases of pregnancy.

trochanter roll Rolled towel support placed against the hips and upper leg to prevent external rotation of the legs.

trough The lowest serum concentration of a medication before the next medication dose is administered.

turgor Normal resiliency of the skin caused by the outward pressure of the cells and interstitial fluid.

U

unsaturated fatty acid Fatty acid in which an unequal number of hydrogen atoms are attached and the carbon atoms attach to one another with a double bond.

ureterostomy Diversion of urine away from a diseased or defective bladder through an artificial opening in the skin.

urge incontinence A type of urinary incontinence that results from sudden, involuntary contraction of the muscles of the urinary bladder, resulting in an urge to urinate.

urinal Receptacle for collecting urine.

urinary diversion Surgical diversion of the drainage of urine such as a ureterostomy.

urinary incontinence Inability to control urination.

urinary reflux Abnormal, backward flow of urine.

urinary retention Retention of urine in the bladder; condition frequently caused by a temporary loss of muscle function.

urine hat Receptacle for collecting urine that fits toilet.

urometer Device for measuring frequent and small amounts of urine from an indwelling urinary catheter system.

urosepsis Organisms in the bloodstream.

utilitarianism Ethic that proposes that the value of something is determined by its usefulness. The greatest good for the greatest number of people constitutes the guiding principle for action in a utilitarian model of ethics.

utilization review (UR) committees Physician-supervised committees to review admissions, diagnostic testing, and treatments provided by physicians or health care providers to patients.

V

validation Act of confirming, verifying, or corroborating the accuracy of assessment data or the appropriateness of the care plan.

Valsalva maneuver Any forced expiratory effort against a closed airway such as when an individual holds his or her breath and tightens his or her muscles in a concerted, strenuous effort to move a heavy object or change positions in bed.

value Personal belief about the worth of a given idea or behavior.

valvular heart disease Acquired or congenital disorder of a cardiac valve characterized by stenosis and obstructed blood flow or valvular degeneration and regurgitation of blood.

variances Unexpected event that occurs during patient care and that is different from CareMap predictions. Variances or exceptions are interventions or outcomes that are not achieved as anticipated. Variance may be positive or negative.

variant Differing from a set standard.

vascular access devices Catheters, cannulas, or infusion ports designed for long-term, repeated access to the vascular system.

vasoconstriction Narrowing of the lumen of any blood vessel, especially the arterioles and the veins in the blood reservoirs of the skin and abdominal viscera.

vasodilation Increase in the diameter of a blood vessel caused by inhibition of its vasoconstrictor nerves or stimulation of dilator nerves.

venipuncture Technique in which a vein is punctured transcutaneously by a sharp rigid stylet (e.g., a butterfly needle), a cannula (e.g., an angiocatheter that contains a flexible plastic catheter), or a needle attached to a syringe.

ventilation Respiratory process by which gases are moved into and out of the lungs.

verbal communication Sending of messages from one individual to another or to a group of individuals through the spoken word.

vertigo Sensation of dizziness or spinning.

vibration Fine, shaking pressure applied by hands to the chest wall only during exhalation.

virulence Ability of an organism to rapidly produce disease.

visual Related to or experienced through vision.

vital signs Temperature, pulse, respirations, and blood pressure.

vitamins Organic compounds essential in small quantities for normal physiological and metabolic functioning of the body. With few exceptions, vitamins cannot be synthesized by the body and must be obtained from the diet or dietary supplements.

voiding Process of urinating.

vulnerable populations Collection of individuals who are more likely to develop health problems as a result of excess risks, limits in access to health care services, or being dependent on others for care.

W

wellness Dynamic state of health in which an individual progresses toward a higher level of functioning, achieving an optimum balance between internal and external environments.

wellness education Activities that teach people how to care for themselves in a healthy manner.

wellness nursing diagnosis Clinical judgment about an individual, group, or community in transition from a specific level of wellness to a higher level of wellness.

wheezes, wheezing Adventitious lung sounds caused by a severely narrowed bronchus.

work redesign Formal process used to analyze the work of a certain work group and change the actual structure of the jobs performed.

worldview Cognitive stance or perspective about phenomena characteristic of a particular cultural group.

wound culture Specimen collected from a wound to determine the specific organism that is causing an infectious process.

Y

yearning and searching Second phase of Bowlby's phases of mourning. It is characterized by emotional outbursts of tearful sobbing and acute distress.

Z

Z-track injection Technique for injecting irritating preparations into muscle without tracking residual medication through sensitive tissues.
