People face situations in everyday life that evoke the **stress response** (see Chapter 38). The mind varies the biochemical functions of the major organ systems in response to feedback. Thoughts and feelings influence the production of chemicals (i.e., neurotransmitters, neurohormones, and peptides) that circulate throughout the body and convey messages via cells to various systems within the body. The stress response is a good example of the way in which systems cooperate to protect an individual from harm. Physiologically the cascade of changes associated with the stress response causes increased heart and respiratory rates; tightened muscles; increased metabolic rate; and a general sense of foreboding, fear, nervousness, irritability, and negative mood. Other physiological responses include elevated blood pressure; dilated pupils; stronger cardiac contractions; and increased levels of blood glucose, serum cholesterol, circulating free fatty acids, and triglycerides. Although these responses prepare a person for short-term stress, the effects on the body of long-term stress sometimes include structural damage and chronic illness such as angina, tension headaches, cardiac arrhythmias, pain, ulcers, and atrophy of the immune system organs (Kreitzer and Koithan, 2014).

The **relaxation response** is the state of generalized decreased cognitive, physiological, and/or behavioral arousal. Relaxation also involves arousal reduction. The process of relaxation elongates the muscle fibers, reduces the neural impulses sent to the brain, and thus decreases the activity of the brain and other body systems. Decreased heart and respiratory rates, blood pressure, and oxygen consumption and increased alpha brain activity and peripheral skin temperature characterize the relaxation response. It occurs through a variety of techniques that incorporate a repetitive mental focus and the adoption of a calm, peaceful attitude (Lindquist et al., 2014).

Relaxation helps individuals develop cognitive skills to reduce the negative ways in which they respond to situations within their environment. Cognitive skills include the following:

- Focusing (the ability to identify, differentiate, maintain attention on, and return attention to simple stimuli for an extended period)
- Passivity (the ability to stop unnecessary goal-directed and analytic activity)
- Receptivity (the ability to tolerate and accept experiences that are uncertain, unfamiliar, or paradoxical).

The long-term goal of relaxation therapy is for people to continually monitor themselves for indicators of tension and consciously let go and release the tension contained in various body parts.

Progressive relaxation training teaches an individual how to effectively rest and reduce tension in the body. The person learns to detect subtle localized muscle tension sequentially, one muscle group at a time (e.g., the upper arm muscles, the forearm muscles). In doing so, an individual learns to differentiate between high-intensity tension, subtle tension, and relaxation, by practicing with different muscle groups (Dossey and Keegan, 2012). One active progressive relaxation technique involves the use of slow, deep abdominal breathing while tightening and relaxing an ordered succession of muscle groups, focusing on the associated bodily sensations while letting go of extraneous thoughts. Choose a logical order when guiding a patient through progressive relaxation. For example, begin with the muscles in the face, followed by those in the arms, hands, abdomen, legs, and feet; or begin with the feet and work up the body.

The goal of **passive relaxation** is to still the mind and body intentionally without the need to tighten and relax any particular body part. One effective passive relaxation technique incorporates slow, abdominal breathing exercises while imagining warmth and relaxation flowing through specific body parts such as the lungs or hands.

Clinical Applications of Relaxation Therapy. Research shows that relaxation techniques effectively lower blood pressure and heart rate, decrease muscle tension, improve well-being, and reduce symptom distress in people experiencing a variety of situations (e.g., complications from medical treatments, chronic illness, or loss of a significant other) (Bloch et al., 2010; Jones et al., 2013). Research also indicates that relaxation, alone or in combination with imagery, yoga (Figure 33-1), and music, reduces pain and anxiety while improving well-being (Nightingale et al., 2013; Weeks and Nilsson, 2011). Other benefits of relaxation include the reduction of hypertension (Nagele et al., 2014); depression (Jorm et al., 2008); and menopausal symptoms, including vasomotor responses, insomnia, mood, and musculoskeletal pain (Innes et al., 2010).

Relaxation enables individuals to exert control over their lives. Some experience a decreased feeling of helplessness and a more positive psychological state overall. Relaxation also reduces workplace stress on nursing units, often leading to improved staff satisfaction, staff relationships and communication, and workload perceptions (Clarke et al., 2009).

Limitations of Relaxation Therapy. During relaxation training individuals learn to differentiate between low and high levels of muscle tension. During the first months of training sessions, when the person is learning how to focus on body sensations and tensions, there are reports of increased sensitivity in detecting muscle tension. Usually these feelings are minor and resolve as the person continues with the training. However, be aware that on occasion some relaxation techniques result in continued intensification of symptoms or the development of altogether new symptoms (Dossey and Keegan, 2012).

An important consideration when choosing a relaxation technique is the physiological and psychological status of the individual. Some patients with chronic illness such as cancer seek relaxation training to reduce their stress response. However, techniques such as active progressive relaxation require a moderate expenditure of energy, which often increases fatigue and limits an individual's ability to complete relaxation sessions and practice. Therefore active progressive relaxation is not appropriate for patients with advanced disease or decreased energy reserves. Passive relaxation or guided imagery is more appropriate for these individuals.

Meditation and Breathing

Meditation is any activity that limits stimulus input by directing attention to a single unchanging or repetitive stimulus so the person is able to become more aware of self (Lindquist et al., 2014). It is a general term for a wide range of practices that involve relaxing the body and stilling the mind. The root word, *meditari,* means to consider or pay attention to something. Although meditation has its roots in eastern religious practices (Hindu, Buddhism, and Taoism), conventional health care practitioners began to recognize its healing potential in the early 1970s (Lindquist et al., 2014). The four components of meditation were identified by Benson (1975) as (1) a quiet space, (2) a comfortable position, (3) a receptive attitude, and (4) a focus of attention. Meditation is a process that anyone can use to calm down; cope with stress; and, for those with spiritual inclinations, feel one with God or the universe.

Meditation is different from relaxation; its purpose is to become "mindful," increasing our ability to live freely and escape destructive patterns of negativity. It is self-directed; it does not necessarily require a teacher and can be learned from books or audiotapes (Kabat-Zinn, 2011). Most meditation techniques involve slow, relaxed, deep, abdominal breathing that evokes a restful state, lowers oxygen consumption, reduces respiratory and heart rates, and reduces anxiety (Chiesa and Serretti, 2010).

Clinical Applications of Meditation. Several studies support the clinical benefits of meditation. For example, meditation reduces overall systolic and diastolic blood pressures and significantly reduces hypertensive risk (Nidich et al., 2009). It has also been shown to reduce relapses in alcohol treatment programs (Bowen et al., 2009). Patients with cancer who use mindfulness-based cognitive therapies often experience less depression, anxiety, and distress and report an improved quality of life (Musial et al., 2011). Patients suffering from post-traumatic stress disorders and chronic pain also benefit from mindfulness meditation (Kim et al., 2013). In addition, meditation increases productivity, improves mood, increases sense of identity, and lowers irritability (Dossey and Keegan, 2012).

Considerations for the appropriateness of meditation include a person's degree of self-discipline; it requires ongoing practice to achieve lasting results. Most meditation activities are easy to learn and do not require memorization or particular procedures. Patients typically find mindfulness and meditation self-reinforcing. The peaceful, positive mental state is usually pleasurable and provides an incentive for individuals to continue meditating.

FIGURE 33-1 Yoga is a discipline that focuses on muscles, posture, breathing, and consciousness.

Limitations of Meditation. Although meditation contributes to improvement in a variety of physiological and psychological ailments, it is contraindicated for some people. For example, a person who has a strong fear of losing control can perceive it as a form of mind control and thus will be resistant to learning the technique. Some individuals also become hypertensive during meditation and require a much shorter session than the average 15- to 20-minute session.

Meditation sometimes increases the effects of certain drugs. Therefore monitor individuals learning meditation closely for physiological changes with respect to their medications. Prolonged practice of meditation techniques sometimes reduces the need for antihypertensive, thyroid-regulating, and psychotropic medications (e.g., antidepressants and antianxiety agents). In these cases adjustment of the medication is necessary.

Imagery

Imagery or visualization is a mind-body therapy that uses the conscious mind to create mental images to stimulate physical changes in the body, improve perceived well-being, and/or enhance self-awareness. Frequently imagery, combined with some form of relaxation training, facilitates the effect of the relaxation technique. Imagery can be self-directed, in which individuals create their mental images, or guided, during which a practitioner leads an individual through a particular scenario (Lindquist et al., 2014). When guiding an imagery exercise, direct a patient to begin slow abdominal breathing while focusing on the rhythm of breathing. Then direct the patient to visualize a specific image such as ocean waves coming to shore, walking along a country road with birds chirping, or sitting by a running stream with each inspiration and receding with each exhalation. Next instruct the patient to take notice of the smells, sounds, and temperatures that he or she is experiencing. As the imagery session progresses, instruct the patient to visualize warmth entering the body during inspiration and tension leaving the body during exhalation.

Imagery often evokes powerful psychophysiological responses such as alterations in gastric secretions, body chemistry, blood flow, wound healing, and heart rate (Pincus and Sheikh, 2009). Most imagery techniques involve visual images; some also include auditory, proprioceptive, gustatory, and olfactory senses. An example of this involves visualizing a lemon being sliced in half and squeezing the lemon juice on the tongue. This visualization produces increased salivation as effectively as the actual event. Creative visualization is self-directed imagery based on the principle of mind-body connectivity (i.e., every mental image leads to physical or emotional changes) (Gawain, 2002). Box 33-2 lists teaching strategies for helping patients adopt creative visualization. People typically respond to their environment according to the way they perceive it and by their own visualizations and expectancies. Therefore you need to individualize imagery for each patient (Lindquist et al., 2014).

Clinical Applications of Imagery. You can use imagery in a number of pediatric and adult patient populations. For example, it helps control or relieve pain, decrease nightmares, and improve sleep (Pincus and Sheikh, 2009). It also aids in the treatment of chronic conditions such as asthma, cancer, sickle cell anemia, migraines, autoimmune disorders, atrial fibrillation, functional urinary disorders, menstrual and premenstrual syndromes, gastrointestinal disorders such as irritable bowel syndrome and ulcerative colitis, and rheumatoid arthritis (Lindquist et al., 2014).

Limitations of Imagery. Imagery is a behavioral intervention that has relatively few side effects (Roffe et al., 2005). Yet increased anxiety and fear sometimes occur when it is used to treat post-

---

BOX 33-2   PATIENT TEACHING
Creative Visualization

Objective
- The patient will demonstrate skills in creative visualization.

Teaching Strategies
- Set goals the patient can meet. Success achieves confidence and increased self-esteem.
- Create a clear image. Although it is sometimes difficult to develop a visual image, if the patient views the goals of the imagery with clear thoughts and in the present tense, he or she will be more successful in creating an effective image.
- Have the patient frequently visualize the image during relaxing states and throughout the day but particularly before bedtime or on wakening, when his or her mind usually is more relaxed.
- Have the patient repeat encouraging statements while focusing on the image. This alleviates any doubts about his or her ability to achieve established goals.

Evaluation
- Observe patient behaviors for presence of anxiety or increased discomfort.
- Ask patient to describe the helpfulness of the visualization experience.
- Ask how the patient is coping with daily stressors.

---

traumatic stress and social anxiety disorders (Cook et al., 2010). Some patients with chronic obstructive pulmonary disease (COPD) and asthma experience increased airway constriction when using guided imagery (Reed, 2007). Thus you need to monitor patients closely when beginning this therapy.

TRAINING-SPECIFIC THERAPIES

Training-specific therapies are CAM treatments that nurses administer only after completing a specific course of study and training. These therapies require postgraduate certificates or degrees indicating completion of additional education and training, national certification, or additional licensure beyond the registered nurse (RN) to practice and administer them. Several training-specific therapies (e.g., biofeedback and acupuncture) are very effective and often recommended by western health care practitioners (NIH/NCCIH, 2015b; Giggins et al., 2013). Although many of these complementary therapies elicit positive effects, all therapies carry some risk, particularly when used in conjunction with conventional medical therapies. Therefore you need advanced knowledge to talk about them effectively with patients and provide education about their safe use.

Biofeedback

Biofeedback is a mind-body technique that uses instruments to teach self-regulation and voluntary self-control over specific physiological responses. Electronic or electromechanical instruments measure, process, and provide information to patients about their muscle tension, cardiac activity, respiratory rates, brain-wave patterns, and autonomic nervous system activity. This feedback is given in physical, physiological, auditory, and/or visual feedback signals that increase a person's awareness of internal processes that are linked to illness and distress. Biofeedback therapies can change thinking, emotions, and behaviors, which in turn support beneficial physiological changes, resulting in improved health and well-being. For example, patients connected to a biofeedback device sometimes hear a sound if their

FIGURE 33-2 A patient using biofeedback can visually see how relaxation affects physiologic functions. (From Okeson JP: *Management of temporomandibular disorders and occlusion,* ed 7, St Louis, 2013, Elsevier.)

pulse rate or blood pressure increases out of their therapeutic zone. Practitioners then help patients interpret these sounds and use a variety of breathing, relaxation, and imaging exercises to gain voluntary control over their racing heart or their increasing systolic blood pressure (Lindquist et al., 2014).

Biofeedback is an effective addition to more traditional relaxation programs because it immediately demonstrates to patients their ability to control some physiological responses and the relationship among thoughts, feelings, and physiological responses. It helps individuals focus on and monitor specific body parts by providing immediate feedback about which stress-relaxation behaviors work most effectively. Eventually patients notice positive physiological changes without the need for instrument feedback. One of the most critical components of any behavioral program is adherence to a treatment regimen. Patients who are compliant have more positive results.

Biofeedback is used in numerous situations (Figure 33-2). Studies suggest that it may be helpful in stroke recovery, smoking cessation, attention deficit hyperactivity disorder (ADHD), epilepsy, headache disorders, and a variety of gastrointestinal and urinary tract disorders (Arns et al., 2009; Schoenberg and David, 2014). Although biofeedback produces effective outcomes in many patients, there are several precautions, particularly in those with psychological or neurological conditions. During biofeedback sessions repressed emotions or feelings sometimes surface. For this reason practitioners who offer biofeedback need to be trained in more traditional psychological methods or have qualified professionals available for referral. In addition, long-term use of biofeedback sometimes lowers blood pressure, heart rates, and other physiological parameters. As with other biobehavioral interventions, monitor patients closely to determine the need for medication adjustments.

Acupuncture

As a key component of TCM, **acupuncture** is one of the oldest practices in the world. When used outside of TCM, it is viewed as a mind-body therapy and is called *medical acupuncture.* In the United States medical acupuncture is often provided by specially trained health care providers.

Acupuncture regulates or realigns the **vital energy *(qi)*,** which flows like a river through the body in channels that form a system of 20 pathways called meridians. An obstruction in these channels blocks energy flow in other parts of the body. Acupuncturists insert needles into the skin in specific areas along the channels called **acupoints,** through which the *qi* can be influenced and flow reestablished.

Current evidence shows that acupuncture modifies the response of the body to pain and how pain is processed by central neural pathways and cerebral function (NIH/NCCIH, 2015b). It is effective for a variety of health problems such as low back pain, myofascial pain (e.g., temporomandibular joint disorder and trigeminal neuralgia), hot flashes, simple and migraine headaches, osteoarthritis, plantar heel pain, and chronic shoulder pain (Frisk et al., 2014; Ang and Kaptchuk, 2011).

Acupuncture is a safe therapy when the practitioner has the appropriate training and uses sterilized needles. Although needle complications occur (e.g., infection, fainting), they are rare if the practitioner takes appropriate precautions. In addition, caution patients about the use of acupuncture in cases of pregnancy, history of seizures, and immunosuppression. Treatment is contraindicated in people who have bleeding disorders and skin infections.

Therapeutic Touch

Therapeutic touch (TT), developed in the 1970s, is one of the "touch therapies" identified by NCCIH. It affects the energy fields that surround and penetrate the human body with the conscious intent to help or heal (Dossey and Keegan, 2012). Blending ancient eastern traditions with modern nursing theory, TT uses the energy of the provider to positively influence the patient's energy field.

TT consists of placing a practitioner's open palms either on or close to the body of a person (Figure 33-3). It occurs in five phases: centering, assessing, unruffling, treating, and evaluating. To begin, the practitioner centers physically and psychologically, becoming fully present in the moment and quieting outside distractions. Then he or she scans the body of the patient with the palms (roughly 5 to 15 cm [2 to 6 inches] from the body) from head to toe. While assessing the patient's energetic biofield, the practitioner focuses on the quality of the *qi* and areas of energy obstructions, redirecting the energy to harmonize and move. Using long, downward strokes over the energy fields of the body, the practitioner touches the body or maintains the hands in a position a few inches away from the body. The final phase consists of evaluating the patient, ensuring that energy is flowing freely, and determining additional outcomes and responses to the treatment.

The evidence supporting the effectiveness of TT is inconclusive, although it may be effective in treating pain in adults and children, dementia, trauma, and anxiety during acute and chronic illnesses (O'Mathúna and Ashford, 2012). Box 33-3 summarizes the importance of touch in older adults. Although the use of TT causes very few complications or side effects, it is contraindicated in situations when patients are sensitive to human interaction and touch (e.g., those who have been physically abused or have psychiatric disorders).

Traditional Chinese Medicine

TCM is a whole system of medicine that began approximately 3600 years ago. Chinese medicine views health as "life in balance," which manifests as lustrous hair, a radiant complexion, engaged interactions, a body that functions without limitations, and emotional balance. Health promotion encourages healthy diet, moderate regular exercise, regular meditation/introspection, healthy family and social relationships, and avoidance of environmental toxins such as cigarette smoke.

Several concepts and principles guide the TCM system of assessment, diagnosis, and intervention. The most important of these is the concept of **yin and yang,** which represent opposing yet complementary phenomena that exist in a state of dynamic equilibrium. Examples are night/day, hot/cold, and shady/sunny. Yin represents shade, cold, and inhibition; whereas yang represents fire, light, and excitement. Yin

FIGURE 33-3 During a therapeutic touch session, the practitioner intentionally directs energy to facilitate the patient's healing process.

TABLE 33-2	Three Causes of Disease According to Traditional Chinese Medicine
Cause of Disease	**Influences**
Internal causes	Internal causes originate in emotions and affect different organs: anger (liver), joy (heart), fear (kidney), grief/sadness (lung), pensiveness/worry (spleen), and shock (heart/kidney).
External causes	Six "evils" primarily linked to weather and climate (wind, cold, fire, damp, summer heat, and dryness) are manifested as linked patterns such as wind-cold, wind-heat, fire-toxin.
Nonexternal, noninternal causes	Additional causes of disharmony include congenital weak constitutions (birth defects), trauma, overexertion, excessive sexual activity, poor-quality diet, and parasites and poisons.

BOX 33-3 FOCUS ON OLDER ADULTS

The Importance of Touch

- Touch is a primal need, as necessary as food, growth, or shelter. It is like a nutrient transmitted through the skin, and "skin hunger" is like a form of malnutrition that has reached epidemic proportions in the United States, especially among older adults (Fontaine, 2014).
- Older adults need touch as much as or more than any other age-group. However, the elderly often experience "skin hunger." Older adults often have fewer family members or friends to touch them, especially when other senses are reduced (Dossey and Keegan, 2012).
- Simple touch helps older adults feel more connected to and accepted by those around them and more in tune with their environment. Touch enhances self-esteem and sense of worth.
- Nurses who react adversely to skin changes caused by aging often find it difficult to touch older adults. This reluctance communicates a negative message to the older adult (Dossey and Keegan, 2012). Therefore be aware of your own reactions to touch when caring for older adults to ensure a therapeutic approach to patient-centered care.

also represents the inner part of the body, specifically the viscera, liver, heart, spleen, lung, and kidney; whereas yang represents the outer part, specifically the bowels, stomach, and bladder. Harmony and balance in every aspect of life are the keys to health, including yin/yang balance. Practitioners believe that disease occurs when there is an imbalance in these two paired opposites. Imbalance occurs as excess or deficiencies in three areas: external, internal, or neither internal nor external (Table 33-2). It ultimately leads to disruption of vital energy, *qi,* which then compromises the body-mind-spirit of the person, causing "*disease.*" Disruptions in *qi* along the meridians can be evaluated systematically and treated by TCM practitioners.

TCM practitioners use four methods to evaluate a patient's condition: observing, hearing/smelling, asking/interviewing, and touching/palpating. In Chinese medicine outward manifestations reflect the internal environment. For example, the color, shape, and coating of the tongue reflect the general condition of the internal organs. The pulses provide information about the condition and balance of *qi,* blood, yin and yang, and internal organs. Therapeutic modalities include acupuncture, Chinese herbs, tui na massage, **moxibustion** (burning moxa, a cone or stick of dried herbs that has healing properties on or near the skin) **cupping** (placing a heated cup on the skin to create a slight suction), **tai chi** (originally a martial art that is now viewed as a moving meditation in which patients move their bodies slowly, gently, and with awareness while breathing deeply), *qi gong* (originally a martial art, now viewed as a series of carefully choreographed movements or gestures that are designed to promote and manipulate the flow of *qi* within the body), lifestyle modifications, and dietary changes.

In spite of widespread use of TCM in Asia, evidence about its effectiveness is limited. Most research in this field focuses on the study of individual treatment components of TCM such as acupuncture and herbal therapies. However, some evidence shows that TCM is helpful in treating fibromyalgia (Cao et al., 2010) and addressing symptoms associated with menopause (Taylor-Swanson et al., 2014).

There is some concern about the safety of Chinese herbal treatments that are used in teas, remedies, and supplements. The U.S. Food and Drug Administration (FDA) does not regulate, inspect, or ensure that the ingredients of these herbs are safe and without toxins. Recent reports about these products suggest that many Chinese herbs are contaminated with drugs, toxins, or heavy metals or that many ingredients may not be clearly listed or labeled. Further, these herbs can be very powerful, interacting with drugs and causing serious complications. When assessing a person using TCM, you need to ask him or her about the therapies he or she receives, including the types of herbs that he or she is using. Some patients consider these as teas or dietary additives, powders, or supplements and not as over-the-counter medications.

Natural Products and Herbal Therapies

Researchers estimate that approximately 25,000 plant species are used medicinally throughout the world. It is the oldest form of medicine known to man, and archeological evidence suggests that herbal remedies have been used for over 60,000 years. Herbal medicines are a prominent part of health care worldwide.

A natural product is a chemical compound or substance produced by a living organism and includes herbal medicines (also known as

botanicals), dietary supplements, vitamins, minerals, mycotherapies (fungi-based products), essential oils (aromatherapy), and probiotics. Many are sold over the counter as dietary supplements. The most frequently used products are garlic, echinacea, saw palmetto, ginkgo biloba, cranberry, soy, ginseng, black cohosh, St. John's wort, glucosamine, peppermint, fish oil/omega 3, soy, and milk thistle.

Herbal medicines are not approved for use as drugs and are not regulated by the FDA. For this reason many are sold as food or food supplements. The Dietary Supplement Health and Education Act of 1994 allows companies to sell herbs as dietary supplements as long as their labels do not contain health claims. Natural products in the United States are prepared primarily from plant materials. They are provided as tinctures or extracts, elixirs, syrups, capsules, pills, tablets, lozenges, powders, ointments or creams, drops, and suppositories.

A number of herbs are safe and effective for a variety of conditions (Table 33-3). Nurses have used cranberry juice to treat urinary tract infections for decades. Research now supports the use of cranberry supplements to prevent urinary tract infections because cranberry molecules bind with the iron that bacteria need to grow and reproduce and substances in cranberry block adherence of bacteria to the walls of the bladder (Wang et al., 2012). Chamomile is a plant substance that has been widely used in teas to promote sleep and relaxation and treat mild gastrointestinal disturbances and premenstrual symptoms. Clinical trials have recently found that chamomile may have modest benefits for people with mild-to-moderate generalized anxiety disorder (Ross, 2013).

Simply because a product is "natural" does not make it "safe." Although herbal medicines provide beneficial effects for a variety of conditions, a number of problems exist. Because they are not regulated, concentrations of the active ingredients vary considerably. Contamination with other herbs or chemicals, including pesticides and heavy metals, is also problematic. Not all companies follow strict quality control and manufacturing guidelines that set standards for acceptable levels of pesticides, residual solvents, bacterial levels, and heavy metals. For this reason, teach patients to purchase herbal medicines only from reputable manufacturers. Labels on herbal products need to contain the scientific name of the botanical, the name and address of the actual manufacturer, a batch or lot number, the date of manufacture, and the expiration date. Using natural products that have been verified by the U.S. Pharmacopeia (USP) is another way to ensure product safety, quality, and purity. Look for the USP Verified Dietary Supplement mark on product labels when buying or recommending natural products.

Some herbs also contain toxic products that have been linked to cancer. Table 33-4 lists several unsafe herbs. Some herbal substances contain powerful chemicals. As with any other medication, examine herbs for interaction and compatibility with other prescribed or over-the-counter substances that are being used simultaneously.

THE INTEGRATIVE NURSING ROLE

Interest in complementary/integrative therapies continues to increase. Most people using and seeking information about these therapies are well educated and have a strong desire to actively participate in decision making about their health care. This increased interest comes not only from health care consumers but also from mainstream physicians who have increasing concerns that current conventional medicine is not meeting the needs of their patients. Although many physicians do not refer their patients for complementary therapies because they are not familiar with them, others are beginning to recognize their benefits. Yet providers continue to have reservations about them because many have not been tested or researched adequately.

In North America and Europe professional groups are increasingly supporting the use of complementary and alternative therapies and monitoring research in this area. Priorities include assessing the public use of complementary therapies, teaching the principles of integrative health care across all professional educational programs, teaching the public to inform health care providers when using various therapeutics as self-care and health promotion strategies, improving public education about complementary therapies, and supporting studies that examine the safety and effectiveness of these therapies in a way that ensures improved quality of care. For example, if health care providers want to recommend the best treatment option for each health condition or symptom cluster, providers need to be aware of the evidence supporting complementary therapies and how to safely refer patients to complementary therapy providers. On the other hand, complementary therapy providers need to participate in the research process, working with scientists to demonstrate the effectiveness of these therapies on patient outcomes within the more rigorous framework of western science. All providers, including nurses, need to encourage open, honest dialogue about the use of complementary therapies by patients and better understand the benefits of therapies that encourage active participation by their patients in preventing or managing illness rather than relying solely on surgery or drugs.

Integrative health care, a strategy that is gaining popularity, involves interprofessional group practices in which patients receive care simultaneously from more than one type of practitioner. Patients have the option to choose the type of practitioner that they believe is beneficial for their particular health problem. Patients with the most to gain are those who have chronic health problems (e.g., fibromyalgia, chronic fatigue syndrome, or chronic pain) that have historically been difficult to treat with traditional biomedical approaches. An interprofessional group practice represents a truly integrated system in which all practitioners work side by side to improve the well-being of their patients.

This integrative approach is patient-centered and is focused on the whole person well-being and health. Nurses should be essential participants in this type of health care delivery system because many already practice the use of touch, relaxation techniques, imagery, and breathwork using the principles of integrative nursing (Kreitzer and Koithan, 2014). Familiarize yourself with the evidence in each modality that you incorporate into your practice. Know which patient is most likely to benefit from each therapy, when to use the various therapies, which complications might occur, and which precautions are needed when using these therapies.

QSEN **QSEN: BUILDING COMPETENCY IN PATIENT-CENTERED CARE** You are caring for a 48-year-old woman, Carmen, with stage 3 breast cancer who has returned to the hospital after being discharged after a mastectomy. She developed an infection in her suture line and around her drain site. Just before changing her dressings, you notice that she is more withdrawn and unwilling to speak more than one or two words and only to answer direct questions. When you question her further, she states that she can't stop thinking about her future and fears that "this will be how it's going to be…one hospital visit after another." She also says that she's concerned about the amount of pain medication that she's taking and that she's "tired of feeling drowsy and out-of-it" when her family comes to visit but doesn't know how else to manage her fear and pain. Which techniques could you offer Carmen to alleviate her suffering? Are there strategies that would help address her fears of the future and begin to view it in a more positive light?

ⓔ *Answers to QSEN Activities can be found on the Evolve website.*

TABLE 33-3 Select Herbs and Corresponding Effects

Common Name and Uses	Effects	Potential Drug Interactions
Aloe		
Skin disorders, including inflammation and acute injuries (used topically)	Acceleration of wound healing	Furosemide (Lasix) and loop diuretics
GI ulcerations, including Crohn's disease and ulcerative colitis (taken orally)	Unknown mechanism, although there is a known laxative effect	May enhance effects of laxatives when taken orally
Chamomile		
Inflammatory diseases of GI and upper respiratory tracts	Antiinflammatory	Drugs that cause drowsiness (alcohol, barbiturates, benzodiazepines, narcotics, antidepressants)
Generalized anxiety disorder	Calming agent	
Echinacea		
Upper respiratory tract infections	Stimulant of immune system	Antirejection and other drugs that weaken immune system; may interact with antiretrovirals and other drugs used in treatment of HIV/AIDS
Feverfew		
Wound healing	Antiinflammatory	Warfarin (Coumadin) and blood thinners
Arthritis	Inhibition of serotonin and prostaglandins	Aspirin and ibuprofen
Garlic		
Elevated cholesterol levels	Inhibition of platelet aggregation	Warfarin and blood thinners
Hypertension		Saquinavir (Fortovase) and other anti-HIV drugs
Ginger		
Nausea and vomiting	Antiemetic	Warfarin and blood thinners Aspirin and NSAIDs
Gingko Biloba		
Alzheimer's disease and dementia	Memory improvement, although these effects are in question given results in two clinical trials (Solomon et al., 2002; Snitz et al., 2009)	Warfarin and anticoagulants; aspirin and NSAIDs
Ginseng		
Age-related diseases	Increased physical endurance, improved immune function	Warfarin and anticoagulants; aspirin and NSAIDs; MAO inhibitors
Licorice		
GI disorders, including gastric ulcers and hepatitis C	Unknown	Corticosteroids and other immunosuppressive drugs; digoxin; antihypertensive drugs
Saw Palmetto		
Benign prostatic hyperplasia	Prevention of conversion of testosterone to dihydrotestosterone (needed for prostate cell multiplication)	Finasteride (Propecia) and antiandrogen drugs
Chronic pelvic pain	Unknown mechanism	None known
Valerian		
Sleep disorders, mild anxiety, and restlessness	Central nervous system depression	Barbiturates and other sleep medications; alcohol; antihistamines

Data from National Institutes of Health/National Center for Complementary and Alternative Medicine: *Herbs at a glance,* 2014, http://nccam.nih.gov/health/herbsataglance.htm. Accessed August 19, 2014.
AIDS, Acquired immunodeficiency disease; *GI,* gastrointestinal; *HIV,* human immunodeficiency virus; *MAO,* monoamine oxidase; *NSAID,* nonsteroidal antiinflammatory drug.

TABLE 33-4   **Unsafe Herbs**

Common Name	Effects	Comments
Calamus (Indian type most toxic)	Fever Digestive aid	Contains varying amounts of carcinogenic *cis*-isoasarone Documented cases of kidney damage and seizures with oral preparations
Chaparral	Anticancer Used for bronchitis in traditional healing systems (Native American and Hispanic folk medicine) Found in "natural" weight-loss products	No proven efficacy Induces severe liver toxicity in some cases and severe uterine contractions
Coltsfoot	Antitussive	Contains carcinogenic pyrrolizidine alkaloids Hepatotoxic
Comfrey	Wound healing and acute injuries Used for antiinflammatory effects in osteoarthritis and rheumatoid arthritis	Contains carcinogenic pyrrolizidine alkaloids May induce venoocclusive disease Hepatotoxic
Ephedra (ma huang)	Central nervous system stimulant Bronchodilator Cardiac stimulation Weight loss	Unsafe for people with hypertension, diabetes, or thyroid disease Avoid consumption with caffeine
Life root	Menstrual flow stimulant	Hepatotoxic
Pokeweed	Antirheumatic Anticancer	Do not use with children, but many websites state that it is safe with observation, monitoring, and proper dosing; often used with folk remedies and in Native American healing

Data from National Institutes of Health/National Center for Complementary and Alternative Medicine: *Herbs at a glance,* 2014, http://nccam.nih.gov/health/herbsataglance.htm. Accessed August 19, 2014; Natural Standard, 2014, https://naturalmedicines.therapeuticresearch.com/databases/food,-herbs-supplements.aspx. In addition, you need enough knowledge to discuss the full range of possible therapeutic options, both biomedical and complementary, so you can help patients make informed health care decisions. Always ask patients directly about their use of complementary therapies, including self-care activities such as yoga, meditation, or dietary supplements. Be knowledgeable about the evidence for different complementary therapies so you can make appropriate therapy recommendations for patients. Know about the different credentialing processes and how to refer patients to competent providers. Understand thoroughly the potential benefits and risks so you clearly and fully disclose information. Be knowledgeable so you can give advice to patients about when to seek conventional care and when it is safe to consider complementary care services. For example, if a patient complains of right lower abdominal pain, nausea, and vomiting, be suspicious of appendicitis and recommend a physician consultation. However, if the patient has a chronic gastrointestinal disorder and has a diagnosis of irritable bowel syndrome, he or she may benefit from relaxation and herbal therapy. Be aware of the safety precautions for each complementary therapy and incorporate these in your teaching plans. Finally understand your state Nurse Practice Act with regard to complementary therapies and practice only within the scope of these laws.

Nurses work very closely with their patients and are in the unique position of becoming familiar with the patient's spiritual and cultural viewpoints. They are often able to determine which complementary therapies are more appropriately aligned with these beliefs and offer recommendations accordingly. Being knowledgeable about CAM therapies will help you provide accurate information to patients and other health care professionals.

KEY POINTS

- Integrative health care programs use the full complement of treatment approaches (biomedical and complementary) when providing patient-centered care to patients.

- The stress response is an adaptive response that allows individuals to respond to stressful situations.
- Complementary therapies require commitment and regular involvement by a patient to be most effective and have prolonged beneficial outcomes.
- Choose complementary therapies appropriately according to a patient's overall health status, presenting symptom severity and distress, beliefs and cultural values, access to health care options, and insurance coverage/ability to pay.
- Continuously evaluate a patient's response to complementary therapies because medication doses may need to change on the basis of physiological responses.
- Complementary therapies accessible to nursing include relaxation, meditation and mindfulness techniques, and imagery.
- Many complementary therapies require additional education and certification, including biofeedback, touch therapies, and acupuncture.
- Although there is increasing evidence to support the use of complementary therapies, additional research of sufficient quality and rigor is needed.

CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

1. Margaret Thompson is a 76-year-old Catholic woman who was diagnosed with a slow-growing renal tumor. She is scheduled for surgery. You are responsible for the admission assessment and initial care for this patient. Which assessment questions about complementary and alternative therapies will you include during this preoperative period?
2. During the initial assessment Ms. Thompson asks many questions. "Is it cancer? Will the surgery result in a disability? What can I expect? Will I have to be in the intensive care unit (ICU)?" You conclude that she is afraid of both the surgical procedure and the

outcome. Which types of specific nursing-accessible complementary therapies will you offer her during the preoperative period to reduce her anxiety and help her prepare for surgery?

3. In the days following surgery you are assigned to care for Ms. Thompson. Although physically she is recovering quite well from the procedure, you note that she is becoming more despondent and depressed. Preparing for discharge, which complementary and alternative medicine (CAM) therapies do you recommend to help her deal with her depression and cancer diagnosis?

▌ REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. When planning patient education, it is important to remember that patients with which of the following illnesses often find relief in complementary therapies?
   1. Lupus and diabetes
   2. Ulcers and hepatitis
   3. Heart disease and pancreatitis
   4. Chronic back pain and arthritis

2. Which complementary therapies are most easily learned and applied by a nurse? (Select all that apply.)
   1. Massage therapy
   2. Traditional Chinese medicine
   3. Progressive relaxation
   4. Breathwork and guided imagery
   5. Therapeutic touch

3. Which statement best describes the evidence associated with complementary therapies as a whole?
   1. Many clinical trials in complementary therapies support their effectiveness in a wide range of clinical problems.
   2. It is difficult to find funding for studies about complementary therapies. Therefore we should not expect to find evidence supporting its use.
   3. The science supporting the effectiveness of complementary therapies is early in its development.
   4. Most of the research examining complementary and alternative therapies has found little evidence, suggesting that, although people like them, they are not effective.

4. While planning care for a patient, a nurse understands that providing integrative care includes treating which of the following?
   1. Disease, spirit, and family interactions
   2. Desires and emotions of the patient
   3. Mind-body-spirit of patients and their families
   4. Muscles, nerves, and spine disorders

5. In addition to an adequate patient assessment, when a nurse uses one of the nursing-accessible complementary therapies, he or she must ensure that which of the following has occurred?
   1. The family has provided permission.
   2. The patient has provided permission and consent.
   3. The health care provider has given approval or provided orders for the therapy.
   4. He or she has documented that the patient has a complete understanding of complementary and alternative medicine.

6. What role do patients have in complementary and alternative therapies?
   1. Submissive to the practitioner
   2. Actively involved in the treatment
   3. Allow practitioner to experiment
   4. Total believer in what is being taught

7. A nurse is caring for a patient experiencing a stress response. The nurse plans care with the knowledge that systems respond to stress in what manner? (Select all that apply.)
   1. Always fail and cause illness and disease
   2. Cause negative responses over time
   3. React the same way for all individuals
   4. Protect an individual from harm in the short term

8. Meditation may compound the effects of which of these medications?
   1. Prednisone and antibiotics
   2. Insulin and vitamins
   3. Cough syrups and aspirin
   4. Antihypertensive and thyroid-regulating medications

9. A patient who has been using relaxation wants a better response. The nurse recommends the addition of biofeedback. What is the expected outcome related to using this additional modality?
   1. To eat less food
   2. To control diabetes
   3. To live longer with acquired immunodeficiency syndrome (AIDS)
   4. To learn how to control some autonomic nervous system responses

10. Which of the following statements best explains the actions of therapeutic touch (TT)?
    1. Intentionally mobilizes energy to balance, harmonize, and repattern the recipient's biofield
    2. Intentionally heals specific diseases or corrects certain symptoms
    3. Is overwhelmingly effective in many conditions
    4. Is completely safe and does not warrant any special precautions

11. Traditional Chinese medicine (TCM) is used by many patients. Which statement most accurately describes intervention(s) offered by TCM providers?
    1. Uses acupuncture as its primary intervention modality
    2. Uses many modalities based on the individual's needs
    3. Uses primarily herbal remedies and exercise
    4. Is the equivalent of medical acupuncture

12. A nurse is planning care for a group of patients who have requested the use of complementary health modalities. Which patient is not a good candidate for guided imagery?
    1. Pregnant patient
    2. Hypertensive patient
    3. Patient with post-traumatic stress disorder (PTSD)
    4. A pediatric patient

13. Several nurses on a busy unit are using relaxation strategies while at work. What is the desired workplace outcome from this intervention? (Select all that apply.)
    1. Improved health among the staff
    2. Increased patient safety
    3. Improved staff satisfaction
    4. Improved staff relationships
    5. Fewer overtime assignments

14. A nursing professor is teaching a nursing student about caring patients who use herbal preparations in addition to prescribed medications. Which of the following statements made by the student indicates that the student understands herbal preparations?
    1. "Herbal preparations are regulated by the Food and Drug Administration (FDA); therefore I need to tell patients that they are completely safe."
    2. "They are natural products and therefore are safe as long as you use them for the conditions that are indicated."
    3. "These preparations are covered by insurance, including Medicare, Medicaid, and private payers."

4. "We need to treat herbal preparations as though they are "drugs" because many have active ingredients that can interact with other medications and change physiological responses."

15. The nurse manager of a community clinic arranges for staff in-services about various complementary therapies available in the community. What is the purpose of this training? (Select all that apply.)
    1. Nurses have a long history of providing some of these therapies and need to be knowledgeable about their positive outcomes.
    2. Nurses are often asked for recommendations and strategies that promote well-being and quality of life.
    3. Nurses play an essential role in patient education to provide information about the safe use of these healing strategies.
    4. Nurses appreciate the cultural aspects of care and recognize that many of these complementary strategies are part of a patient's life.
    5. Nurses play an essential role in the safe use of complementary therapies.
    6. Nurses learn how to provide all of the complementary modalities during their basic education.

Answers: 1. 4; **2.** 3, 4; **3.** 3; **4.** 3; **5.** 2; **6.** 2; **7.** 2, 4; **8.** 4; **9.** 4; **10.** 1; **11.** 2; **12.** 3; **13.** 3, 4; **14.** 4; **15.** 1, 2, 3, 4, 5.

Self-Concept

OBJECTIVES

- Discuss factors that influence the components of self-concept.
- Identify stressors that affect self-concept and self-esteem.
- Describe the components of self-concept as related to psychosocial and cognitive developmental stages.
- Explore ways in which a nurse's self-concept and nursing actions affect a patient's self-concept and self-esteem.
- Discuss evidence-based practices applicable for identity confusion, disturbed body image, low self-esteem, and role conflict.
- Examine cultural considerations that affect self-concept.
- Apply the nursing process to promote a patient's self-concept.

KEY TERMS

Body image, p. 703

Identity, p. 703

Identity confusion, p. 705

Role ambiguity, p. 705

Role conflict, p. 705

Self-concept is an individual's view of self. It is subjective and involves a complex mixture of unconscious and conscious thoughts, attitudes, and perceptions. Self-concept, or how a person *thinks* about oneself, directly affects self-esteem, or how one *feels* about oneself. Although these two terms often are used interchangeably, nurses need to differentiate the two so they correctly and completely assess a patient and develop an individualized plan of care on the basis of the patient's needs.

Patients face a variety of health problems that threaten their self-concept and self-esteem. The loss of bodily function, decline in activity tolerance, and difficulty managing a chronic illness are examples of situations that change a patient's self-concept. You will help patients adjust to alterations in self-concept and strengthen components of self-concept to promote successful coping and positive health outcomes.

SCIENTIFIC KNOWLEDGE BASE

The development and maintenance of self-concept and self-esteem begin at a young age and continue across the life span. Parents and other primary caregivers influence the development of a child's self-concept and self-esteem. In addition, individuals learn and internalize cultural influences on self-concept and self-esteem in childhood and adolescence. There is a significant emphasis on fostering a school-age child's self-concept. In general young children tend to rate themselves higher than they rate other children, suggesting that their view of themselves is positively inflated. Adolescence is a particularly critical developmental period when many variables, including school, family,

and friends, affect self-concept and self-esteem (Mantilla et al., 2014). The adolescent experience can adversely affect self-esteem, often more strongly for girls than for boys. For example, some adolescent girls are more sensitive about their appearance and how others view them. Thus it is important to assess changes in identity formation and self-esteem among early, middle, and late adolescence because changes in self-concept occur over time (Figure 34-1).

Job satisfaction and overall performance in adulthood are also linked to self-esteem. Self-expanding opportunities such as exploring new ideas, solving problems in creative ways, and learning new skills predict job satisfaction and commitment and promote self-concept clarity and self-esteem (McIntyre et al., 2014). Sometimes when individuals lose a job, their sense of self diminishes, they lose motivation to be socially active, and they even become depressed. They lose their job identity, and this alters their self-perceptions and self-care practices. Establishing a stable sense of self that transcends relationships and situations is a developmental goal of adulthood.

Cultural variations in self-concept and self-esteem across the life span can impact health behaviors. In adolescent girls cultural pride and self-esteem serve as protective factors against risk behaviors, including intentions to have sexual intercourse (Pai and Lee, 2012). Cultural identity of older adults is one of the major elements of self-concept and a key aspect of self-esteem (Touhy and Jett, 2014). Be aware of the cultural perspectives of aging when providing patient care. Sensitivity to factors that affect self-concept and self-esteem in diverse cultures is essential to ensure an individualized approach to health care.

How individuals view themselves and their perception of their health are closely related. Lower self-esteem is a risk factor that leaves

FIGURE 34-1 Adolescents' participation in group activities can foster self-esteem. (iStock.com/Bastiaan Slabbers.)

one vulnerable to health problems, whereas higher self-esteem and strong social relationships support good health. A patient's belief in personal health often enhances his or her self-concept. Statements such as, "I can get through anything" or "I've never been sick a day in my life" indicate that a person's thoughts about personal health are positive. Illness, hospitalization, and surgery affect self-concept. Chronic illness often affects the ability to provide financial support and maintain relationships, which then affects an individual's self-esteem and perceived roles within the family. Negative perceptions regarding health status are reflected in such statements as, "It's not worth it anymore" or "I'm a burden to my family." Furthermore, chronic illness affects identity and body image as reflected by verbalizations such as, "I'll never get any better" or "I can't stand to look at myself anymore."

What individuals think and how they feel about themselves affect the way in which they approach self-care physically and emotionally and how they care for others. Furthermore, a person's behaviors are generally consistent with both self-concept and self-esteem. Individuals who have a poor self-concept often do not feel in control of situations and worthy of care, which influences decisions regarding health care. Patients often have difficulty making even simple decisions such as what to eat. Knowledge of variables that affect self-concept and self-esteem is critical to provide effective treatment.

NURSING KNOWLEDGE BASE

In providing evidence-based practices to patients, incorporate professional nursing knowledge developed from the humanities, sciences, nursing research, and clinical practice. A broad knowledge base allows nurses to have a holistic view of patients, thus promoting quality patient care that best meets the self-concept needs of each patient and family. Understanding a patient's self-concept is a necessary part of all nursing care (Stuart, 2013).

Factors Influencing the Development of Self-Concept

The development of self-concept is a complex lifelong process that involves many factors. Erikson's psychosocial theory of development (1963) remains beneficial in understanding key tasks that individuals face at various stages of development. Each stage builds on the tasks of the previous stage. Successful mastery of each stage leads to a solid sense of self (Box 34-1).

Learn to recognize an individual's failure to achieve an age-appropriate developmental stage or his or her regression to an earlier stage in a period of crisis. This understanding allows you to

---

BOX 34-1 Self-Concept: Developmental Tasks

Trust versus Mistrust (Birth to 1 Year)
- Develops trust following consistency in caregiving and nurturing interactions
- Distinguishes self from environment

Autonomy versus Shame and Doubt (1 to 3 Years)
- Begins to communicate likes and dislikes
- Increasingly independent in thoughts and actions
- Appreciates body appearance and function (e.g., dressing, feeding, talking, and walking)

Initiative versus Guilt (3 to 6 Years)
- Identifies with a gender
- Enhances self-awareness
- Increases language skills, including identification of feelings

Industry versus Inferiority (6 to 12 Years)
- Incorporates feedback from peers and teachers
- Increases self-esteem with new skill mastery (e.g., reading, mathematics, sports, music)
- Aware of strengths and limitations

Identity versus Role Confusion (12 to 20 Years)
- Accepts body changes/maturation
- Examines attitudes, values, and beliefs; establishes goals for the future
- Feels positive about expanded sense of self

Intimacy versus Isolation (Mid-20s to Mid-40s)
- Has stable, positive feelings about self
- Experiences successful role transitions and increased responsibilities

Generativity versus Self-Absorption (Mid-40s to Mid-60s)
- Able to accept changes in appearance and physical endurance
- Reassesses life goals
- Shows contentment with aging

Ego Integrity versus Despair (Late 60s to Death)
- Feels positive about life and its meaning
- Interested in providing a legacy for the next generation

---

individualize care and determine appropriate nursing interventions. Self-concept is always changing and is based on the following:
- Sense of competency
- Perceived reactions of others to one's body
- Ongoing perceptions and interpretations of the thoughts and feelings of others
- Personal and professional relationships
- Academic and employment-related identity
- Personality characteristics that affect self-expectations
- Perceptions of events that have an impact on self
- Mastery of prior and new experiences
- Cultural identity

Self-esteem is often highest in childhood, fluctuates during adolescence, gradually rises throughout adulthood, and either diminishes or increases again in old age, depending on self-concept clarity (Diehl and Hay, 2011; Stuart, 2013). Although this pattern varies, in general it holds true across gender, socioeconomic status, and culture. Children often report high self-esteem because their sense of self is inflated by a variety of extremely positive sources, and periodic declines may be

associated with shifts to more realistic information about the self. Adolescence is a time of marked maturational changes and shifting levels of self-esteem that set the stage for rises in self-concept in young adulthood (Maldonado et al., 2013).

Erikson's emphasis on the generativity stage (1963) (see Chapter 11) explains the rise in self-esteem and self-concept in adulthood. The individual focuses on being increasingly productive and creative at work while at the same time promoting and guiding the next generation. On the basis of Erikson's stages of development, a decline in self-concept in later adulthood reflects a diminished need for self-promotion and a shift in self-concept to a more modest and balanced view of self. Many report a decline in self-esteem in later adulthood caused in part by physical and emotional changes associated with aging, but older adults with self-concept clarity demonstrate psychological well-being (Diehl and Hay, 2011; Touhy and Jett, 2014). When aging is associated with deterioration of health, nursing interventions must focus on health behavior changes to promote self-care and self-concept (Wurm et al., 2013). Identifying specific nursing interventions to address the unique needs of patients at various life stages is essential.

Components and Interrelated Terms of Self-Concept

A positive self-concept gives a sense of meaning, wholeness, and consistency to a person. A healthy self-concept has a high degree of stability, which generates positive feelings toward self. The components of self-concept are identity, body image, and role performance. Because how one thinks about oneself (self-concept) affects how one feels about oneself (self-esteem), both concepts need to be evaluated.

Identity. **Identity** involves the internal sense of individuality, wholeness, and consistency of a person over time and in different situations. It implies being distinct and separate from others. Being "oneself" or living an authentic life is the basis of true identity. Children learn culturally accepted values, behaviors, and roles through identification and modeling. They often gain an identity from self-observations and from what individuals tell them. An individual first identifies with parenting figures and later with other role models such as teachers or peers. Relationships with parents, teachers, and peers have unique and combined effects on young children's general, academic, and social self-concept (Verschueren et al., 2012). To form an identity, a child must be able to bring together learned behaviors and expectations into a coherent, consistent, and unique whole (Erikson, 1963).

The achievement of identity is necessary for intimate relationships because individuals express identity in relationships with others (Stuart, 2013). Sexuality is a part of identity, and its focus differs across the life span. For example, as an adult ages the focus shifts from procreation to companionship, physical and emotional intimacy, and pleasure seeking (Touhy and Jett, 2014). Gender identity is a person's private view of maleness or femaleness; gender role is the masculine or feminine behavior exhibited. This image and its meaning depend on culturally determined values (see Chapters 9 and 22).

Cultural differences in identity exist (Box 34-2). Cultural identity develops from identification and socialization within an established group and through the experience of integrating the response of individuals outside the group into one's self-concept. Differences in cultural identity (e.g., Mexican American or Cuban American, homosexual or heterosexual) exist through identification with traditions, customs, and rituals within one's cultural group (e.g., Hispanic, Latino, gender identity). When cultural identity is central to self-concept and is positive, cultural pride and self-esteem tend to be strong (Rhea and Thatcher, 2013). An individual who experiences discrimination, prejudice, or environmental stressors such as low-income or high-crime

---

⊕ BOX 34-2 CULTURAL ASPECTS OF CARE

Promoting Self-Concept and Self-Esteem in Culturally Diverse Patients

Cultural identity is an important component of a person's self-concept and self-esteem. Early in growth and development an individual develops this identity within the context of family. As an individual matures, the cultural aspects of his or her self-concept are reinforced through social, family, or cultural experiences. In addition, a person's self-concept is strengthened or questioned through political, social, or cultural influences experienced in the home, school, and workplace environments. Positive or negative cultural role modeling, identity, and past experiences influence self-care, self-concept, and self-esteem (Rhea and Thatcher, 2013).

Implications for Patient-Centered Care
- Develop an open, nonrestrictive attitude for assessing and encouraging cultural practices to improve patients' self-concept.
- Understand that the relationship among self-esteem, stress, and social support can facilitate the development of nursing strategies to promote effective coping in culturally diverse adolescents (Rhea and Thatcher, 2013).
- Ask patients what they think is important to help them feel better or gain a stronger sense of self.
- Encourage cultural identity and pride by individualizing self-care practices and offering treatment choices to meet patients' self-concept needs.
- Facilitate culturally sensitive health promotion activities that address at-risk behaviors identified through evidence-based practice (e.g., smoking, drinking, eating disorder risks, premature sexual experiences, excessive and violent video gaming (Dudovitz et al., 2013).

---

neighborhoods often conceptualizes himself or herself differently than an individual who experiences better living conditions.

Body Image. **Body image** involves attitudes related to the body, including physical appearance, structure, or function. Feelings about body image include those related to sexuality, femininity and masculinity, youthfulness, health, and strength. These mental images are not always consistent with a person's actual physical structure or appearance. Some body image distortions have deep psychological origins such as the eating disorder anorexia nervosa. Other alterations occur as a result of situational events such as the loss or change in a body part. Be aware that most men and women experience some degree of dissatisfaction with their bodies, which affects body image and overall self-concept. Individuals often exaggerate disturbances in body image when a change in health status occurs. The way others view a person's body and the feedback offered are also influential. For example, a controlling, violent husband tells his wife that she is ugly and that no one else would want her. Over the years of marriage she incorporates this devaluation into her self-concept.

Cognitive growth and physical development also affect body image. Normal developmental changes such as puberty and aging have a more apparent effect on body image than on other aspects of self-concept. Hormonal changes during adolescence influence body image. The development of secondary sex characteristics and the changes in body fat distribution have a tremendous impact on an adolescent's self-concept. For both male and female adolescents, negative body image is a risk factor for many psychological conditions that impact health behaviors. For example, an adolescent girl may have a distorted body image and view herself as fat, which signals an eating disorder. Your assessment may reveal that an adolescent engages in self-harmful

FIGURE 34-2 An individual's appearance influences self-concept. (iStock.com/stocknroll.)

behaviors such as cutting; self-mutilation can indicate self-concept and self-esteem issues that warrant nursing intervention (Rissanen et al., 2011). A threat to body image and overall self-concept can affect adherence to recommended health regimens, including diet, exercise, health screening practices, and taking medications as prescribed. Changes associated with aging (e.g., menopause; wrinkles; graying hair; and decrease in visual acuity, hearing, and mobility) also affect body image in an older adult.

Cultural and societal attitudes and values influence body image. Culture and society dictate the accepted norms of body image and influence one's attitudes (Figure 34-2). Cultural background plays an integral role in body satisfaction in adolescent girls and is reflected in differences in body satisfaction among groups. For example, identification with and pride in their cultural background can act as a partial buffer against advertisements, magazines, television, and movies depicting the thin-ideal white image and help Latina teenage girls feel more comfortable with themselves and their appearance (Schooler and Daniels, 2014). Furthermore, body image is more favorable in cultures in which girls describe more reasonable views about physical appearance, report less social pressure for thinness, and have less tendency to base self-esteem on body image. Low self-concept clarity increases a women's vulnerability to body image issues as a result of the internalization of the thin-ideal and appearance-related social comparisons (Vartanian and Dey, 2013). Values such as ideal body weight and shape and attitudes toward piercing and tattoos are culturally based. American society emphasizes youth, beauty, and wholeness. Western cultures have been socialized to dread the normal aging process, whereas eastern cultures view aging very positively and respect older adults. Body image issues are often associated with impaired self-concept and self-esteem.

Role Performance. **Role performance** is the way in which individuals perceive their ability to carry out significant roles (e.g., parent, supervisor, partner, or close friend). Normal changes associated with maturation result in changes in role performance. For example, when a man has a child, he becomes a father. The new role of father requires many changes in behavior if the man is going to be successful. Roles that individuals follow in given situations involve socialization, expectations, or standards of behavior. The patterns are stable and change only minimally during adulthood.

Ideal societal role behaviors are often hard to achieve in real life. Individuals have multiple roles and personal needs that sometimes conflict. Successful adults learn to distinguish between ideal role expectations and realistic possibilities. To function effectively in multiple roles, a person must know the expected behavior and values, desire to conform to them, and be able to meet the role requirements. Fulfillment of role expectations leads to an enhanced sense of self. Difficulty or failure to meet role expectations leads to deficits and often contributes to decreased self-esteem or altered self-concept.

Self-Esteem. **Self-esteem** is an individual's overall feeling of self-worth or the emotional appraisal of self-concept. It is the most fundamental self-evaluation because it represents the overall judgment of personal worth or value. Self-esteem is positive when one feels capable, worthwhile, and competent. A person's self-esteem is related to his or her evaluation of his or her effectiveness at school, within the family, and in social settings. The evaluation of others also is likely to have a profound influence on a person's self-esteem.

Considering the relationship between a person's actual self-concept and his or her ideal self enhances understanding of that person's self-esteem. The ideal self consists of the aspirations, goals, values, and standards of behavior that a person considers ideal and strives to attain. In general, a person whose self-concept comes close to matching the ideal self has high self-esteem, whereas a person whose self-concept varies widely from the ideal self suffers from low self-esteem (Stuart, 2013). Once established, basic feelings about the self tend to be constant, even though a situational crisis can temporarily affect self-esteem.

Factors Influencing Self-Concept

A self-concept stressor is any real or perceived change that threatens identity, body image, or role performance (Figure 34-3). An individual's perception of the stressor is the most important factor in determining his or her response. The ability to reestablish balance following a stressor is related to numerous factors, including the number of stressors, duration of the stressor, and health status (see Chapter 38). Stressors challenge a person's adaptive capacities. Changes that occur in physical, spiritual, emotional, sexual, familial, and sociocultural health affect self-concept. Being able to successfully adapt to stressors is likely to lead to a positive sense of self, whereas failure to adapt often leads to a negative self-concept.

Any change in health is a stressor that potentially affects self-concept. A physical change in the body sometimes leads to an altered body image, affecting identity and self-esteem. Chronic illnesses often alter role performance, which change an individual's identity and self-esteem. An essential process in the adjustment to loss is the development of a new self-concept. A loss of a partner can lead to a loss of identity and a lower self-esteem. Unlike the loss in self-esteem shown in vulnerable older adults, the resiliency demonstrated in some older adults may reflect more sophisticated cognitive strategies to manage losses.

The stressors created as a result of a crisis also affect a person's health. If the resulting identity confusion, disturbed body image, low self-esteem, or role conflict is not relieved, illness can result. For example, the diagnosis of cancer places additional demands on a person's established living pattern. It changes his or her appraisal of and satisfaction with the current level of physical, emotional, and social functioning. Assess self-esteem, effectiveness of coping strategies, and social support in all patients. During self-concept crises, supportive and educative resources are valuable in helping a person learn new ways of coping with and responding to the stressful event or situation to maintain or enhance self-concept.

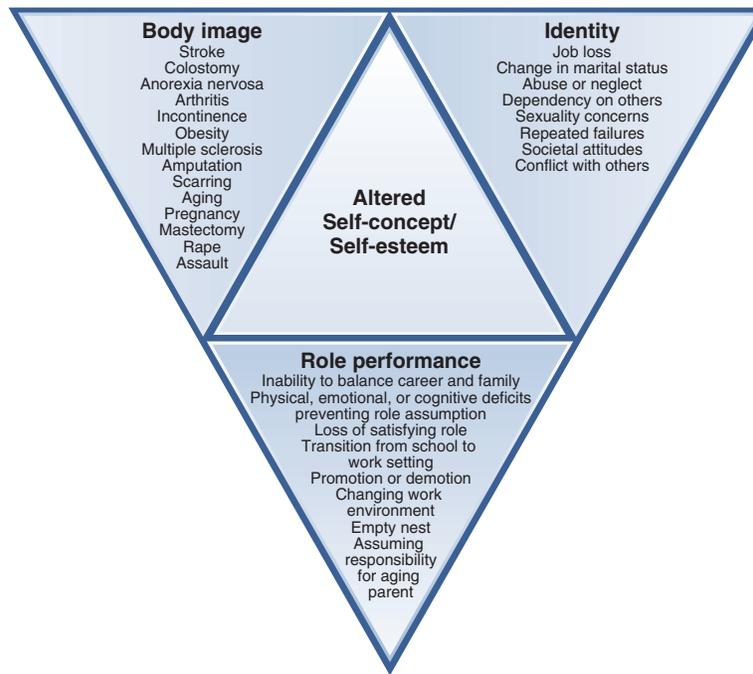
Identity Stressors. Stressors affect an individual's identity throughout life, but individuals are particularly vulnerable during adolescence. Adolescents are trying to adjust to the physical, emotional, and mental changes of increasing maturity, which results in insecurity


FIGURE 34-3 Common stressors that influence self-concept.

and anxiety. It is also a time when the adolescent is developing academic and psychosocial competence (Preckel et al., 2013).

Compared to an adolescent, an adult generally has a more stable identity and thus a more firmly developed self-concept. Cultural and social stressors rather than personal stressors have more impact on an adult's identity. For example, an adult has to balance career and family or make choices regarding honoring religious traditions from one's family of origin. **Identity confusion** results when people do not maintain a clear, consistent, and continuous consciousness of personal identity. Inability to adapt to identity stressors can result in identity confusion regardless of stage of life.

Body Image Stressors. A change in the appearance, structure, or function of a body part requires an adjustment in body image. An individual's perception of the change and the relative importance placed on body image affects the significance of a loss of function or change in appearance. For example, if a woman's body image incorporates reproductive organs as the ideal, a hysterectomy needed because of a diagnosis of uterine cancer is a significant alteration and can result in a perceived loss of femininity or wholeness. Changes in the appearance of the body such as an amputation, facial disfigurement, or scars from burns are obvious stressors affecting body image. Mastectomy and colostomy are surgical procedures that alter the appearance and function of the body, yet the changes typically are not apparent to others when the individual is dressed. Although potentially undetected by others, these changes significantly impact the individual. Even some elective changes such as breast augmentation or reduction affect body image. Chronic illnesses such as heart and renal disease affect body image because the body no longer functions at an optimal level. The patient has to adjust to a decrease in activity tolerance that impacts his or her ability to perform normal activities of daily living. In addition, pregnancy, significant weight gain or loss, pharmacological management of illness, or radiation therapy changes body image. Negative body image often leads to adverse health outcomes.

The response of society to physical changes in an individual often depends on the conditions surrounding the alteration. Some social changes have allowed the public to respond more favorably to illness and altered body image. For example, the media frequently presents positive stories about people adjusting in a healthy manner following serious injuries (e.g., surfer Bethany Hamilton's loss of a limb) or adapting to a debilitating illness (e.g., actor Michael J. Fox's Parkinson's disease). These stories change public awareness and the perception of what constitutes a disability and provide positive role models for individuals undergoing self-concept stressors and their families, friends, and society as a whole. In view of the growing epidemic of obesity in western cultures, parents and health care providers need to address weight-management issues without causing further injury to body image. Providing a social environment that focuses on health and fitness rather than a drive for thinness for girls or muscularity for boys can potentially increase adolescent satisfaction with their bodies.

Role Performance Stressors. Throughout life a person undergoes numerous role changes. Situational transitions occur when parents, spouses, children, or close friends die or people move, marry, divorce, or change jobs. It is important to recognize that a shift along the continuum from illness to wellness is as stressful as a shift from wellness to illness. Any of these transitions may lead to role conflict, role ambiguity, role strain, or role overload.

Role conflict results when a person has to simultaneously assume two or more roles that are inconsistent, contradictory, or mutually exclusive. For example, when a middle-age woman with teenage children assumes responsibility for the care of her older parents, conflicts occur in relation to being both a parent to her children and the child of her parents. Negotiating a balance of time and energy between her children and parents creates role conflicts. The perceived importance of each conflicting role influences the degree of conflict experienced. The **sick role** involves the expectations of others and society regarding how an individual behaves when sick. Role conflict occurs when general societal expectations (take care of yourself, and you will get better) and the expectations of co-workers (need to get the job done regardless of illness) collide. The conflict of taking care of oneself while getting everything done is often a major challenge.

Role ambiguity involves unclear role expectations, which makes people unsure about what to do or how to do it, creating stress and

confusion. Role ambiguity is common in the adolescent years. Parents, peers, and the media pressure adolescents to assume adult-like roles; yet many lack the resources to move beyond the role of a dependent child. Role ambiguity is also common in employment situations. In complex, rapidly changing, or highly specialized organizations, employees often become unsure about job expectations.

Role strain combines role conflict and role ambiguity. Some express role strain as a feeling of frustration when a person feels inadequate or unsuited to a role such as providing care for a family member with Alzheimer's disease.

Role overload involves having more roles or responsibilities within a role than are manageable. This is common in an individual who unsuccessfully attempts to meet the demands of work and family while carving out some personal time. Often during periods of illness or change, those involved either as the one who is ill or as a significant other find themselves in role overload.

Self-Esteem Stressors. Individuals with high self-esteem generally are more resilient and better able to cope with demands and stressors than those with low self-esteem. Low self-worth contributes to feeling unfulfilled and disconnected from others. Decreased self-worth potentially can result in depression and unremitting uneasiness or anxiety. Illness, surgery, or accidents that change life patterns also influence feelings of self-worth. Chronic illnesses such as diabetes, arthritis, and cardiac disease require changes in accepted and long-assumed behavioral patterns. Female children and adolescents with chronic illness such as chronic fatigue syndrome and chronic headaches are particularly vulnerable to low self-esteem (Pinquart, 2012). The more the chronic illness interferes with the person's ability to engage in activities contributing to feelings of worth or success, the more it affects self-esteem.

Self-esteem stressors vary with developmental stages. Perceived inability to meet parental expectations, harsh criticism, inconsistent discipline, and unresolved sibling rivalry reduce the level of self-worth of children. A developmental milestone such as pregnancy introduces unique self-concept stressors and has significant health care implications. For some economically disadvantaged youth, safe sex behaviors are not always valued, and pregnancy is an affirmation of cultural identity. Low self-esteem during adolescence also has significant real-world consequences in adulthood, including poor health, criminal behavior, and limited economic prospects compared to adolescents with high self-esteem. Self-esteem and health behaviors are intertwined. Self-concept guides health behaviors and organizes health-related actions (Thomas and Moring, 2014). Stressors affecting the self-esteem of an adult include failure in work and unsuccessful relationships. Self-concept stressors in older adults include health problems, declining socioeconomic status, spousal loss or bereavement, loss of social support, and decline in achievement experiences following retirement (Box 34-3).

Family Effect on Self-Concept Development

The family plays a key role in creating and maintaining the self-concepts of its members. Children develop a basic sense of who they are from their family caregivers. A child also gains accepted norms for thinking, feeling, and behaving from family members. Sometimes well-meaning parents cultivate negative self-concepts in children. Some literature suggests that parents are the most important influences on a child's development, yet variations in parenting approach depend on the culture. Specifically a child's positive self-esteem and school achievement are fostered by parents who respond in a firm, consistent, and warm manner. High parental support and parental monitoring are related to greater self-esteem and lower risk behaviors. Parents who are

---

BOX 34-3   FOCUS ON OLDER ADULTS

Enhancing Self-Concept in Older Adults

Self-concept sometimes is negatively affected in older adulthood because of a number of life changes. However, in some individuals aging promotes improved coping strategies that protect against the declining feelings of self-esteem, despite the physical and emotional changes associated with aging (Touhy and Jett, 2014). Nursing interventions aimed at enhancing self-concept and self-esteem in older adults is essential, particularly during illness, injury, or disability.

Implications for Practice
- Clarify what the life changes mean and the effect on self-concept. Discuss health problems, declining socioeconomic status, spousal loss or bereavement, and loss of social support following retirement.
- Conduct supportive conversations to understand challenges to the patient's perceptions of body image adjustments as part of aging and changes associated with illness, injury, or disability.
- Assess for preoccupation with physical complaints. Thoroughly assess patient's complaints and, if no physical explanation exists, encourage him or her to verbalize needs (e.g., fear, insecurity, loneliness) in a nonphysical way (Stuart, 2013).
- Identify positive and negative coping mechanisms. Support effective strategies.
- Provide resources to help patient learn new positive coping mechanisms.
- Encourage the use of storytelling and review of old photographs.
- Modify nursing interventions with patients experiencing dementia to support self-concept; recognize that self-concept in early dementia is largely intact (Clare et al., 2012).
- Communicate that the older adult is worthwhile by actively listening to and accepting the person's feelings, being respectful, and praising healthy behaviors.
- Allow additional time to complete tasks. Reinforce the older adult's efforts at independence (Touhy and Jett, 2014).

---

harsh, inconsistent, or have low self-esteem themselves often behave in ways that foster negative self-concepts in their children. Positive communication and social support foster self-esteem and well-being in adolescence. To reverse a patient's negative self-concept, first assess the family's style of relating (see Chapter 10). Family and cultural factors sometimes influence negative health practices such as excessive drinking (Box 34-4). Self-concept change demands an evidence-based practice approach supported by the entire health care team.

Nurse's Effect on Patient's Self-Concept

Your acceptance of a patient with an altered self-concept can promote positive change. Often this simply involves sitting with a patient and forming a therapeutic relationship. When a patient's physical appearance has changed, it is likely that both the patient and the family look to nurses and observe their verbal and nonverbal responses and reactions to the changed appearance. You need to remain aware of your own feelings, ideas, values, expectations, and judgments. Self-awareness is critical in understanding and accepting others. Nurses derive their self-concepts and professional identity from their public image; work environment; education; and their professional, social, and cultural values (Ten Hoeve et al., 2014). They need to assess and clarify the following self-concept issues about themselves:
- Thoughts and feelings about lifestyle, health, and illness
- Awareness of how their own nonverbal communication affects patients and families
- Personal values and expectations and how these affect patients

Self-Concept and the Impact on Adolescent Drinking Behaviors

PICO Question: How does self-concept influence drinking behaviors in at-risk adolescents?

Evidence Summary

Low self-concept may precede or perhaps even motivate adolescent drinking (Dudovitz et al., 2013). Because many teens engage in behaviors that increase the potential for morbidity and mortality, helping youth develop a healthy self-concept may prevent health risk behaviors, including teen drinking (CDC, 2014). In 2013 two thirds of high school students reported drinking; 34.9% reported current alcohol use, and 20.8% endorsed binge drinking (CDC, 2014). Overall the prevalence of current drinking in both males and females was higher among white students, followed by Hispanic, and then black students. Identifying risk and protective factors is important when creating drinking-prevention programs. Enhancing opportunities to learn communication skills and engage in alternative behaviors may make drinking less of an adolescent risk behavior.

Application to Nursing Practice

- Drinking-prevention efforts should include stress management and improving self-esteem.
- A priority nursing action is the assessment of child and adolescent coping strategies. Appropriate techniques include effective communication, conflict resolution, and stress management (Dudovitz et al., 2013).
- Families, peers, teachers, and health care providers should instill students' cultural pride, which promotes self-concept and the use of protective factors against risk behaviors such as drinking.
- Family, social, and behavioral factors are important issues to address during preadolescence and adolescence.
- Identifying risk factors for early drug and alcohol use, including genetic predisposition, family environment, and cultural identity, needs to be a priority for health care providers (CDC, 2014).

- Ability to convey a nonjudgmental attitude toward patients and families
- Preconceived attitudes toward cultural differences in self-concept and self-esteem

Some patients with a change in body appearance or function are extremely sensitive to the verbal and nonverbal responses of the health care team. A positive, matter-of-fact approach to care provides a model for the patient and family to follow. For example, when you observe a positive change in a patient's behavior, note it and allow the patient to establish its meaning. Nurses have a significant effect on patients by conveying genuine interest and acceptance. Including self-concept issues in the planning and delivery of care can influence patient outcomes positively. Building a trusting nurse-patient relationship that incorporates both the patient and family in the decision-making process enhances self-concept and self-esteem. You can individualize your approach by highlighting a patient's unique needs and incorporating alternative health care practices or methods of spiritual expression into the plan of care. It is important that health care providers understand the degree to which self-esteem and sexuality affect patient outcomes.

Your nursing care significantly affects a patient's body image. For example, the body image of a woman following a mastectomy is positively influenced by showing acceptance of the mastectomy scar. On the other hand, a nurse who has a shocked or disgusted facial expression contributes to the woman developing a negative body image.

Patients closely watch the reactions of others to their wounds and scars, and it is very important to be aware of your responses toward the patient. Statements such as, "This wound is healing nicely" or "This tissue looks healthy" are affirmations for the body image of the patient. Nonverbal behaviors convey the level of caring that exists for a patient and affect self-esteem. Anticipate personal reactions, acknowledge them, and focus on the patient instead of the unpleasant task or situation. Nurses who put themselves in the patient's situation incorporate measures to ease embarrassment, frustration, anger, and denial.

Preventive measures, early identification, and appropriate treatment minimize the intensity of self-esteem stressors and the potential effects for a patient and his or her family. Learn to design specific self-concept interventions to fit a patient's profile of risk factors. It is essential to assess a patient's perception of a problem and work collaboratively to resolve self-concept issues. Interventions designed to promote active living and healthy eating may be beneficial for preventing childhood obesity, improving self-esteem, preventing chronic diseases, and improving health outcomes in adulthood.

QSEN QSEN: BUILDING COMPETENCY IN PATIENT-CENTERED CARE. You are a third-year nursing student who feels insecure in the clinical setting. You are caring for Mrs. Johnson who had a bilateral mastectomy. This is your first time caring for this type of patient, and you hope that your clinical instructor won't ask you questions about your patient because you "forget" everything when your assigned faculty approaches; you feel embarrassed that you sometimes "hide" or "look busy" to avoid interacting with your instructor. You wonder, "How can I attend to my patient's physical care and self-concept and self-esteem issues when I can't even deal with my own?" Which actions must you take to improve your self-esteem and self-concept as a student nurse?

Answers to QSEN Activities can be found on the Evolve website.

CRITICAL THINKING

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients and families, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require you to anticipate information, analyze the data, and make decisions regarding your patient's care. During assessment consider all elements that build toward making an appropriate nursing diagnosis.

In the case of self-concept, it is essential to integrate knowledge from nursing and other disciplines, including self-concept theory, communication principles, and a consideration of cultural and developmental factors. Previous experience in caring for patients with self-concept alterations helps to individualize care. Self-concept profoundly influences a person's response to illness. A critical thinking approach to care is essential.

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care. Use of the nursing process is continuous until the patient's self-concept is improved, restored, or maintained.

◆ Assessment

During the assessment process thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered

BOX 34-5   Behaviors Suggestive of Altered Self-Concept

- Avoidance of eye contact
- Slumped posture
- Unkempt appearance
- Overly apologetic
- Hesitant speech
- Overly critical or angry
- Frequent or inappropriate crying
- Negative self-evaluation
- Excessively dependent
- Hesitant to express views or opinions
- Lack of interest in what is happening
- Passive attitude
- Difficulty in making decisions
- Self-harm behaviors

BOX 34-6   Nursing Assessment Questions

Nature of the Problem
- How would you describe yourself?
- Which aspects of your appearance do you like?
- Tell me about the things you do that make you feel good about yourself.
- Tell me about your primary roles. How effective are you at carrying out each of these roles?

Onset and Duration
- When did you start to think or feel differently about yourself?
- How long have you struggled with _____ (specify identity, body image, role performance, or self-esteem)?
- Can you remember a time when you felt good about yourself?

Effect on Patient
- Tell me how your self-concept affects your ability to take care of yourself.
- What impact does your self-esteem have on relationships?
- How does your self-esteem affect other areas of your life?
- Have you considered hurting yourself (specify self-mutilation, suicidal gestures)?

Knowledge
- Components of self-concept
- Self-concept stressors
- Therapeutic communication principles
- Nonverbal indicators of distress
- Cultural factors influencing self-concept
- Growth and development concepts
- Pharmacological effects of medications

Experience
- Caring for a patient who had an alteration in body image, self-esteem, role, or identity
- Personal experience of threat to self-concept

ASSESSMENT
- Observe for behaviors that suggest an alteration in the patient's self-concept
- Assess the patient's cultural background
- Assess the patient's coping skills and resources
- Determine the patient's feelings and perceptions about changes in body image, self-esteem, or role
- Assess the quality of the patient's relationships

Standards
- Support the patient's autonomy to make choices and express values that support positive self-concept
- Apply intellectual standards of relevance and plausibility for care to be acceptable to the patient
- Safeguard the patient's right to privacy by judiciously protecting information of a confidential nature

Attitudes
- Display curiosity in considering why a patient might behave in a particular manner
- Display integrity when your beliefs and values differ from the patient's; admit to any inconsistencies in your values or your patient's
- Take risks if necessary in developing a trusting relationship with the patient

FIGURE 34-4 Critical thinking model for self-concept assessment.

clinical decisions required for safe nursing care. In assessing self-concept and self-esteem, first focus on each component of self-concept (identity, body image, and role performance). Assessment needs to include looking for the range of behaviors suggestive of an altered self-concept or self-esteem (Box 34-5), actual and potential self-concept stressors (see Figure 34-3), and coping patterns. Gathering comprehensive assessment data requires the critical synthesis of information from multiple sources (Figure 34-4). In addition to direct questioning (Box 34-6), gather much of the data regarding self-concept through observation of the patient's nonverbal behavior and by paying attention to the content of the patient's conversations. Take note of the manner in which patients talk about the people in their lives because this provides clues to both stressful and supportive relationships and key roles the patient assumes. Use knowledge of developmental stages to determine which areas are likely to be important to the patient and inquire about these aspects of the person's life. For example, ask a 70-year-old patient about his life and what has been important to him. The individual's conversation likely provides data relating to role performance, identity, self-esteem, stressors, and coping patterns.

Through the Patient's Eyes. An important factor in assessing self-concept is the person's viewpoint of his or her health condition and its influence on self-concept. Give patients the opportunity to tell their stories of how they perceive their illness or condition affecting their identity, their image of themselves, and their ability to lead a normal lifestyle. Assess their expectations of health care by asking them how interventions will make a difference. This is also an opportunity to discuss the patient's goals. For example, a nurse working with a patient who is experiencing anxiety related to an upcoming diagnostic study asks the patient about his expectations of the relaxation exercise that they have been practicing together. The patient's response gives the nurse valuable information about his beliefs and attitudes regarding the efficacy of the interventions and the potential need to modify the nursing approach.

Coping Behaviors. The nursing assessment also includes consideration of previous coping behaviors; the nature, number, and intensity of the stressors; and the patient's internal and external resources. Knowledge of how a patient has dealt with stressors in the past provides insight into his or her style of coping. Patients do not address all issues in the same way, but they often use a familiar coping pattern for newly encountered stressors. Identify previous coping strategies to

determine whether these patterns have contributed to healthy functioning or created more problems. For example, the use of drugs or alcohol during times of stress often creates additional stressors (see Chapter 38).

Significant Others. Exploring resources and strengths such as availability of significant others or prior use of community resources is important in formulating a realistic and effective plan of care. Valuable information comes from conversations with family and significant others. Significant others sometimes have insights into the person's way of dealing with stressors. They also have knowledge about what is important to the person's self-concept. The way in which a significant other talks about the patient and the significant other's nonverbal behaviors provide information about which kind of support is available for the patient.

◆ **Nursing Diagnosis**

Carefully consider the assessment data to identify a patient's actual or potential problem areas. Rely on knowledge and experience, apply appropriate professional standards, and look for clusters of defining characteristics that indicate a nursing diagnosis. The following list (Herdman and Kamitsuru, 2014) provides examples of self-concept–related nursing diagnoses:

- *Disturbed Body Image*
- *Caregiver Role Strain*
- *Disturbed Personal Identity*
- *Ineffective Role Performance*
- *Readiness for Enhanced Self-Concept*
- *Chronic Low Self-Esteem*
- *Situational Low Self-Esteem*
- *Risk for Situational Low Self-Esteem*

Making nursing diagnoses about self-concept is complex. Often isolated data are defining characteristics for more than one nursing diagnosis (Box 34-7). For example, a patient expresses feelings of uncertainty and inadequacy. These are defining characteristics for both *Anxiety* and *Situational Low Self-Esteem.* Realizing that the patient is demonstrating defining characteristics of more than one nursing diagnosis guides you to gather specific data to validate and differentiate the underlying problem. To further assess the possibility of *Anxiety* as the nursing diagnosis, consider whether the person has any of the following defining characteristics: Is the person experiencing increased muscle tension, shakiness, a sense of being "rattled," or restlessness? These symptoms suggest *Anxiety* as the more appropriate diagnosis. On the other hand, if he or she expresses a predominantly negative

self-appraisal, including inability to handle situations or events and difficulty making decisions, these characteristics suggest that *Situational Low Self-Esteem* is more appropriate. To further aid in differentiating between the two provisional diagnoses, information regarding recent events in the person's life and how he or she has viewed himself or herself in the past provide insight into the most appropriate nursing diagnosis. As you gather additional data, usually the priority nursing diagnosis becomes evident.

Validate the nursing diagnosis by sharing observations with the patient and allow him or her to verify perceptions. This approach often results in the patient providing additional data, which further clarifies the situation. For example, "I noticed that you jumped when I touched your arm. Are you feeling uneasy today?" allows the patient to verify whether he or she is in fact anxious and describe his or her concerns.

◆ **Planning**

During planning synthesize knowledge, experience, critical thinking attitudes, and standards (Figure 34-5). Critical thinking ensures that a patient's plan of care integrates information known about the

Knowledge
- Principles of caring to establish trust
- Nursing interventions to promote self-awareness and facilitate change in self-concept
- Family dynamics
- Available services offered by health care providers and community agencies

Experience
- Establishing rapport with diverse patients
- Observing previous patient responses to planned nursing interventions to enhance or support a patient's self-concept

PLANNING
- Select therapies that strengthen or maintain the patient's coping skills
- Involve the patient to ensure that realistic therapies are chosen
- Refer to community services as appropriate
- Minimize stressors affecting the patient's self-concept

Standards
- Maintain the patient's dignity and identity
- Demonstrate ethical standards of care

Attitudes
- Think independently; explore various approaches to address the issue/problem
- Be creative; be willing to try unique interventions
- Exhibit perseverance; changes in self-concept often happen slowly; continue to support the vision that change is possible

FIGURE 34-5 Critical thinking model for self-concept planning.

BOX 34-7   Nursing Diagnostic Process

Situational Low Self-Esteem

Assessment Activities	Defining Characteristics
Ask patient to explain thoughts and feelings about self.	Patient is tearful and reports negative thoughts about self. She reports not wanting to have any visitors.
Observe patient's behavior and ask family if she is experiencing emotional or behavior changes.	Spouse describes withdrawal and avoidance of intimacy. He describes wife as unable to make decisions.
Determine if patient has had issues with self-esteem in the past and her plans to improve her self-esteem.	Patient denies any self-esteem issues since adolescence. She is receptive to counseling to discuss ways to return to high self-esteem.

Disturbed Body Image

ASSESSMENT

Mrs. Johnson, a 45-year-old married woman who had a bilateral radical mastectomy resulting from malignant breast cancer, has been assigned to Susan Carr, nursing student. Susan completed Mrs. Johnson's physical assessment. After Mrs. Johnson has been medicated adequately for pain, Ms. Carr sits down to discuss how the mastectomy has affected Mrs. Johnson's self-concept and self-esteem.

Assessment Activities

Assess identity and body image concerns (e.g., sexual role, femininity). Ask how the loss of breasts has affected her sense of self.

Observe Mrs. Johnson's mood and affect and her nonverbal communication and interactions with others.

Assess Mrs. Johnson's involvement in self-care activities.

Ask Mrs. Johnson if she would like opportunities to participate in treatment activities.

Findings/Defining Characteristics*

Mrs. Johnson **looks away, shakes her head**, and states, "**I feel like less of a woman**. My husband says I'm still attractive, but I don't believe him."

Mrs. Johnson demonstrates intermittent eye contact, frequent **crying when alone,** pulling hospital gown tightly across chest, and superficial conversations with family members.

Mrs. Johnson is unable to decide when to bathe, comb her hair, or apply typical makeup. She avoids looking in a mirror.

Mrs. Johnson avoids looking at or touching her chest and **does not ask questions** about her condition. "I don't know if I want to do anything right now."

*__Defining characteristics__ are shown in bold type.

NURSING DIAGNOSIS: Disturbed body image related to negative view of self after mastectomy

PLANNING

Goals

Mrs. Johnson will demonstrate self-care practices within 2 days and will verbalize improved self-concept within 4 days.

Expected Outcomes (NOC)[†]

Self-Esteem

Mrs. Johnson meets basic grooming and hygiene needs within 2 days and verbalizes improved feelings of self-acceptance and self-worth within 4 days.

Role Performance

Mrs. Johnson describes role changes associated with mastectomy and verbalizes commitment to accessing community resources by day of discharge.

Body Image

Mrs. Johnson demonstrates a positive adjustment to changes in body appearance within 1 week.

[†]Outcome classification labels from Moorhead S et al: *Nursing outcomes classification (NOC),* ed 5, St Louis, 2013, Mosby.

INTERVENTIONS (NIC)[‡]

Self-Esteem Enhancement

Use communication techniques to facilitate an environment and activities that will increase self-esteem.

Monitor Mrs. Johnson's statements of self-worth.

Encourage increased responsibility for self and help patient accept dependence on others as appropriate.

Role Enhancement

Help Mrs. Johnson identify specific role changes brought on by mastectomy.

Body Image Enhancement

Provide patient-centered care to support self-care practices and acceptance of alterations in physical appearance.

RATIONALE

A therapeutic nurse-patient relationship promotes positive patient outcome, including the patient's assuming responsibility for her own care (Stuart, 2013).

Self-esteem and body image are strong predictors of depression. The nurse must assess thoughts and feelings, including depression and risk for suicide, to ensure the patient's safety and make appropriate referrals.

Promoting self-care enhances self-concept, including improving role performance (Stuart, 2013).

Only after the nurse accurately defines the problem can alternative choices be proposed (Stuart, 2013).

A threat to body image and overall self-concept often influences self-care practices and acceptance of changes in physical appearance.

[‡]Intervention classification labels from Bulechek GM et al, editors: *Nursing interventions classification (NIC),* ed 6, St Louis, 2013, Mosby.

EVALUATION

Nursing Actions	Patient Response/Finding	Achievement of Outcome
Ask Mrs. Johnson how effective she feels in her ability to identify and express feelings verbally and nonverbally.	Mrs. Johnson reports, "I've been able to talk with my husband, even about my concerns that he won't find me attractive anymore."	Improved verbal and nonverbal communication noted
Monitor changes in Mrs. Johnson's statements about herself.	Mrs. Johnson is making fewer negative comments and evaluating body image more realistically but remains dissatisfied with appearance.	Small improvement in self-esteem; body image more realistic but remains negative
		Discusses body image with husband and nursing student
Observe Mrs. Johnson's participation in self-care related to mastectomy.	Mrs. Johnson is more assertive in completing basic hygiene; has used a mirror to examine mastectomy scar.	Meeting self-care needs

individual and key critical thinking elements (see the Nursing Care Plan). Professional standards are especially important to consider when developing a plan of care. These standards often establish ethical or evidence-based practice guidelines for selecting effective nursing interventions.

Another method to help plan care is a concept map. An example of an illustrative concept map (Figure 34-6) shows the relationship of a primary health problem (postoperative bilateral radical mastectomy) and four nursing diagnoses and several interventions. The concept map shows how the nursing diagnoses are interrelated. It also helps to show the interrelationships among nursing interventions. A single nursing intervention can be effective for more than one diagnosis.

Goals and Outcomes. Develop an individualized plan of care for each nursing diagnosis. Work collaboratively with the patient to set realistic expectations for care. Make sure that goals are individualized and realistic with measurable outcomes. In establishing goals consult with the patient about whether they are achievable. Consultation with significant others, mental health clinicians, and community resources results in a more comprehensive and workable plan. When you set goals, consider the data necessary to demonstrate that the patient's problem would change if the nursing diagnosis were managed. The outcome criteria should reflect these changes. For example, a patient is diagnosed with *Situational Low Self-Esteem related to a recent job layoff.* Establish a goal: "Patient's self-esteem and self-concept will

CONCEPT MAP

Nursing diagnosis: Disturbed body image
- Does not touch her chest
- Unable to look in mirror
- Avoids new social interactions
- Fears husband's response to loss of breasts

Interventions
- Assist patient to develop a realistic perception of her body image
- Tell patient that her feelings are similar to feelings of other people in the same situation
- Show acceptance of mastectomy when providing care

Nursing diagnosis: Acute pain
- Rates postoperative pain as a 9 on a scale of 0 to 10
- States "no relief from pain" with PCA
- Has poor sleeping patterns
- Has a lack of appetite
- Has decreased nutritional intake

Interventions
- Ask patient to describe past methods used to control pain
- Explore the need for opioid and nonnarcotic analgesics
- Discuss patient's fears of undertreated pain and addiction

Primary health problem: Postoperative bilateral radical mastectomy
Priority assessments: Self-esteem, effects of scars on body image, pain level, and feelings of fear and anxiety

Nursing diagnosis: Situational low self-esteem
- States she is unable to "cope"
- Has difficulty making decisions
- Has feelings of uselessness

Interventions
- Assess patient for signs and symptoms of depression and potential for suicide
- Actively listen to and demonstrate respect for patient
- Ask patient to identify personal strengths and talents

Nursing diagnosis: Fear
- Has decreased self-confidence
- Reports being unable to solve personal problems
- Panics when people ask about the cancer
- Experiences daily fatigue
- Worries that reconstruction "won't work"

Interventions
- Help patient distinguish between real and imagined threats
- Encourage patient to write about fears in a journal
- Explore feelings that contribute to fear

——— Link between medical diagnosis and nursing diagnosis   - - - - - Link between nursing diagnoses

FIGURE 34-6 Concept map for Mrs. Johnson. *PCA,* Patient-controlled analgesia.

improve in 1 week." Examples of expected outcomes directed toward that goal include the following:

- The patient discusses a minimum of three areas of her life in which she is functioning well.
- The patient is able to voice the recognition that losing her job is not reflective of her worth as a person.
- The patient attends a support group and networking session for out-of-work professionals.

Setting Priorities. A care plan presents the goals, expected outcomes, and interventions for a patient with an alteration in self-concept. Interventions help the patient adapt to the stressors that led to the self-concept disturbance and support and reinforce the development of coping methods. Often a patient perceives a situation as overwhelming and feels hopeless about returning to the level of previous functioning. He or she often needs time to adapt to physical changes but can work toward progressive improvement in self-concept and self-esteem.

Establishing priorities includes using therapeutic communication to address self-concept issues, which ensures that the patient's ability to address physical needs is maximized. Look for strengths in both the individual and the family and provide resources and education to turn limitations into strengths. Patient teaching creates understanding of the normalcy of certain situations (e.g., nature of a chronic disease; change in relationships; effect of a loss). Often, once patients understand their situations, their sense of hopelessness and helplessness is lessened.

Teamwork and Collaboration. A patient's perceptions of significant others are important to incorporate into the plan of care. Individuals who have experienced deficits in self-concept before the current episode of treatment have often established a system of support that includes mental health clinicians, clergy, and other community resources. Before including family members, consider the patient's desires for their involvement and cultural norms regarding who most frequently makes decisions in the family. Patients who are experiencing threats to or alterations in self-concept often benefit from collaboration with mental health and community resources to promote increased awareness. Additional resources include physical therapy, occupational therapy, behavioral health, social services, and pastoral care. Knowledge of available resources allows appropriate referrals.

◆ **Implementation**

As with all the steps of the nursing process, a therapeutic nurse-patient relationship is central to the implementation phase. Collaboratively you develop the goals and outcome criteria and then consider nursing interventions for promoting a healthy self-concept and helping a patient move toward his or her goals. To identify effective nursing interventions, consider each nursing diagnosis and individualize interventions that address the diagnosis. Collaborating with members of the health care team maximizes the comprehensiveness of the approach to self-concept issues. Regardless of the health care setting, it is important to work with patients and their families or significant others to promote a healthy self-concept. For example, select nursing interventions that help patients regain or restore the elements that contribute to a strong and secure sense of self. The approaches chosen vary according to the level of care required.

Health Promotion. Work with patients to help them develop healthy lifestyle behaviors that contribute to a positive self-concept. Measures that support adaptation to stress such as proper nutrition, regular exercise within the patient's capabilities, adequate sleep and

rest, and stress-reducing practices contribute to a healthy self-concept. Nurses are in a unique position to identify lifestyle practices that put a person's self-concept at risk or suggest altered self-concepts. For example, a young teacher visits a clinic with complaints of being unable to sleep and experiencing anxiety attacks. In gathering the nursing history, lifestyle practices such as too little rest, a large number of life changes occurring simultaneously, and excessive use of alcohol emerge. These data, when taken together suggest actual or potential self-concept disturbances. Determine how the patient views the various lifestyle elements to facilitate his or her insight into behaviors and make referrals or provide needed health teaching.

Acute Care. In the acute care setting some patients experience potential threats to their self-concept because of the nature of the treatment and/or diagnostic procedures. Threats to a person's self-concept often result in anxiety and/or fear. As a nurse you need to address the patient's numerous stressors, including fear of unknown diagnoses (diagnostic tests), the need to modify lifestyle, and anticipated changes in functioning. In the acute care setting there is often more than one stressor, thus increasing the overall stress level for the patient and family.

Nurses in the acute care setting encounter patients who face the need to adapt to an altered body image as a result of surgery or other physical change. With shortened lengths of stay, addressing these needs is difficult to do while in an acute care setting; thus appropriate follow-up and referrals, including home care, are essential. Remain sensitive to the patient's level of acceptance of any changes. Forcing confrontation with a change before the patient is ready likely delays his or her acceptance. Signs that a person is receptive to accepting a change include asking questions related to how to manage a particular aspect of what has happened or looking at the changed body area. As the patient expresses readiness to integrate the body change into his or her self-concept, let him or her know about support groups that are available and offer to make the initial contact.

Restorative and Continuing Care. Often in a home care environment a nurse has more of an opportunity to work with a patient to reach the goal of attaining a more positive self-concept. Interventions designed to help a patient reach the goal of adapting to changes in self-concept or attaining a positive self-concept are based on the premise that the patient first develops insight and self-awareness concerning problems and stressors and then acts to solve the problems and cope with the stressors. One way to achieve this is by reframing the patient's thoughts and feelings in a more positive way. Incorporate this approach into patient teaching for alterations in self-concept, including situational low self-esteem, that sometimes are present in the home care setting (Box 34-8).

Increase the patient's self-awareness by allowing him or her to openly explore thoughts and feelings. A priority nursing intervention is the expert use of therapeutic communication skills to clarify the expectations of a patient and family. Open exploration makes the situation less threatening for a patient and encourages behaviors that expand self-awareness. Use a nonjudgmental approach when accepting the patient's thoughts and feelings, help the patient clarify interactions with others, and be empathic.

Help the patient define problems clearly and identify positive and negative coping mechanisms. Work closely with him or her to analyze adaptive and maladaptive responses, contrast alternatives, devise a plan, and discuss outcomes. Collaborate with the patient to identify alternative solutions and develop realistic goals to facilitate real change and encourage further goal-setting behaviors. Design opportunities that result in success, reinforce the patient's skills and strengths, and

BOX 34-8 PATIENT TEACHING

Alterations in Self-Concept

Objective
- Situational low self-esteem will be reduced in the home care setting.

Teaching Strategies
- Encourage opportunities for patient to care for self (Stuart, 2013).
- Elicit patient's perceptions of strengths and weaknesses.
- Reaffirm that patient is responsible for behavior.
- Identify stressors with patient and ask for appraisal of them.
- Explore patient's coping responses to problems.
- Incorporate psychiatric co-morbidities (e.g., depression, anxiety, somatoform disorders) and alterations to self-esteem and body image when planning treatment approaches.
- Collaboratively identify alternative solutions and encourage alternatives not previously tried.
- Continue to reinforce strengths and successes.

Evaluation
- Confirm perception and actual use of improved communication skills.
- Observe level of participation in decisions that affect care.
- Observe patient establishing a simple routine.
- Observe patient taking necessary action to use appropriate coping responses (Stuart, 2013).

help him or her find needed assistance. Encourage the patient to commit to decisions and actions to achieve goals by teaching him or her to move away from ineffective coping mechanisms and develop successful coping strategies. Supporting attempts that are helpful is essential because with each success a patient is motivated to make another attempt.

◆ Evaluation

Through the Patient's Eyes. Use critical thinking to evaluate the patient's perceived success in meeting each goal and the established expected outcomes (Figure 34-7). Frequent evaluation of patient progress is necessary. Apply knowledge of behaviors and characteristics of a healthy self-concept when reviewing the actual behaviors that patients display. This determines whether outcomes have been met.

Patient Outcomes. Expected outcomes for a patient with a self-concept disturbance include displaying behaviors indicating a positive self-concept, verbalizing statements of self-acceptance, and validating acceptance of change in appearance or function. Key indicators of a patient's self-concept are nonverbal behaviors. For example, a patient who has had difficulty making eye contact demonstrates a more positive self-concept by making more frequent eye contact during conversation. Social interaction, adequate self-care, acceptance of the use of prosthetic devices, and statements indicating understanding of teaching all indicate progress. Investing in satisfying activities, exerting choices in daily life, understanding their own needs during transitions, and adapting to life circumstances are evidence of self-esteem and self-efficacy in older adults (Touhy and Jett, 2014). A positive attitude toward rehabilitation and increased movement toward independence facilitate a return to preexisting roles at work or at home. Patterns of interacting also reflect changes in self-concept. For example, a patient who has been hesitant to express personal views more readily offers opinions and ideas as self-esteem increases.

Knowledge
- Behaviors reflecting self-esteem
- Characteristics of a positive, healthy body image

Experience
- Observing previous patient responses to self-concept interventions

EVALUATION
- Observe the patient's nonverbal behaviors
- Ask the patient to share opinions and ideas
- Observe the patient's appearance
- Ask the patient if expectations are being met

Standards
- Use established expected outcomes to evaluate the patient's response to care (e.g., the ability to express concerns openly and to achieve role clarity)

Attitudes
- Exhibit perseverance to find successful therapies if the patient has a permanent alteration affecting body image

FIGURE 34-7 Critical thinking model for self-concept evaluation.

The goals of care sometimes become unrealistic or inappropriate as a patient's condition changes. Revise the plan if needed, reflecting on successful experiences with other patients. Patient adaptation to major changes can take a year or longer, but the fact that this period is long does not suggest problems with adaptation. Look for signs that the patient has reduced some stressors and that some behaviors have become more adaptive. If initial outcomes regarding self-concept are not met, individualize the following questions:
- Tell me what you will do if you are not able to return to work (may substitute school or home) as planned.
- Who will you contact if you are not feeling any better about yourself in 2 weeks?
- What are you doing to actively improve how you view yourself and your perception of how others view you?
- How will you know that your feeling of worth is improving?

Changes in self-concept take time. Although change is often slow, care of a patient with a self-concept disturbance is rewarding.

▮ KEY POINTS

- Self-concept is an integrated set of conscious and unconscious attitudes and perceptions about self.
- Components of self-concept are identity, body image, and role performance.
- Each developmental stage involves factors that are important to the development of a healthy, positive self-concept.
- Identity is particularly vulnerable during adolescence.
- Body image stressors include changes in physical appearance, structure, or functioning caused by normal developmental changes or illness.

- Self-esteem stressors include developmental and relationship changes, illness, surgery, accidents, and the responses of other individuals to changes resulting from these events.
- Role stressors, including role conflict, role ambiguity, and role strain, originate in unclear or conflicting role expectations; the effects of illness often aggravate this.
- A nurse's self-concept and nursing actions have an effect on a patient's self-concept.
- Planning and implementing nursing interventions for self-concept disturbance involve expanding a patient's self-awareness, encouraging self-exploration, aiding in self-evaluation, helping formulate goals in regard to adaptation, and helping a patient achieve these goals.

█ CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

1. On the second postoperative day you enter the room and find Mrs. Johnson crying. She states that she has just gotten off the phone with her 23-year-old daughter and has agreed to care for her 3-month-old granddaughter while the daughter returns to work. You were informed in shift report that Mrs. Johnson had a restless night and has not taken pain medication since 2030. You assess that she is in moderate pain, which you immediately treat with hydrocodone. Within 40 minutes Mrs. Johnson reports that the hydrocodone has decreased her pain rating from a 6 to a 3 on a scale of 0 to 10 but has left her somewhat drowsy. Mrs. Johnson has shared with you some of her concerns about whether or not she can actually provide child care for her granddaughter but states, "Maybe it will make me feel worthwhile and will take my mind off of how disgusting I look." She continues, "I just want to be normal again." How would you address her comment regarding "being normal again" and her lack of understanding of her physical condition, including pain management, increased fatigue, and limitations regarding lifting?

2. As a part of your home care experience, you are assigned to visit Mrs. Johnson who, in addition to caring for her infant granddaughter, is also caring for her mother, who is increasingly agitated and aggressive secondary to Alzheimer's disease. When you go to the home, you find Mrs. Johnson tearful. She says, "I can't do this anymore. She doesn't like anything I cook. She calls me 2 or 3 times during the night to sit with her; sometimes she doesn't even recognize me. The baby is crying constantly; I think she senses my stress. I feel so overwhelmed." Which additional assessment data would be important to gather? What priority nursing diagnosis could be made for Mrs. Johnson?

3. You suspect that Mrs. Johnson's depressed mood and loss of interest in usual activities exceeds your previous diagnosis of situational low self-esteem. Describe which assessment data are needed to modify your plan of care. Identify your priority actions.

█ REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. A 50-year-old woman is recovering from a bilateral mastectomy. She refuses to eat, discourages visitors, and pays little attention to her appearance. One morning the nurse enters the room to see the patient with her hair combed and makeup applied. Which of the following is the best response from the nurse?
   1. "What's the special occasion?"
   2. "You must be feeling better today."
   3. "This is the first time I've seen you look this good."
   4. "I see that you've combed your hair and put on makeup."

2. A 30-year-old patient diagnosed with major depressive disorder has a nursing diagnosis of *Chronic Low Self-Esteem related to negative view of self.* Which of the following would be appropriate interventions by the nurse? (Select all that apply.)
   1. Encourage reconnecting with high school friends
   2. Role play to increase assertiveness skills
   3. Focus on identifying strengths and accomplishments
   4. Provide time for journaling to explore underlying thoughts and feelings
   5. Explore new job opportunities

3. Several staff members complain about an adult patient's constant questions such as, "Should I have a cup of coffee or a cup of tea?" and "Should I take a shower now or wait until later?" Which interpretation of the patient's behavior helps the nurses provide optimal care?
   1. Asking questions is attention-seeking behavior.
   2. Inability to make decisions reflects a self-concept issue.
   3. Dependence on staff must be stopped immediately.
   4. Indecisiveness is aimed at testing how the staff reacts.

4. A depressed patient is crying and verbalizes feelings of low self-esteem and self-worth such as, "I'm such a failure … I can't do anything right." What is the nurse's best response?
   1. Remain with the patient until he or she validates feeling more stable.
   2. Tell the patient that is not true and that every person has a purpose in life.
   3. Review recent behaviors or accomplishments that demonstrate skill ability.
   4. Reassure the patient that you know how he is feeling and that things will get better.

5. An adult woman is recovering from a mastectomy for breast cancer and is frequently tearful when left alone. The nurse's approach should be based on an understanding of which of the following?
   1. Patients need support in dealing with the loss of a body part.
   2. The patient's family should take the lead role in providing support.
   3. The nurse should explain that breast tissue is not essential to life.
   4. The patient should focus on the cure of the cancer rather than loss of the breast.

6. When caring for an 87-year-old patient, the nurse needs to understand that which of the following most directly influences the patient's current self-concept?
   1. Attitude and behaviors of relatives providing care
   2. Caring behaviors of the nurse and health care team
   3. Level of education, economic status, and living conditions
   4. Adjustment to role change, loss of loved ones, and physical energy

7. A 20-year-old patient diagnosed with an eating disorder has a nursing diagnosis of *Situational Low Self-Esteem.* Which of the following nursing interventions would be appropriate to address self-esteem? (Select all that apply.)
   1. Offer independent decision-making opportunities.
   2. Review previously successful coping strategies.
   3. Provide a quiet environment with minimal stimuli.
   4. Support a dependent role throughout treatment.
   5. Increase calorie intake to promote weight stabilization.

8. The nurse asks the patient, "How do you feel about yourself?" The nurse is assessing the patient's:
   1. Identity.
   2. Self-esteem.
   3. Body image.
   4. Role performance.
9. The nurse can increase a patient's self-awareness through which of the following actions? (Select all that apply.)
   1. Helping the patient define her problems clearly
   2. Allowing the patient to openly explore thoughts and feelings
   3. Reframing the patient's thoughts and feelings in a more positive way
   4. Having family members assume more responsibility during times of stress
   5. Recommending self-help reading materials
10. When developing an appropriate outcome for a 15-year-old girl, the nurse considers that a primary developmental task of adolescence is to:
   1. Form a sense of identity.
   2. Create intimate relationships.
   3. Separate from parents and live independently.
   4. Achieve positive self-esteem through experimentation.
11. What is an appropriate nursing diagnosis for an individual who experiences confusion in the mental picture of his physical appearance?
   1. Acute Confusion
   2. Disturbed Body Image
   3. Chronic Low Self-Esteem
   4. Situational Low Self-Esteem
12. In planning nursing care for an 85-year-old male, what is the most important basic need that must be met?
   1. Assurance of sexual intimacy
   2. Preservation of self-esteem
   3. Expanded socialization
   4. Increase in monthly income
13. Which of the following assessment findings suggest an altered self-concept? (Select all that apply.)
   1. Uneven gait
   2. Slumped posture and poor personal hygiene
   3. Avoidance of eye contact when answering a question
   4. Requests for visits from the chaplain
   5. Frequent use of the call light
14. The home health nurse is visiting a 90-year-old man who lives with his 89-year-old wife. He is legally blind and is 3 weeks' post right hip replacement. He ambulates with difficulty with a walker. He comments that he is saddened now that his wife has to do more for him and he is doing less for her. Which of the following is the priority nursing diagnosis?
   1. Self-Care Deficit, Toileting
   2. Deficient Knowledge Regarding Resources for the Visually Impaired
   3. Disturbed Body Image
   4. Risk for Situational Low Self-Esteem
15. On the basis of knowledge of the developmental tasks of Erikson's Industry versus Inferiority, the nurse emphasizes proper technique for use of an inhaler with a 10-year-old boy so he will:
   1. Increase his self-esteem with mastery of a new skill.
   2. Accept changes in his appearance and physical endurance.
   3. Experience success in role transitions and increased responsibilities.
   4. Appreciate his body appearance and function.

Answers: 1. 4; **2.** 3, 4; **3.** 4; **4.** 1; **5.** 1; **6.** 4; **7.** 1, 2; **8.** 2; **9.** 1, 2, 3; **10.** 1; **11.** 2; **12.** 2; **13.** 2, 3; **14.** 4; **15.** 1.

Sexuality

Sexuality is part of a person's personality and is important for overall health. Even though discussion of sexual topics has increased over the years, many adults lack knowledge regarding **sexuality.** Although patients may be hesitant to bring up their concerns, they often share their feelings when a nurse addresses sexuality in a relaxed, matter-of-fact manner. To feel comfortable addressing sexuality, nurses need therapeutic communication skills and to be knowledgeable about sexual functioning, issues, and assessment. Many values and issues surround sexuality. Religious teachings, cultural influences on **gender roles,** beliefs about **sexual orientation,** and social and environmental climates influence the values systems for both patients and health care providers.

Sexuality has many definitions. Expression of an individual's sexuality is influenced by interaction among biological, sociological, psychological, spiritual, economic, political, religious, and cultural factors (WHO, n.d.). In addition, values, attitudes, behaviors, relationships with others, and the need to establish emotional closeness with others influence sexuality.

Sexuality differs from *sexual health*. According to WHO (n.d.), **sexual health** is "a state of physical, emotional, mental, and social well-being in relation to sexuality; it is not merely the absence of disease,

dysfunction, or infirmity." People who are sexually healthy have a positive and respectful approach to sexuality and sexual relationships. They also have a potential for having pleasurable and safe sexual experiences that are free from coercion, discrimination, and violence.

SCIENTIFIC KNOWLEDGE BASE

A sound scientific knowledge base regarding sexuality provides you with the necessary information to help your patients achieve sexual health. A basic understanding of sexual development, sexual orientation, **contraception,** abortion, and **sexually transmitted infections (STIs)** is necessary.

Sexual Development

Sexuality changes as a person grows and develops. Each stage of development brings changes in sexual functioning and the role of sexuality in relationships.

Infancy and Early Childhood. The first 3 years of life are crucial in the development of **gender identity** (Edelman and Mandle, 2014). The child identifies with the parent of the same sex and develops a

FIGURE 35-1 Adolescents function within a powerful network of peers as they explore their sexual identity. (©bikeriderlondon.)

complementary relationship with the parent of the opposite sex. Children become aware of differences between the sexes, begin to perceive that they are either male or female, and interpret the behaviors of others as behavior appropriate for a female or a male.

School-Age Years. During the school years parents, educators, and peer groups serve as role models and teachers about how men and women act with and relate to one another. School-age children generally have questions regarding the physical and emotional aspects of sex. They need accurate information from home and school about changes in their bodies and emotions during this period and what to expect as they move into puberty (Edelman and Mandle, 2014). Knowledge about normal emotional and physical changes associated with puberty decreases anxiety as these changes begin to happen.

Puberty/Adolescence. The emotional changes during puberty and adolescence are as dramatic as the physical ones. Adolescents function within a powerful peer group, with the almost constant anxiety of "Am I normal?" and "Will I be accepted?" (Figure 35-1). They face many decisions and need accurate information on topics such as body changes, sexual activity, emotional responses within intimate sexual relationships, STIs, contraception, and pregnancy. Adolescence is often a time when individuals explore their primary sexual orientation (Hockenberry and Wilson, 2015; Pascoe, 2013).

Adolescents may identify with a sexual minority group such as **lesbian**, **gay**, **bisexual**, or **transgender** (LGBT) (Young-Bruehl, 2010). A transgender individual's self-recognition as a male or female is in conflict with his or her biological sex characteristics or what is culturally determined as belonging to a male or female (Olson et al., 2011; Rosenthal, 2014). Transgender patients may pursue treatments or modification procedures to promote physical characteristics consistent with their gender identification (Rosenthal, 2014). Adolescents often face significant stress related to sexual identity and benefit from education about sexuality issues (Doty et al., 2010; Johnson and Amella, 2014; Lim et al., 2014). LGBT individuals are at a higher risk for depression; suicide; and abuse of tobacco, alcohol, and drugs than the general population.

In the United States almost 50% of high school students report that they have had sexual intercourse at least 1 time, and 15% of high school students had had four or more sexual partners (Kann et al., 2014; CDC, 2014d). Adolescents who engage in risky sexual behaviors experience negative health outcomes such as STIs and unintended pregnancy (Dunne et al., 2014; Scott et al., 2011). In addition, the pattern of risk-taking behavior tends to be established and continue throughout life.

Parents need to understand the importance of providing factual information, sharing their values, and promoting sound decision-making skills. They need to know that, even with the best guidance and information, adolescents make their own decisions and need to be held accountable for them. Support from peers, family, school counselors, clergy, nurses, and other health professionals is important during this time.

Young Adulthood. Although young adults have matured physically, they continue to explore and mature emotionally in relationships. Intimacy and sexuality are issues for all young adults whether they are in a sexual relationship, choose to abstain from sex, remain single by choice, are homosexual, or are widowed. People are sexually healthy in numerous ways. Sexual activity is often defined as a basic need, and healthy sexual desire is channeled into forms of intimacy throughout a lifetime. At times young adults require support and education or therapy to achieve mutually satisfying sexual relationships.

Middle Adulthood. Changes in physical appearance in middle adulthood sometimes lead to concerns about sexual attractiveness. In addition, actual physical changes related to aging affect sexual functioning. Decreasing levels of estrogen in **perimenopausal** woman lead to diminished vaginal lubrication and decreased vaginal elasticity. Both of these changes often lead to **dyspareunia,** or the occurrence of pain during intercourse. Decreasing levels of estrogen may also result in a decreased desire for sexual activity. As men age they are likely to experience changes such as an increase in the postejaculatory refractory period and delayed ejaculation. Anticipatory guidance regarding these normal changes, using vaginal lubrication, and creating time for caressing and tenderness ease concerns regarding sexual functioning. Some aging adults also need to adjust to the impact of chronic illness, medications, aches, pains, and other health concerns about sexuality.

Later in the adult years some individuals have to adjust to the social and emotional changes associated with children moving away from home. This results in either a time of renewed intimacy between partners or a time when formerly intimate partners realize that they no longer care for one another or have common interests. In either case, when children leave home, intimate relationships usually change.

Older Adulthood. Sexuality in older adults is an important aspect of health that often is overlooked by health care providers. Studies show a positive correlation between sexual activity and physical health in older adults (Lindau and Gavrilova, 2010; Stewart and Graham, 2013). Research indicates that many older adults are more sexuality active than previously thought and engage in high-risk sexual encounters, resulting in a steady increase of human immunodeficiency virus (HIV) and STI rates over the past 12 years (Box 35-1).

Factors that determine sexual activity in older adults include present health status, medications, past and present life satisfaction, and the status of marital or intimate relationships. For example, many older women are widowed or divorced and lack available sexual partners, which accounts for their decline in sexual activity. Nurses working with older adults need to assess the sexuality of their patients, sexual interest and functioning, and plan accordingly (Buttaro et al., 2014; Ayaz, 2013). It is essential to maintain a nonjudgmental attitude and convey that sexual activity is normal in later years. Emphasize that it is not essential to maintaining quality of life, especially when patients have decided not to remain sexually active.

To be effective in promoting sexual health, nurses need to understand the normal sexual changes that occur as people age. The excitement phase prolongs in both men and women, and it usually takes longer for them to reach orgasm. The refractory time following orgasm

is also longer. Both genders experience a reduced availability of sex hormones. Men often have erections that are less firm and shorter acting. Women usually do not have difficulty maintaining sexual function unless they have a medical condition that impairs their sexual activity. Typically the infrequency of sex in older women is related to the age, health, and sexual function of their partner. Women continue to experience changes related to menopause, and those with problems related to urinary incontinence often experience embarrassment during intercourse. Couples who have physically disabling conditions often need information about which positions are more comfortable when having sexual intercourse.

Sexual Orientation

Sexual orientation describes the predominant pattern of a person's sexual attraction over time. Many stereotypical myths remain about people who are LGBT. Current evidence indicates that they experience decreased access to health care and do not readily seek preventive care (Lim et al., 2014; Williamson, 2010). Nonjudgmental nurses who have a solid knowledge base help to discourage these myths and provide nursing care that includes attention to the person's sexual orientation.

Contraception

Numerous contraceptive options are available to sexually active couples today. They provide varying levels of protection against unwanted pregnancies. Some methods do not require a prescription, whereas others require a prescription or some other type of intervention from a health care provider. Methods that are effective for contraception do not always reduce the risk of STIs. For example, the pill and intrauterine contraceptive device (IUD) are effective as birth control but not for protection from STIs. A latex condom should be used during each act of intercourse to reduce the risk of STIs. Effectiveness varies with each contraceptive method and the consistency of use. Unplanned pregnancies occur because contraceptives are not used, are used inconsistently, or are used improperly (Schwartz and Gabelnick, 2011; Trussell and Guthrie, 2011).

Nonprescription Contraceptive Methods. Nonprescription methods for contraception include abstinence, barrier methods, and timing of intercourse with regard to a woman's ovulation cycle. Although abstinence from sexual intercourse is 100% effective, it is often difficult for both men and women to use consistently. Any act of unprotected intercourse potentially results in pregnancy and exposure to STIs.

Barrier methods include over-the-counter spermicidal products and condoms. Spermicidal products (e.g., creams, jellies, foams, and sponges) are put into the vagina before intercourse to create a spermicidal barrier between the uterus and ejaculated sperm. A latex **condom** is a thin rubber sheath that fits over the penis to prevent entrance of sperm into the vagina. A diaphragm is a barrier method, which must be used with a spermicide with each sexual encounter. Vaginal spermicides and condoms are most effective when instructions are followed carefully; their combined use is more effective in preventing pregnancy than the use of either one alone (Cates and Harwood, 2011).

Nonprescription methods of contraception based on the physiological changes of the menstrual cycle include the rhythm, basal body temperature, cervical mucus, and fertility-awareness methods. Couples who use these methods need to understand the reproductive cycle of the woman's body and the subtle signs and signals that her body gives during the cycle. To prevent pregnancy couples abstain from sexual intercourse during designated fertile periods.

Methods That Require a Health Care Provider's Intervention. Contraceptive methods that require the intervention of a health care provider include hormonal contraception, IUDs, the diaphragm, the cervical cap, and **sterilization.** Hormonal contraception is available in several forms: oral contraceptive pills, vaginal contraceptive rings, hormonal injections, subdermal implant, transdermal skin patches, and IUDs. Hormonal contraception alters the hormonal environment to prevent ovulation, thicken cervical mucus, and thin the lining of the uterus.

An IUD is a plastic device inserted by a health care provider into the uterus through the cervical opening. IUDs contain either copper or progesterone. The primary mechanism by which both types of IUDs prevent pregnancy is to stop the sperm from fertilizing an egg (Dean and Schwarz, 2011; Murphy, 2011). The release of progesterone may also increase cervical mucus thickness and alter the lining of the uterus.

The **diaphragm i**s a round, rubber dome that has a flexible spring around the edge. It is used with a contraceptive cream or jelly and is inserted in the vagina so it provides a contraceptive barrier over the cervical opening. The woman needs to be refitted after a significant change in weight (10-lb gain or loss) or pregnancy. The cervical cap functions like the diaphragm; however, it covers only the cervix. It may be left in place longer, and some perceive it as more comfortable than the diaphragm.

Sterilization is the most effective contraception method other than abstinence. Female sterilization, or **tubal ligation,** involves cutting, tying, or otherwise ligating the fallopian tubes. In male sterilization, or **vasectomy,** the vas deferens, which carries the sperm away from the testicles, is cut and tied. Both a tubal ligation and a vasectomy usually are considered permanent surgical procedures.

Sexually Transmitted Infections

The incidence of STIs continues to increase. Approximately 20 million people in the United States are diagnosed with an STI each year, with the highest incidence occurring in men who have sex with men, bisexual men, and youths between the ages of 15 and 24 (CDC, 2014a). The prevalence of STIs is a major health concern for several reasons. Black and Hispanic populations are diagnosed with STIs more frequently than whites, and women have more complications associated with STIs than men (Healthy People 2020, n.d.; CDC, 2013a). In addition, race, poverty, access to health care, and sexual practices contribute to disparities in the STI rates.

Treatment of STIs in America costs about $16 million annually (CDC, 2014a). Commonly diagnosed STIs include syphilis, gonorrhea, chlamydia, trichomoniasis, and infection with the human papillomavirus (HPV) and herpes simplex virus (HSV) type II (genital warts and genital herpes, respectively).

As the name implies, STIs are transmitted from infected individuals to partners during intimate sexual contact. The site of transmission is usually genital, but sometimes it is oral-genital or anal-genital. People most likely to be infected share one key characteristic: unprotected sex with multiple partners. Gonorrhea, chlamydia, syphilis, and pelvic inflammatory disease (PID) are caused by bacteria and are usually curable with antibiotics. Patients need to take antibiotics for the full course of treatment. However, an emerging concern is that some of these bacterial infections (e.g., gonorrhea and syphilis) are now developing antibiotic-resistant strains. Infections such as HSV types I and II, HPV, and HIV are caused by viruses and cannot be cured.

A major problem in dealing with STIs is finding and treating the people who have them. Some people do not know that they are infected because symptoms are sometimes absent or go unnoticed. Common symptoms of an STI include discharge from the vagina, penis, anus, or throat; pain during sex or when urinating; and unexplained rash or lesions (Phillippi and Latendresse, 2014). Because sexual behavior often includes the whole body rather than just the genitalia, many parts of the body are potential sites for an STI. The perineum, anus, and rectum frequently are involved in sexual activity. Furthermore, any contact with another person's body fluids around the head or an open lesion on the skin, anus, or genitalia can transmit an STI.

Sometimes people do not seek treatment because they are embarrassed to discuss sexual symptoms or concerns. Often they are hesitant to talk about their sexual behavior if they believe that it is not "normal." Any sexual behavior that embarrasses a patient often hinders the detection of an STI. Develop communication skills and a nonjudgmental attitude to provide effective care for those diagnosed with one. Detect valuable clues about an STI by establishing trust, talking with patients, and asking questions in a caring manner. Assess attitudes toward sexuality and adjust the intervention to make it acceptable to the patient's sexual value system.

Human Immunodeficiency Virus Infection.
HIV infection is a bloodborne pathogen and is present in most body fluids. It is sometimes spread through sexual contact. Transmission occurs when there is an exchange of body fluid. Primary routes of transmission include contaminated intravenous (IV) needles, anal intercourse, vaginal intercourse, oral-genital sex, and transfusion of blood and blood products.

The natural history of HIV progresses in three stages. The primary infection stage lasts for about a month after contracting the virus. During this time the person often experiences flulike symptoms. Then he or she enters the clinical latency phase; at this time there are no symptoms of infection. HIV antibodies appear in the blood about 6 weeks to 3 months after infection. If left untreated, people who are infected with HIV live about 10 years. The last stage, acquired immunodeficiency syndrome (AIDS), happens when a person begins to show symptoms of the disease. AIDS is a serious, debilitating, and eventually fatal disease. Highly active antiretroviral therapy (HAART) and having an experienced HIV clinician greatly increase the survival time of people who live with HIV/AIDS (Marrazzo and Cates, 2011).

Human Papillomavirus Infection.
HPV is the most common STI in the United States, with approximately 14 million new infections every year (CDC, 2014b). Most HPV infections are asymptomatic and self-limiting. However, certain types can cause cervical cancer in women and anogenital cancers and genital warts in both men and women. HPV is spread through direct contact with warts, semen, and other body fluids from others who have the disease. The textured warts often have a cauliflower appearance and are most common on the penis and scrotum in men and the vagina and cervix in women. A vaccine that protects both men and woman against nine types of HPV that most commonly cause health concerns is now available (ACOG, 2015; CDC, 2015b) (Box 35-2).

Chlamydia.
The bacteria *Chlamydia trachomatis* causes chlamydia. It is the most commonly reported infectious disease in the United States, affecting about 3 million Americans each year (CDC, 2014c). Chlamydia is spread by contact with fluids from the infected site. The infection can be transmitted during the birthing process and cause conjunctivitis and pneumonia in newborn babies. It frequently infects the cervix and, if left untreated, can cause PID, ectopic pregnancy, and infertility from damage to the female reproductive organs. Most people do not realize that they are infected with chlamydia because it causes few symptoms (CDC, 2015a). For this reason the CDC recommends annual screening for all sexually active women up to age 25. High-risk populations are people who have multiple sex partners or are infected with other STIs and men who have sex with men.

NURSING KNOWLEDGE BASE

Factors Influencing Sexuality

Use critical thinking skills and basic nursing knowledge when addressing patients' sexual health needs. Draw from the following areas of nursing knowledge: sociocultural dimensions of sexuality, decisional issues, and alterations in sexual health.

Sociocultural Dimensions of Sexuality

People assign different meanings to sexuality on the basis of their culture, gender, education, socioeconomic status, and religion (Giger, 2013). Society plays a powerful role in shaping sexual values and attitudes and supporting specific expression of sexuality in its members.

Each cultural and social group has its own set of rules and norms that guide sexual behavior, sexual health, and the willingness to discuss this private part of life. For example, cultural norms influence how people find partners, whom they choose as partners, how they relate to one another, how often they have sex, and what they do when they have sex. Personal beliefs enable certain practices and prohibit others (Box 35-3).

Impact of Pregnancy and Menstruation on Sexuality.
Sexual interest and activity of women and their partners vary during pregnancy and menstruation. Some cultures encourage sexual intercourse or male-female contact during menstruation and pregnancy, but

BOX 35-2   EVIDENCE BASED PRACTICE

Health Risk Behaviors Associated with the Human Papilloma Virus Vaccine

PICO Question: Do youths who receive the human papilloma virus (HPV) vaccine engage in more sexual risk behaviors than youths who do not receive the vaccine?

Evidence Summary

HPV is the most common sexually transmitted infection (STI) in the United States and is associated with development of anogenital cancers and genital warts in males and females (ACOG, 2015; CDC, 2013c; CDC, 2014b). The vaccine targets the specific HPVs linked to cancer and warts. It is recommended for all youths ages 11 to 26 years, but vaccination rates in the United States are low (ACOG, 2015; Dorell et al., 2014; Marchand et al., 2013). Parental acceptance of the vaccine influences vaccination status, and parents have voiced concern that vaccination will promote sexual risk taking in youths despite evidence indicating otherwise (Dorrell et al., 2014; Marchand et al., 2013; Roberts et al., 2010). In a study of females ages 13 to 21, vaccination was not associated with an increase in number of sexual partners or a decrease in the use of condoms (Mayhew et al., 2014). Administration of the HPV vaccine to almost 1400 females ages 11 to 12 did not result in an increase in the occurrence of pregnancy, STIs, or the need for contraception over the next 3 years (Bednarczyk et al., 2012). College-age females who received the vaccine did not differ in age of first intercourse, number of sexual partners, or condom use when compared to nonvaccinated peers (Marchand et al., 2013). Less research has been conducted on male vaccination compliance, but barriers such as lack of knowledge concerning health risks, need for vaccination of males versus females, and provider recommendation to parents have all been shown to impact vaccination rates in males (Donahue et al., 2014; Fontenot et al., 2014). Health care professionals need to consider these findings to encourage vaccine understanding and acceptance among parents and youths.

Application to Nursing Practice

- Vaccine recommendation by health care professionals can increase vaccine acceptance by the public and reduce the incidence of HPV-related cancers (ACOG, 2015; Donahue et al., 2014).
- Nurses need to discuss the benefits of the vaccine with parents and youths ages 11 to 26 years and offer catch-up vaccines as needed (ACOG, 2015; CDC, 2013c).
- Reduce parental concerns by sharing research that indicates that vaccine administration does not increase sexual activity or risk behaviors (Bednarczyk et al., 2012; Marchand et al., 2013; Mayhew et al., 2014).
- Continue to teach safe sex practices.

⊕ BOX 35-3   CULTURAL ASPECTS OF CARE

Cultural Factors and Human Immunodeficiency Virus

All sexually active individuals are at risk for HIV; however, some cultures have higher infection rates. For example, Latinos in the United States are 3 times more likely than non-Latino whites to be diagnosed with human immunodeficiency virus (HIV) (Adih et al., 2010). Latino males are 2 times more likely than white males to have HIV, and females are 4 times more likely to be HIV positive than their white counterparts (Peragallo et al., 2012). The majority of HIV cases result from heterosexual activity, and Latino youths are less likely than other ethnic groups to use condoms (Casey and Gomez-Lobo, 2013; Deordorff et al., 2013; Peragallo et al., 2012).

Cultural-specific norms and values that contribute to sexual risk behaviors include gender roles, religion, and sexual communication patterns (Peragallo et al., 2012; Warren et al., 2011). *Marianismo* refers to women who are virtuous and submissive; whereas *machismo* views men as strong, independent, and in a position of authority (Deordorff et al., 2010). In the Latino culture, women are expected to remain virgins before marriage, whereas men are not expected to control sexual desires. Traditional Latino culture maintains that it is not appropriate for men and women to discuss sexual issues, even within families or intimate relationships (Deordorff et al., 2013). Health care providers need to consider cultural values and their influence on sexual practices when working with the Latino population (Lee et al., 2013).

Implications for Patient-Centered Care

- Establish a therapeutic relationship with a patient/family before discussing sexual health.
- Provide both males and females written and verbal information in English and Spanish, or in their native language, regarding contraception, sexually transmitted infections (STIs), and HIV testing and management options (Warren et al., 2011).
- Target adolescents by expanding education on STIs, HIV, and contraception in middle- and high-school curriculum.
- Promote gender neutrality by addressing assertive communication and negotiation strategies among females.
- Increase HIV testing at community clinics and offer combined laboratory work for STIs and HIV to promote acceptance (Adih et al., 2010).
- Promote cultural-specific bilingual multimedia and community education about HIV risk-reduction strategies (Adih et al., 2010).

---

others strictly forbid it. For example, in the Hindu culture a woman avoids worship, cooking, and other members of the family during menstruation. Research has found no physiological contraindication to intercourse during menstruation or during most pregnancies. Female sexual interest tends to fluctuate during pregnancy, with increased interest during the second trimester and often decreased interest during the first and third trimesters. There is often a decrease in libido during the first trimester because of nausea, fatigue, and breast tenderness. During the second trimester blood flow to the pelvic area increases to supply the placenta, resulting in increased sexual enjoyment and libido. During the third trimester the increased abdominal size often makes finding a comfortable position difficult (Link, 2012).

Discussing Sexual Issues.   Sexuality is a significant part of each person's being, yet sexual assessment and interventions are not always included in health care (Ayaz, 2013; Ivarsson et al., 2010; Sobecki et al., 2012; Steinke et al., 2013). The area of sexuality is often emotionally charged for nurses and patients. Sometimes nurses avoid discussing sexual issues with patients because they lack information or have different values than their patients. Nurses who have difficulty discussing topics related to sexuality need to explore their discomfort and develop a plan to address it. If you are uncomfortable with topics related to sexuality, the patient is unlikely to share sexual concerns with you. You need to be aware of your personal beliefs before discussing sexuality with your patients.

Decisional Issues

Individuals make many decisions about their sexuality. Some nurses help patients make decisions about contraception and abortion.

Contraception.   Decisions patients make regarding contraception have far-reaching effects on their lives. Pregnancy, whether planned or

unplanned, significantly affects the life of the mother and father and often their support network. Effects are physical, interpersonal, social, financial, and societal. The choice to use contraception is multifaceted and not completely understood. Factors that affect the effectiveness of contraception include the type of method used, the couple's understanding of the method, the consistency of use, and compliance with the requirements of the chosen method. Choice of contraception method varies in relation to the age, ethnicity, marital status, income, education, sexual orientation, and previous pregnancies of the woman (Casey and Gomez-Lobo, 2013; Godfrey et al, 2011; Jones et al., 2012). Mobile apps are available to help patients and health professionals monitor reproductive health (e.g., to remind you when to take oral contraceptives, to replace your transdermal patch or vaginal ring, or when your most fertile time is occurring). Some examples of women's health apps include Clue, Period Tracker, Glow, Glow Nurture, Ovia Fertility, and iBreastCheck (Garcia, 2014).

Abortion. Half of all pregnancies in the United States are unplanned; unintended pregnancy rates are highest among low-income women, women ages 18 to 24 and over 40, cohabiting women, and minority women (Finer and Zolna, 2014). Approximately 40% of unintended pregnancies end in abortion. Abortions have been performed since ancient times. The safety and availability of abortions in the United States improved after the 1973 Supreme Court decision *Roe v Wade,* which established the right of every woman to have an abortion. They are safer and less costly when performed in the early weeks of pregnancy.

Abortion is a hotly debated issue. Women and their partners who face an unwanted pregnancy may consider it. If caring for a patient contemplating abortion, provide an environment in which the patient is able to discuss the issue openly, allowing exploration of various options with an unwanted pregnancy. Discuss religious, social, and personal issues in a nonjudgmental manner with patients. Reasons for choosing an abortion vary and include terminating an unwanted pregnancy or aborting a fetus known to have birth defects. When a woman chooses abortion as a way of dealing with an unwanted pregnancy, the woman and often her partner experience a sense of loss, grief, and/or guilt.

Be aware of personal values related to abortion. As a nurse you are entitled to your personal views. You should not be forced to participate in counseling or procedures contrary to your beliefs and values. It is essential to choose specialties or places of employment where personal values are not compromised and the care of a patient in need of health care is not jeopardized.

Prevention of Sexually Transmitted Infections. Responsible sexual behavior includes knowing one's sexual partner and the partner's sexual history, being able to openly discuss drug-use history with the partner, not allowing drugs or alcohol to influence decision making and sexual practices, and using STI and contraceptive protective devices.

Alterations in Sexual Health

Infertility. Infertility is the inability to conceive after 1 year of unprotected intercourse. A couple who wants to conceive but is unable to has special needs. Some experience a sense of failure and think that their bodies are defective. Sometimes the desire to become pregnant grows until it permeates most waking moments. Some individuals become preoccupied with creating just the right circumstances for conception. With advances in reproductive technology, infertile couples face many choices that involve religious and ethical values and financial limitations.

Choices for the infertile couple include pursuit of adoption, medical assistance with fertilization, or adapting to the probability of remaining childless. Organizations such as RESOLVE: The National Organization of Infertility, a national support group for couples with infertility, or international adoption groups provide couples with support and offer referral sources.

Sexual Abuse. Sexual abuse is a widespread health problem. Abuse crosses all gender, socioeconomic, age, and ethnic groups. Most often it is at the hands of a former intimate partner or family member. Sexual abuse has far-ranging effects on physical and psychological functioning (Edelman and Mandle, 2014). Sometimes it begins, continues, or even intensifies during pregnancy. Cues that raise a question of possible sexual abuse include extreme jealousy and refusal to leave a woman's presence. The overall appearance is sometimes that of a very concerned and caring husband or boyfriend, when the underlying reason for this behavior is very different.

Nurses are in an ideal position to assess occurrences of sexual violence, help patients confront these stressors, and educate individuals regarding community services. Nurses are mandated reporters and must report suspected abuse to the proper authorities. When you suspect or recognize abuse, mobilize support for the victim and the family. When abuse is suspected, remember to *not* ask the potential victim about any abusive behaviors in the presence of the suspected abuser. Provide privacy for the abuse victim and obtain information in a protective environment. When there is abuse, all family members usually require therapy to promote healthy interactions and relationships.

Rape victims often need to work through the crisis before feeling comfortable with intimate expressions of affection. The partner needs to know how to help and support the victim. Children who have been molested sexually need to understand that they are not at fault for the incident. The parents need to understand that their response is critical to how the child reacts and adapts.

Personal and Emotional Conflicts. Ideally sex is a natural, spontaneous act that passes easily through a number of recognizable physiological stages and ends in one or more orgasms. In reality this sequence of events is more the exception than the rule. You will care for patients who have problems with one or more of the stages of sexual activity, including the feeling of wanting sex, the physiological processes and emotions of having sex, and the feelings experienced after sex. For example, some women and men who are taking antidepressants report that their ability to reach orgasm is affected negatively.

Sexual Dysfunction. Sexual dysfunction, the absence of complete sexual functioning, is common. The incidence of sexual dysfunction in the general population is estimated to be as high as 40% in men and 60% to 80% in women (Buttaro et al., 2014; Touhy and Jett, 2014). It is more prevalent in men and women with poor emotional and physical health (Box 35-4). Sometimes the exact cause cannot be determined.

The incidence of erectile dysfunction (ED) increases with age but can occur in men under 40 (Capogrosso et al., 2013; Syme, 2014). Risk factors are similar to those for heart disease (i.e., diabetes mellitus, hyperlipidemia, hypertension, hypothyroidism, chronic renal failure, smoking, obesity, alcohol abuse, and lack of exercise). The etiology of ED is often multifactorial. Neurogenic problems, medications, or endocrine or psychogenic factors can cause it. An age-related decrease in testosterone often results in decreased tone of the erectile tissues.

Data from Bach LE et al: The association of physical and mental health with sexual activity in older adults in a retirement community, *J Sex Med* 10:2671, 2013; Basson R et al: Sexual function in chronic illness, *J Sex Med* 7:374, 2010; Bispo GS et al: Cardiovascular changes resulting from sexual activity and sexual dysfunction after myocardial infarction: integrative review, *J Clin Nurs* 22:3522, 2013; Buster J: Managing female sexual dysfunction, *Fertil Steril* 100(4):905, 2013; Conaglen HM, Conaglen JV: Drug-induced sexual dysfunction in men and women, *Aust Prescriber* 36(2):42, 2013.

One of the most common problems affecting women of all ages is **hypoactive sexual desire disorder** (HSDD) (Buster, 2013; Buttaro et al., 2014; Kingsberg, 2011; Rosen et al., 2012). Biological, organic, or psychosocial factors can contribute to the incidence of HSDD. Chronic medical conditions such as breast or gynecological cancers and hormonal fluctuations, pain, or depression and anxiety can contribute to a decreased interest in sexual intimacy (Bach et al., 2013).

CRITICAL THINKING

Successful critical thinking requires synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Nurses use clinical judgment to anticipate information needs, analyze assessment data, and make appropriate decisions regarding patient care. Figure 35-2 shows how to use elements of critical thinking and patient assessment data to develop appropriate nursing diagnoses.

In the case of sexuality, integrate knowledge from nursing and other disciplines. Have a thorough understanding of safe sex practices and the risks and behaviors associated with sexual problems to anticipate how to assess a patient and interpret findings. Use previous experiences to provide care for patients with sexual issues in a more reflective and helpful way. Patients have different customs and values from those of your own. Professional standards require respect for each patient as an individual. Critical thinking attitudes such as integrity require you to recognize when personal opinions and values are in conflict with those

Knowledge
- Ways to phrase questions about sexuality
- Sexual development and human sexual response patterns
- Impact of self-concept on sexuality
- Sexual orientation
- Effective contraceptive methods
- STIs and associated risk factors
- Safe sex practices
- Behaviors suggestive of current or past sexual abuse
- Diseases and/or medications that affect sexual function
- Interpersonal relationship factors and sexual functioning

Experience
- Communicating with patients and developing rapport
- Working with patients and exploring sexual concerns (e.g., working in OB-GYN setting)
- Personal sexual experience and response

ASSESSMENT
- Assess the patient's developmental stage with regard to sexuality
- Perform physical assessment of urogenital area
- Determine the patient's sexual concerns
- Assess the presence of high-risk behaviors, use of safe sex practices and contraception
- Assess medical conditions and medications that might affect sexual functioning

Standards
- Apply intellectual standards of relevance and plausibility for care to be acceptable to the patient
- Safeguard the patient's right to privacy by judiciously protecting information of a confidential nature
- Demonstrate ethics of care

Attitudes
- Display curiosity; consider why a patient might behave or respond in a particular manner
- Display integrity; your beliefs and values differ from patient's; admit to any inconsistencies between your values and the patient's
- Take risks if necessary to explore both personal sexual issues and concerns and those of the patient

FIGURE 35-2 Critical thinking model for sexuality assessment. *OB-GYN,* Obstetric-gynecological; *STI,* sexually transmitted infection.

of the patient and to consider how to proceed in a way that is mutually beneficial.

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach to help you develop and implement an individualized plan of care. Assess all relevant factors, including physical, psychological, social, and cultural, to determine a patient's sexual well-being. The nursing role in addressing sexual concerns ranges from ongoing assessment to providing information, counseling, and referral. Keep in mind that nurses are not expected to have answers to all sexual issues and concerns identified.

◆ Assessment

During the assessment process thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care.

Through the Patient's Eyes. As in any patient assessment, it is important to understand a patient's expectations regarding care. Questions such as "What would you like to have happen in regard to your sexual health problems?" and "What initial steps might you take?" help a patient identify desired outcomes. It is important to set aside personal views and consider a patient's needs and preferences for care.

Factors Affecting Sexuality. In gathering a sexual history consider physical, functional, relationship, lifestyle, developmental, and self-esteem factors that influence sexual functioning. Sexual desire varies among individuals; some people want and enjoy sex every day, whereas others want sex only once a month, and still others have no sexual desire and are quite comfortable with that fact. Sexual desire becomes an issue if the person wants to satisfy it more often, if he or she believes that it is necessary to measure up to some cultural norm, or if there is a discrepancy between the sexual desires of the partners in a relationship.

Ask patients to describe factors that typically influence their sexual desire. Knowing a patients' medical history and probing for information is helpful. For example, minor illness, medications, and fatigue often decrease sexual desire. Lifestyle factors such as the use or abuse of alcohol, lack of sleep, lack of time, or the demands of caring for a new baby are other influencing factors. For example, working parents sometimes feel so overburdened that they perceive sexual advances from a partner as an additional demand on them. Confirm factors that potentially affect sexual desire and determine with the patient the extent to which sexual function is impaired.

Self-concept issues (see Chapter 34), including identity, body image, role performance, and self-esteem, affect a patient's sexuality. Consider how these factors relate to a patient's condition. For example, poor body image associated with chronic disease magnifies feelings of rejection. This often results in diminished or absent sexual desire.

Issues in a relationship often affect sexual desire. After the initial glow of a new relationship has faded, some couples find that they have major differences in their values or lifestyles. Ask couples to describe how close they feel to each other and how often they interact on an intimate level. Assess communication patterns between sexual partners to determine sexual satisfaction within a relationship.

Sexual Health History. Most patients want to know how medications, treatments, and surgical procedures influence their sexual relationship even though they often do not ask questions. With experience

---

BOX 35-6 Nursing Assessment Questions

- Are you sexually active?
- With whom do you have sex: men, women, or both?
- How many sexual partners do you have (or have you ever had)?
- How do you feel about the sexual aspects of your life?
- Have you noticed any changes in the way you feel about yourself?
- How has your illness, medication, or surgery affected your sex life?
- It is not unusual for people with your condition to be experiencing some sexual changes. Have you noticed any changes, or do you have any concerns?
- Are you in a relationship in which someone is hurting you?
- Has anyone ever forced you to have sex against your will?
- Tell me what you know about safe sex practices, use of contraceptives, or prevention of sexually transmitted infections.
- Tell me the safe sex practices that you follow.

---

nurses recognize that most patients welcome the opportunity to talk about their sexuality, especially when they are experiencing difficulties. The PLISSIT model provides an approach that nurses can use to assess sexuality in patients (Ayaz, 2013) (Box 35-5).

Incorporate assessment questions related to sexuality in the nursing history (Box 35-6). Using an opening statement puts a patient at ease when introducing these questions (e.g., "Sex is an important part of life, and a person's health status often affects sexuality. Many people have questions and concerns about their sexual health. What questions or concerns do you have now?"). Use knowledge of developmental stages to determine which areas are likely to be important for your patient. For example, when gathering a sexual history from an older adult, it is important to keep in mind that some have difficulty discussing intimate details with health care providers.

Nurses who conduct sexual assessments of children and adolescents face special challenges. Use language that is accurate and that the child or adolescent understands. Also promote normal development, avoid minimizing problems, and screen for sexual concerns while making the child or adolescent feel at ease. The sexual counseling of minors raises ethical and legal issues regarding a patient's rights to health care and education on the one hand and a parents' or guardian's right to supervise information on the other. Children and adolescents frequently respond when they know that having questions related to sexuality is normal. Being open, positive, and interested when introducing sexual questions is helpful.

In light of the prevalence of intimate partner violence, questions relating to abusive relationships are important. Address these questions in private. Recognizing both subjective and objective signs and symptoms of abuse in children and adults helps to identify this too-common problem (Table 35-1).

Some individuals are too embarrassed or do not know how to ask sexual questions directly. Look for clues that a person has questions.

TABLE 35-1 Signs and Symptoms That Indicate Possible Current Sexual Abuse or a History of Sexual Abuse

Types of Findings	Symptoms Often Found in Children	Symptoms Often Found in Adults
Injuries and/or physical signs	Bruises, bleeding, soreness, infection, or irritation of external genitalia, anus, mouth, or throat Sexually transmitted infections Recurrent urinary tract infections Unintended pregnancy Chronic pain Difficulty walking or sitting Unusual odor in genital area Penile discharge Torn, stained, or bloody underclothing	Welts, bruising, swelling, scars, burns, or lacerations on arms, legs, breasts, or abdomen Wounds that do not match the patient's "story" Multiple bruises in various stages of healing Vaginal or rectal bleeding Fractures of face, nose, ribs, or arms Trauma to labia, vagina, cervix, or anus Vomiting or abdominal tenderness
Behavior, nonverbal and/or vague somatic complaints	Physical aggression Sexual acting out Excessive masturbation Expressions of low self-esteem Poor school performance Poor peer relationships Sleep disturbances Social withdrawal and excessive daydreaming Running away from home Substance abuse or suicide attempts	Facial grimacing Absence of facial response or flat affect Anxiety Depression Panic attacks Difficulty sleeping Anorexia Slow, unsteady gait

Data from Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children,* ed 10, St Louis, 2015, Elsevier; Touhy TA, Jett K: *Ebersole & Hess' Gerontological nursing and healthy aging,* ed 4, St Louis, 2014, Elsevier.

For example, a patient expresses concern about how his or her partner will respond now or makes a sexual comment or joke. Observing for and listening to concerns about sexuality take practice. With experience you develop skill in clarifying and paraphrasing to help individuals express sexual concerns. By including sexuality in the nursing history, you acknowledge that it is an important component of health and create an opportunity for a person to discuss sexual concerns.

Sexual Dysfunction. Many illnesses, injuries, medications, and aging changes have a negative effect on sexual health. Sexual dysfunction is either temporary or permanent. Apply knowledge about conditions and medications that frequently cause sexual dysfunction while assessing a patient's risks (see Box 35-4). Awareness of the possible effects of physical problems, altered self-concept, medications, and the factors addressed thus far on sexual functioning helps in conducting a thorough assessment. Some patients bring up the topic of sexual dysfunction. Other times issues become evident as the patient answers other nursing history questions.

BOX 35-7 Nursing Diagnostic Process
Sexual Dysfunction

Assessment Activities	Defining Characteristics
Review medical and medication history	History of hypertension History of uncomplicated myocardial infarction (MI) Takes propranolol (Inderal)
Have patient describe sexual problems	Less interested in having intercourse with wife since taking propranolol Rarely has sexual intercourse with wife Sometimes has trouble having an erection
Patient's fears and concerns	Fearful will have chest pain or another MI while having intercourse

Physical Assessment. The physical examination is important in evaluating the cause of sexual concerns or problems and usually provides the best opportunity to teach an individual about sexuality. In examining a woman's breasts and the external and internal genitalia, a nurse has the opportunity to assess the woman's reaction, answer questions, and provide information about the examination of anatomical and physiological structures. For example, a nurse teaches a woman how to perform breast self-examination during physical assessment (see Chapter 31). During physical assessment of the genitalia, he or she teaches men how to perform testicular self-examination (see Chapter 31). Knowledge of normal scrotal anatomical structures helps men detect signs of testicular cancer. Instruct both men and women on signs and symptoms of STIs during the examination when patients' histories suggest risks for them.

◆ **Nursing Diagnosis**

After completing an assessment, you apply critical thinking to the diagnostic process and select diagnoses applicable to the patient's needs. Assessment data that will include defining characteristics related to sexuality often include history of surgery of reproductive organs, changes in appearance or body image, a history of or current physical or sexual abuse, chronic illness, or developmental milestones such as puberty or menopause. To make a nursing diagnosis related to sexual dysfunction, consider anatomical, physiological, sociocultural, ethical, and situational issues thoroughly. Possible nursing diagnoses related to sexual functioning are listed here:

- *Anxiety*
- *Ineffective Coping*
- *Interrupted Family Processes*
- *Deficient Knowledge (Contraception/STIs)*
- *Sexual Dysfunction*
- *Ineffective Sexuality Pattern*
- *Social Isolation*

Clarify defining characteristics and ensure that the patient perceives a problem or difficulty with regard to sexuality (Box 35-7). Determining the etiological or contributing factors helps to plan effectively and select the appropriate nursing interventions. For example, nursing interventions appropriate for the nursing diagnosis of *Sexual Dysfunction* will differ for different etiological factors. *Sexual Dysfunction related to misinformation about the risk of sexually transmitted infections* requires counseling and education on how to maintain safe sexual practices. In contrast, patients who experience *Sexual Dysfunction related to physical abuse* need counseling and referral to community resources (e.g., crisis services and physical abuse support group).

Knowledge
- PLISSIT model
- Community resources for sex education information
- Community resources for contraception and STI treatment and counseling

Experience
- Establishing rapport with diverse patients
- Care of patients with HIV infection
- Care of patients with various sexual orientations

PLANNING
- Create an atmosphere in which the patient can explore sexual concerns
- Refer to appropriate resources for exploration of sexual concerns
- Explore the patient's understanding, beliefs, and attitudes regarding sexuality and sexual functioning

Standards
- Maintain the patient's dignity and identity
- Promote an environment in which the patient's values, customs, and spiritual beliefs are respected
- Report STIs as required by law
- Report cases of suspected abuse as required by law

Attitudes
- Think independently; explore various approaches to address the issue/problem
- Be creative and try unique interventions
- Demonstrate perseverance: changes in self-concept often happen slowly; continue to support the vision that change is possible
- Take risks by asking about the patient's concerns even when the topic is sensitive

FIGURE 35-3 Critical thinking model for sexuality planning. *HIV,* Human immunodeficiency virus; *STI,* sexually transmitted infection.

◆ Planning

Goals and Outcomes. Synthesize information from multiple resources to develop an individualized plan of care (Figure 35-3). Critical thinking ensures that a patient's plan of care integrates all that a nurse knows about an individual's sexuality. Professional standards are especially important to consider when developing a plan of care. Maintain a patient's dignity and identity at all times. For example, to convey respect for the patient's gender preferences, include a lesbian or gay partner in the plan to the degree that the patient wishes.

Develop an individualized plan of care for each nursing diagnosis (see the Nursing Care Plan). Set realistic goals and measurable outcomes with the patient. For example, a patient who has dyspareunia

has a nursing diagnosis of *Sexual Dysfunction related to decreased sexual desire.* You and your patient develop a goal to report decreased anxiety and greater satisfaction with sexual activity within 1 month. Expected outcomes include that the patient does the following:

- Discusses stressors that contribute to sexual dysfunction with partner within 2 weeks
- Identifies alternative, satisfying, and acceptable sexual practices for self and partner within 4 weeks

A concept map is another method that is useful in organizing patient care (Figure 35-4). The concept map shows the relationship of a medical diagnosis (decreased libido and depression) to the four nursing diagnoses identified from the patient assessment data. It also shows the links and relationship to the nursing diagnosis and interventions appropriate for each diagnosis. For example, *Ineffective Coping* affects and contributes to social isolation; and, as long as the patient has ineffective coping, the social isolation continues or perhaps worsens.

Setting Priorities. The care plan shows the goals, expected outcomes, and interventions for a patient experiencing sexual dysfunction. Nursing interventions for patients with sexual concerns focus on supporting a patient's need for intimacy and sexual activity. Patients often feel overwhelmed and hopeless about returning to the level of previous sexual functioning. They usually need time to adapt to physical and psychosocial changes that affect their sexuality and sexual health.

The priority in addressing needs related to sexuality includes establishing a therapeutic relationship so the patient feels comfortable in discussing issues related to sexuality. Look for strengths in both the patient and the family while providing education and access to resources to turn limitations into strengths. Patient teaching communicates the normalcy of feelings following certain situations (e.g., the diagnosis of a chronic illness or the loss of a body part). You determine a patient's needs and plan accordingly.

A patient's current problems and needs help you determine the priorities related to his or her sexual health. Priorities for sexual health often include resuming sexual activities. For example, if a patient is recovering from a mastectomy and is having problems resuming an intimate relationship with her spouse because of problems related to body image, you help her adapt to and cope with the changes in her body image associated with the mastectomy. Once the patient's issues related to body image are resolved, she is able to restore intimacy with her spouse and address her sexual health needs.

QSEN QSEN: BUILDING COMPETENCY IN TEAMWORK AND COLLABORATION. Mr. Clements asks what lifestyle changes he will need to make after discharge from the hospital. You know that patients with cardiovascular problems often require an interdisciplinary approach to achieve optimal recovery. Thus you arrange for consultation with different health professionals. You inform Mr. Clements that he will work with a team of experts, including cardiologists, physical therapists, dietitians, and counselors. Discuss how each of these professionals will contribute to Mr. Clements's care during and after hospitalization.

ⓔ *Answers to QSEN Activities can be found on the Evolve website.*

Teamwork and Collaboration. Planning in the area of sexuality often includes collaboration with other health care providers and referrals to community resources (Box 35-8). Nurses generally raise awareness of sexual issues, clarify concerns, and/or provide information. Nurses who have specialized education in sexual functioning and

◎ NURSING CARE PLAN

Sexual Dysfunction

ASSESSMENT

Mr. Clements is a 65-year-old African-American patient who had an uncomplicated myocardial infarction (MI) 3 days ago. He is stable and experienced no complications following his MI. He currently is on a cardiac telemetry nursing unit. According to Mr. Clements' medical record, he last visited his advanced practice nurse in the office 2 months ago and was diagnosed with hypertension. He was given a prescription for propranolol (Inderal). Mr. Clements is married and lives with his wife.

His blood pressure today is 122/82 mm Hg. He reports that he has been taking his medication regularly. You know that patients who have had MIs and are taking antihypertensive medications often experience sexual problems. When assessed, Mrs. Clements expresses that she is still interested in having a sexual relationship with her spouse.

Assessment Activities	*Findings/Defining Characteristics**
Ask Mr. Clements if his interest in sex has changed since he started taking propranolol.	He responds that he has been **less interested in having sexual intercourse with his wife** since he started taking propranolol.
Ask Mr. Clements to compare his sexual relationship with his wife before and after taking propranolol.	He states they used to have intercourse 1 to 3 times per week; and, since he started taking propranolol, **they rarely have intercourse.**
Ask Mr. Clements if he has had difficulties with an erection.	He states that he **sometimes has trouble having an erection.**
Ask Mr. Clements what concerns or fears he has about resuming his sexual relationship with his wife now that he has had an MI.	He states that **he is afraid that after discharge he will have chest pain or another heart attack if he has sexual intercourse** with his wife.

*Defining characteristics** are shown in bold type.

NURSING DIAGNOSIS: Sexual dysfunction related to altered body function (side effects of propranolol) and lack of knowledge

PLANNING

Goal	*Expected Outcomes (NOC)*[†]
Sexual Functioning	
Patient will express satisfaction with sexual relationship with wife within 1 month.	Patient expresses renewed sexual interest within 2 weeks.
	Patient sustains arousal through orgasm within 3 weeks.

[†]Outcome classification labels from Moorhead S et al: *Nursing outcomes classification (NOC),* ed 5, St Louis, 2013, Mosby.

INTERVENTIONS (NIC)[‡]

	RATIONALE
Sexual Counseling	
Establish trust and respect with Mr. Clements. Offer privacy during conversations.	Establishing trust and offering privacy express sense of caring, increasing likelihood of patient's ability to express concerns (Taylor and Gosney, 2011).
Discuss possible effects of MI and propranolol on sexual functioning and resumption of sexual activity.	Discussion enhances understanding about reasons for sexual difficulties and provides safe guidelines for resumption of sexual intercourse following MI (Bispo et al., 2013).
Include Mrs. Clements in discussions about sexual issues as frequently as possible and when appropriate.	Including partner in the plan of care can enhance personal and intimate relationships and improve health outcomes (Arenhall et al., 2011; Bispo et al., 2013).
Anxiety Reduction	
Encourage Mr. Clements to express fears about resuming sexual activity and assure him that others who have had MIs experience similar fears.	Sexual dysfunction sometimes occurs after an MI because of anxiety and/or from side effects of medications (Bispo et al., 2013). Knowing that feelings and fears are normal helps decrease anxiety and encourages return of sexual activity.

[‡]Intervention classification labels from Bulechek GM et al: *Nursing interventions classification (NIC),* ed 6, St Louis, 2013, Mosby.

EVALUATION

Nursing Actions	*Patient Response/Finding*	*Achievement of Outcome*
Ask Mr. Clements if he and his wife are satisfied with their sexual relationship during return office visit.	Mr. Clements reports that his interest in sex is back to normal and he is able to have an erection.	Mr. Clements reports sexual interest and function; he and his wife are satisfied with their relationship.

---

counseling provide more intensive sex therapy. It is necessary to understand the limits of your knowledge base and include other health care providers such as sex therapists, clinical psychologists, and social workers as appropriate to meet patients' needs for sexual health. For example, conflicts in marriage usually require intensive treatment with a mental health professional or certified sex therapist. For the woman who is currently in an abusive relationship, the nurse collaborates with special women's shelters that provide counseling and serve as a safe place for her while further plans are made.

◆ Implementation

Promote sexual health as a component of overall health and wellness by identifying patients at increased risk, providing appropriate information, helping individuals gain insight into their problems, and exploring methods to deal with them effectively.

Health Promotion. Helping patients maintain or gain sexual health involves consideration of factors that influence sexual satisfaction. Educate patients about sexual health, including measures for

CONCEPT MAP

Nursing diagnosis: Sexual dysfunction
- Decreased interaction with spouse
- Blames spouse for dysfunction
- States he does not enjoy sex
- Unwilling to have nonsexual intimacy
- Dysfunction began 4 months after diagnosis of depression

Interventions
- Establish therapeutic relationship with patient
- Confirm that physical reasons for dysfunction are being addressed
- Identify specific sources of concern about sexual activity

Nursing diagnosis: Ineffective coping
- Neglects spouse and their relationship
- Has withdrawn from job, friends, and children
- Blames family for problems
- Will not seek medical treatment for sexual dysfunction

Interventions
- Educate patient about how to manage the treatment effects that affect his sexuality
- Encourage patient to express feelings
- Help patient set realistic goals

Primary health problem: Decreased libido and depression
Priority assessments: Sexual function, coping strategies, interactions with others, and presence of anxiety and/or fear

Nursing diagnosis: Fear
- Verbalizes fear that condition is permanent
- Lack of appetite/weight loss
- Fears that spouse will leave

Interventions
- Help patient identify coping skills used previously to deal with fears
- Assess for anxiety or history of anxiety
- Validate patient's feelings regarding fear

Nursing diagnosis: Social isolation
- Refuses to go out with couples group
- Seeks out solitary hobbies away from family
- Avoids interactions with co-workers

Interventions
- Help patient identify causes of perceived or actual isolation
- Identify individuals who are supportive for patient, and include in care when appropriate
- Make recommendations for how to engage with friends or family; consider patient's cultural values

——— Link between medical diagnosis and nursing diagnosis   - - - - - Link between nursing diagnoses

FIGURE 35-4 Concept map for Mr. Clements.

BOX 35-8   Examples of Community Resources Relating to Sexuality

- Community and free clinics offering contraceptive information and resources
- Health department (often for both family planning and sexually transmitted infections)
- Groups that provide education/services for those with particular conditions include the following:
  - American Diabetes Association
  - American Heart Association
- Muscular Dystrophy Association
- Muscular Sclerosis Society
- Sexual abuse support groups and hot lines
- Women's shelters (for those who have been physically and/or sexually abused)
- Resolve: The National Infertility Association (http://www.resolve.org)
- North America Menopause Society (http://www.menopause.org)

contraception, safe sex practices, and prevention of STIs. Regular breast self-examinations, mammograms, and Papanicolaou (Pap) smears are important sexual health measures for women; testicular self-examinations are important for men. Offer the 9-valent HPV vaccine to males and females who are between 11 and 26 years of age (ACOG, 2015; CDC 2015b). The vaccine is safe for girls as young as 9 years old and is recommended for females ages 11 to 26 if they have not already completed the three required injections. Booster doses currently are not recommended. The vaccine is most effective if administered before sexual activity or exposure (ACOG, 2015).

Exploring an individual's values, discussing levels of satisfaction, and providing sex education require therapeutic communication skills. Structure the environment and timing to provide privacy, comfort, and uninterrupted time (Ayaz, 2013). For example, when discussing methods of contraception with a woman, provide education in a private area with the patient fully dressed rather than in the examination room when the patient is only partially clothed.

Topics of education vary and often are related to a patient's developmental level. For example, a nurse talks to school-age children regarding the appearance of breast buds or pubic hair. When discussing sexual health with patients of childbearing age, always consider a patient's cultural and religious beliefs regarding contraception. The discussion includes the desire for children, usual sexual practices, and acceptable methods of contraception. Review all methods of contraception to allow patients to make informed decisions.

Major developmental crises (e.g., puberty, **climacteric,** or menopause) prompt education about sexuality. Situational crises such as a life change with pregnancy, illness, divorce, extreme financial stress, placement of a spouse in a nursing home, or loss and grief affect sexuality. Effects sometimes last for days, months, or years and are often minimized when the individual is prepared for possible changes in sexual functioning.

Demonstrate recognition, acceptance, and respect for an older adult's sexuality by displaying a willingness to openly discuss sex and sexuality-related concerns. Strategies that enhance sexual functioning include the following (Bach et al., 2013; Buttaro et al., 2014):

- Avoid alcohol (in excess) and tobacco.
- Eat well-balanced meals.
- Plan sexual activity for times when the couple feels rested.
- Take pain medication if needed before sexual intercourse.
- Use pillows and alternate positioning to enhance comfort.
- Encourage touch, kissing, hugging, and other tactile stimulation.
- Communicate concerns and fears with partner and health care provider.

Individuals who have more than one sex partner or whose partner has other sexual experiences need to learn about safe sex practices. Provide information about STI symptoms and transmission, use of condoms, and risky sexual activities (e.g., trauma from penile-anal sex). To prevent HIV infection, teach patients to avoid having multiple sex partners and use condoms to reduce the risk of HIV/AIDS. Role play is useful in helping a person learn to say no or negotiate with a partner to use a condom (Box 35-9). Also teach patients to avoid the use of IV drugs. If people do use IV drugs, tell them to avoid sharing needles with others and to always use new needles. When discussing safe sex, consider patients' physical and emotional health.

Encourage patients to have regular health and screening examinations to maintain sexual health. Often asymptomatic STIs are diagnosed during a physical examination with appropriate laboratory work. Annual health examinations provide an opportunity to discuss contraception and safe sex practices. However, some people do not seek annual health examinations routinely. For example, Arab women

---

BOX 35-9   PATIENT TEACHING

Using a Condom Correctly

Objective
- Patient will verbalize correct use of a condom.

Teaching Strategies
- Develop a trusting relationship with patient.
- Explain to patient to always use a latex or rubber condom when having vaginal, oral, or anal sex and to store condoms in a cool, dry place away from sunlight.
- Encourage patient to read the label on the condom package to check the expiration date and ensure that the condom protects against sexually transmitted infections.
- Instruct patient to never reuse a condom or use a damaged condom.
- Explain how to apply the condom correctly (e.g., put it on as soon as the penis is hard and before vaginal, anal, or oral contact; gently squeeze any air out from the tip of the condom, leaving space for semen; unroll the condom to the base of the penis).
- Teach patient to pull out right after ejaculating and hold onto the condom when pulling out.
- Instruct patient to only use water-based lubricants (e.g., K-Y jelly) to prevent the condom from breaking; do not use petroleum jelly, massage oils, body lotions, or cooking oil.

Evaluation
- Ask patient to describe where condoms are stored.
- Ask patient questions that verify understanding of instruction (e.g., What would you do if you noticed that a condom you just opened had an open slit in it?).

---

frequently do not have breast examinations, mammograms, and cervical cancer screening because of religious and cultural beliefs about modesty (Cohen and Azaiza, 2010). Develop a therapeutic relationship with patients and provide culturally sensitive education that is written at an appropriate reading level (see Chapter 25). Barriers to reproductive health services include cultural beliefs, low socioeconomic status, and low health literacy (Hall et al, 2012). The Affordable Health Care Act offers increased access to health care for previously uninsured individuals (USDHHS, 2012).

Acute Care. Illness and surgery create situational stressors that often affect a person's sexuality. During periods of illness individuals experience major physical changes, the effects of drugs or treatments, the emotional stress of a prognosis, concern about future functioning, and separation from significant others. Never assume that sexual functioning is not a concern merely because of an individual's age or severity of prognosis. After identifying concerns, address them in the context of his or her value system.

When a patient identifies sexual concerns, initiate discussion and education appropriately. Refer to appropriate outpatient resources. Help patients anticipate how their illness or disease will change over time and the adjustments that will be necessary to achieve sexual fulfillment.

Restorative and Continuing Care. You need to establish relationships with couples to encourage honest and open discussions about sexual health during restorative or continuing care. Address needs by taking a sexual health history and implementing a basic model such as PLISSIT to provide options for patients (see Box 35-5). Assessment and management of sexual concerns are important when

promoting sexual intimacy and providing closeness and closure between partners at the end of life.

In the home environment it is important to provide information on how an illness limits sexual activity and give ideas for adapting or facilitating sexual activity. Interventions range from giving permission for a partner to lie in bed and hold a patient to coordinating nursing care and medications to provide opportunity for privacy and intimacy. Often nurses help individuals create an environment that is comfortable for sexual activity in the home. This sometimes involves making recommendations for ways to arrange the bedroom to accommodate physical limitations. For example, some individuals who are in a wheelchair prefer being able to move the chair close to the side of the bed at an angle that allows for more ease in touching and caressing. Suggestions regarding how to accommodate barriers such as Foley catheters or drainage tubes contribute to sexual activity.

In the long-term care setting facilities need to make proper arrangements for privacy during residents' sexual experiences (Katz, 2013). The ideal situation is to set up a pleasant room that is used for a variety of activities that the resident is able to reserve for private visits with a spouse or partner. If this is not possible, make arrangements for the roommate of a patient to be somewhere else to allow a couple time alone. Never leave patients alone in a situation in which they can injure themselves.

◆ **Evaluation**

Through the Patient's Eyes. Evaluate patients' perceptions of nursing interventions to determine if their expectations have been met. Critical thinking ensures that you apply what is known about sexuality and a patient's unique situation.

Have follow-up discussions with the patient or partner to determine if they were satisfied with your approaches. Sexuality is felt more than observed, and sexual expression requires an intimacy that is not amenable to observation.

Patient Outcomes. Evaluate if patient achieved outcomes established in the plan of care (Figure 35-5). Ask patients questions about risk factors, sexual concerns, and their level of satisfaction. Observe behavioral cues such as eye contact, posture, and extraneous hand movements that indicate comfort or suggest continued anxiety or concern as topics are addressed. Anticipate the need to modify expectations with an individual and partner when evaluating outcomes. Sometimes you need to establish more appropriate time frames in which to achieve target goals. Ask patients to define what is acceptable and satisfying while considering the partner's level of sexual satisfaction. When outcomes are not met, begin to ask questions to determine appropriate changes in interventions. Examples of questions include the following:

- What other questions do you have about your sexual health?
- Did you experience less pain during sexual intercourse after taking your pain medication?
- Which positions did you find most comfortable when you had sexual intercourse? Which positions were most awkward?
- What barriers are preventing you from discussing your feelings and fears with your partner?

■ **KEY POINTS**

- Sexuality is related to all dimensions of health, is a part of each individual's identity, and includes biological sex, gender identity, gender role, and sexual partner preference.
- Attitudes toward sexuality vary widely. Religious beliefs, society values, the media, the family, and other factors all influence it.

Knowledge
- Characteristics of normal sexuality and sexual response
- Physical assessment findings
- Impact of medical condition and medication on sexual functioning

Experience
- Establishing rapport with diverse patients
- Care of patients with HIV
- Care of patients with various sexual orientations

EVALUATION
- Evaluate the patient's perceptions of sexual function
- Ask the patient to discuss safe sex practices
- Ask the patient to identify those risk factors that predispose him or her to STIs
- Ask if the patient's expectations are being met

Standards
- Use established expected outcomes to evaluate the patient's response to care (e.g., ability to express concerns openly)
- Determine that the patient's privacy has been safeguarded throughout care

Attitudes
- Persist in trying various approaches to change the patient's unsafe practices and promote contraceptive use
- Display integrity in preserving the patient's confidentiality

FIGURE 35-5 Critical thinking model for sexuality evaluation. *HIV,* Human immunodeficiency virus; *STI,* sexually transmitted infection.

- Nurses' attitudes toward sexuality vary and often differ from those of patients; be sensitive to patients' sexual preferences and needs.
- Sexual development begins in infancy and involves some level of sexual behavior or growth in all developmental stages.
- The physiological sexual response changes with aging, but aging does not lead to diminished sexuality.
- Sexual health contributes to an individual's sense of self-worth and positive interpersonal relationships.
- Sexual dysfunctions result from varied and complex etiologies.
- Interventions for sexual dysfunctions depend on the condition and the patient; they often include giving information, teaching specific exercises, improving communication between partners, and referral to a knowledgeable professional.
- Sexual biases, comfort with touching genitalia, desire for future fertility, financial status, ability to plan sexual contact, and ability to communicate with the sex partner all affect the choice and use of effective contraceptive methods.
- Include a brief review of sexuality whenever assessing a patient's level of wellness.
- Most nursing interventions that enhance sexual health require providing education.
- Evaluate patient satisfaction with outcomes of care by talking with patients regarding satisfaction with sexual functioning and through observations of nonverbal behaviors that suggest anxiety. Include the partner when appropriate.

CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

1. You are assessing Mr. Clements during his 4-week follow-up appointment after discharge from the hospital. You need to include a sexual health history as a routine part of the nursing history. Give examples of nonjudgmental questions you will ask to determine his sexual function.

2. After determining Mr. Clements sexual orientation, how would you establish a therapeutic relationship to put him at ease discussing the intimate aspects of his life?

3. Mr. and Mrs. Clements both vocalize concern about initiating sexual activity since his MI, saying they are concerned that it might cause another MI. Mrs. Clements states that he seems less interested in intimacy than before the MI and tires easily. Provide at least three strategies that they could use to enhance their sexual functioning.

REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. A 16-year-old female tells the school nurse that she doesn't need the human papillomavirus (HPV) vaccine since her partner always uses condoms. The best response by the nurse to this statement is:
   1. Latex condoms are the most effective way to eliminate the risk of HPV transmission.
   2. Your parents may not want you to receive the HPV vaccine since it has been shown to increase sexual risk taking and sexual activity.
   3. The HPV 9-valent vaccine is recommended for males and females and targets the specific viruses that cause cancer and genital warts.
   4. You are past the recommended age to receive the vaccine.

2. Place the following in order of sequence for condom application and usage.
   1. Gently squeeze air out from the tip of the condom; leave space at the tip.
   2. Check the condom package for damage, expiration date, and protection from STIs.
   3. After ejaculating, hold onto condom while pulling out.
   4. Place on erect penis and unroll to the base of the penis.

3. An adolescent who is pregnant for the first time is at her initial prenatal visit. The women's health nurse practitioner (NP) informs her that she will be screening her for sexually transmitted infections (STIs). The patient replies, "I know I don't have an STI because I don't have any symptoms." How should the NP respond? (Select all that apply.)
   1. "Untreated STIs can cause serious complications in pregnancy so we routinely screen pregnant women."
   2. "Bacterial STIs don't usually cause symptoms, but you could have an asymptomatic viral STI."
   3. "Chlamydia screening is recommended for all sexually active women up to age 25 even if asymptomatic."
   4. "People between the ages of 15 and 24 have the highest incidence of STIs."
   5. "There is no need to screen for infection since you aren't having any problems or symptoms."

4. A 42-year-old sexually active female is being assessed by a nurse during her annual physical. The woman states that she has not had a period for the last 2 months. The nurse knows that the most likely cause of this occurrence is:
   1. Pregnancy.
   2. Illicit drug use.
   3. Chlamydia infection.
   4. Early-onset menopause.

5. A cardiac nurse who recently graduated from nursing school is providing discharge instructions to a patient who suffered a myocardial infarction (MI). The nurse knows that sexual issues are common after an MI but doesn't feel comfortable bringing up this topic. What is the best way for the nurse to handle this situation? (Select all that apply.)
   1. Instruct the patient to discuss any sexual concerns with his or her partner after discharge
   2. Avoid discussing the topic unless the patient brings it up
   3. Ask a more experienced nurse to cover this with the patient and learn from the example.
   4. Plan to attend conferences or training in the near future on how to discuss such issues
   5. Encourage the patient to discuss any personal concerns with the cardiologist

6. The nurse is gathering a history from a 72-year-old male patient being admitted to a nursing home. The patient requests a private room. The nurse understands that:
   1. The patient cannot be sexually active since he is moving into a nursing home.
   2. The patient may be requesting a private room to facilitate an intimate relationship with his partner.
   3. There is no need to take a sexual history since most older adults are uncomfortable discussing intimate details of their lives.
   4. Older adults in nursing homes usually do not participate in sexual activity.

7. According to *Healthy People 2020*, certain ethnic groups in the United States are disproportionately affected by sexually transmitted infections (STIs) and human immunodeficiency virus (HIV). What are the likely causes of this issue? (Select all that apply.)
   1. The large percentage of lesbian, gay, bisexual, or transgender individuals in the culture
   2. Values and expectations about sexual behavior by the men or women in the culture
   3. Religious beliefs and cultural attitudes toward the use of contraceptives
   4. Educational background and knowledge of health risks associated with sexual behaviors
   5. The higher incidence of sexual abuse in the affected ethnic groups

8. The nurse is completing an admission history on a patient and says, "As a routine part of your medical history, it's important to include the sexual aspects of your life. Would it be alright if we discussed this?" This is an example of the nurse using the PLISSIT model to:
   1. Place the patient in control of the situation.
   2. Ask permission to discuss sexuality issues.
   3. Provide the patent with limited information about sexual issues.
   4. Ask the patient to provide sensitive information.

9. A 17-year-old girl asks for more information about birth control methods and says that she does not want her parents to know she

is using birth control. The nurse informs the patient that the most effective option for her situation would be:

1. An effective long-term method such as a subdermal implant.
2. A hormonal method such as birth control pills or the transdermal patch.
3. A long-acting hormonal injection given every 12 weeks.
4. Abstinence during her most fertile time.

10. The nurse is providing education on sexually transmitted infections (STIs) to a group of older adults. The nurse knows that further teaching is needed when the participants make which statements? (Select all that apply.)
    1. "I don't need to use condoms since there is no risk for pregnancy."
    2. "I should be screened for an STI each time I'm with a new partner."
    3. "I know I'm not infected because I don't have discharge or sores."
    4. "I was tested for STIs last year so I know I'm not infected."
    5. "The infection rate in older adults is low because most are not sexually active."

11. The nurse is providing community education about how the sexual response changes with age. Which statement made by one of the adults indicates the need for further information?
    1. "Health problems such as diabetes, chronic obstructive pulmonary disease, and hypertension have little effect on sexual functioning and desire."
    2. "It usually takes longer for both sexes to reach an orgasm."
    3. "Most of the normal changes in function are related to alteration in circulation and hormone levels."
    4. "Many medications can interfere with sexual function."

12. The nurse is gathering a sexual health history on a patient being admitted to the hospital for surgery. Which question asked by the nurse demonstrates a nonjudgmental attitude?
    1. Can you tell me your sexual orientation?
    2. How do you and your wife feel about intimacy?
    3. Do you have sex with men, women, or both?
    4. Do you have sexual intercourse at your age?

13. The nurse reviews the health history of a 48-year-old man and notes that he was started on medications for elevated blood pressure and depression at his last annual physical. He tells the nurse that over the past 6 months he is having difficulty sustaining an erection. The nurse understands that: (Select all that apply.)
    1. Nurses are not expected to discuss sexual issues with male patients and the physician should address this.

2. Sexual function can be affected negatively by some medications.
3. Sexually transmitted infections (STIs) can cause complications such as erectile dysfunction and screening should be done.
4. It is not unusual for men with health issues to experience erectile dysfunction.
5. Medications used to treat hypertension and depression seldom interfere with sexual function.

14. The school nurse is counseling an adolescent male who is returning to school after attempting suicide. He denies substance abuse and has no history of treatment for depression. He says he has no friends or family who understand him. Critical thinking encourages the nurse to consider all possibilities, including which of the following? (Select all that apply.)
    1. Adolescents often explore their sexual identity and expose themselves to complications such as sexually transmitted infections (STIs) or unplanned pregnancy.
    2. Peer approval and acceptance are not important in this age-group.
    3. Lesbian, gay, bisexual, and transgender (LGBT) youth often experience stress from identification with a sexual minority group.
    4. Knowledge about normal changes associated with puberty and sexuality can decrease stress and anxiety.
    5. Adolescence is a time of emotional stability and self-acceptance.

15. A 53-year-old female being treated for breast cancer tells the nurse that she has no interest in sex since her surgery 2 months ago. The nurse is aware that: (Select all that apply.)
    1. Sexual issues are expected in a woman this age.
    2. Women experience sexual dysfunction more frequently than men.
    3. Hypoactive sexual desire disorder (HSDD) occurs in women over 65 years of age.
    4. It is not unusual for medical conditions such as cancer to contribute to HSDD.
    5. Disturbances in self-concept affect sexual functioning.

Spiritual Health

The word *spirituality* comes from the Latin word *spiritus,* which refers to breath or wind. The spirit gives life to a person. It signifies whatever is at the center of all aspects of a person's life. Florence Nightingale believed that spirituality was a force that provided energy needed to promote a healthy hospital environment and that caring for a person's spiritual needs was just as essential as caring for his or her physical needs (Reinert and Koenig, 2013). Today **spirituality** is often defined as an awareness of one's inner self and a sense of connection to a higher being, nature, or some purpose greater than oneself (McSherry and Jamieson, 2013; Prentis et al., 2014). A person's health depends on a balance of physical, psychological, sociological, cultural, developmental, and spiritual factors. Spirituality helps individuals achieve the balance needed to maintain health and well-being and cope with illness.

Too often nurses and other health care providers fail to recognize the spiritual dimension of their patients because spirituality is not scientific enough, it has many definitions, and it is difficult to measure. In addition, some nurses and health care providers do not believe in God or an ultimate being, some are not comfortable with discussing the topic, and others claim that they do not have time to address patients' spiritual needs (McSherry and Jamieson, 2013; Ronaldson et al., 2012). The concepts of spirituality and religion are often interchanged, but spirituality is a much broader and more unifying concept than religion (Rykkje et al., 2013).

The human spirit is powerful, and spirituality has different meanings for different people. Nurses need to be aware of their own spirituality to provide appropriate and relevant spiritual care to others.

They need to care for the whole person and accept a patient's beliefs and experiences (Cockell and McSherry, 2012). Being able to determine the importance that spirituality holds for patients depends on your ability to develop caring relationships (see Chapter 7).

SCIENTIFIC KNOWLEDGE BASE

The relationship between spirituality and healing is not completely understood. However, an individual's intrinsic spirit seems to be an important factor in healing. Healing often takes place because of believing. Research shows that spirituality positively affects and enhances physical and psychological health, quality of life, health promotion behaviors, and disease prevention activities (Conway-Phillips and Janusek, 2014; White, 2013).

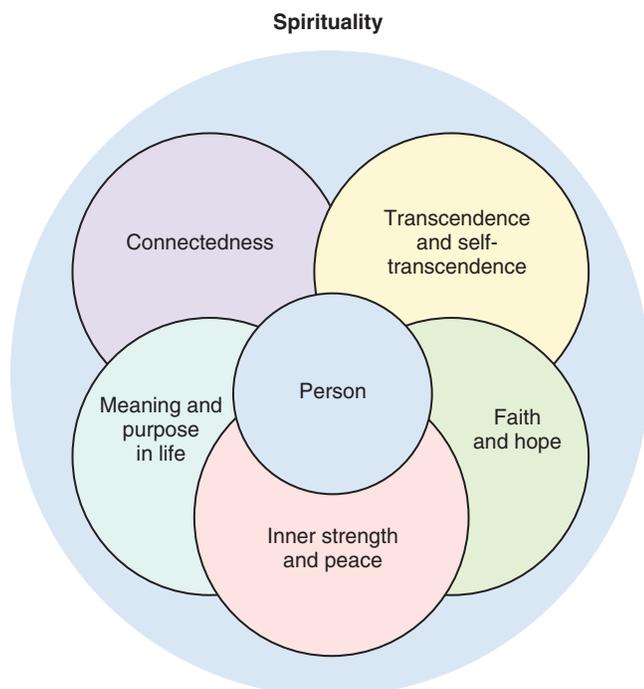
Many of the beneficial effects of spirituality are tied to hormonal and neurological function. For example, regular performance of relaxation exercises was found to reduce physiological dysregulation, including inflammation markers in elderly persons (Glei et al., 2012). Integrative body-mind techniques that include relaxation, guided imagery, mindfulness training, and music reduce perceptions of pain and anxiety (Fan et al., 2014). Laughter reduces pain; positively affects depression, life satisfaction, insomnia, and sleep quality; improves blood sugar levels; and elevates self-reports of health (Gilbert, 2014; Hirosaki et al., 2013). A person's inner beliefs and convictions are powerful resources for healing. When you support the spirituality of patients and their families, you help them achieve desirable health outcomes.

NURSING KNOWLEDGE BASE

Nursing research shows the association between spirituality and health. For example, family caregivers of patients with brain tumors who expressed high levels of spirituality experienced less depression and anxiety and better mental health when compared with family caregivers who expressed lower levels of spirituality (Newberry et al., 2013). Research has also shown that prayer often helps African-American women diagnosed with breast cancer cope effectively with cancer-related fatigue (Morgan et al., 2014). The interest in studying the relationship between spirituality and health has greatly contributed to nursing science.

Current Concepts in Spiritual Health

A variety of concepts describing spiritual health are a part of professional nursing practice. To provide meaningful and supportive spiritual care, it is important to understand the concepts of spirituality, spiritual well-being, faith, religion, and hope. Each concept offers direction in understanding the views that individuals have of life and its value.

Spirituality. Spirituality is a complex concept that is unique to each individual; it depends on a person's culture, development, life experiences, beliefs, and ideas about life (Cohen et al., 2012). It is an inherent human characteristic that exists in all people, regardless of their religious beliefs (McSherry and Jamieson, 2013). It gives individuals the *energy* needed to discover themselves, cope with difficult situations, and maintain health. Energy generated by spirituality helps patients feel well and guides choices (e.g., type and extent of health care) made throughout life. Spirituality enables a person to love, have faith and hope, seek meaning in life, and nurture relationships with others. Because it is subjective, multidimensional, and personal, researchers and scholars cannot agree on a universal definition of spirituality (McSherry and Jamieson, 2013). However, five distinct but overlapping constructs are used to define it (Figure 36-1).


Spirituality

FIGURE 36-1 The concept of spirituality has five distinct but overlapping constructs.

- **Self-transcendence**—a sense of authentically connecting to one's inner self (Haugan et al., 2012). This contrasts with **transcendence,** the belief that a force outside of and greater than the person exists beyond the material world (Hatamipour et al., 2015). Self-transcendence is a positive force. It allows people to have new experiences and develop new perspectives that are beyond ordinary physical boundaries. Examples of transcendent moments include the feeling of awe when holding a new baby or looking at a beautiful sunset.
- **Connectedness**—being *intrapersonally* connected within oneself; *interpersonally* connected with others and the environment; and *transpersonally* connected with God, or an unseen higher power. Through connectedness patients move beyond the stressors of everyday life and find comfort, faith, hope, and empowerment (Phillips-Salimi et al., 2012).
- **Faith**—allows people to have firm beliefs despite lack of physical evidence. It enables them to believe in and establish transpersonal connections. Although many people associate faith with religious beliefs, it exists without them (Dyess, 2011).
- **Hope**—has several meanings that vary on the basis of how it is being experienced; it usually refers to an energizing source that has an orientation to future goals and outcomes (Kavradim et al., 2013; Soundy et al., 2014).

Spirituality gives people the ability to find a dynamic and creative sense of *inner strength* to be used when making difficult decisions. This source of energy helps people stay open to change and life challenges, provides confidence in decision making, and promotes connections with others and a positive outlook on life (Viglund et al., 2014). *Inner peace* fosters calm, positive, and peaceful feelings despite life experiences of chaos, fear, and uncertainty. These feelings help people feel comforted even in times of great distress (Hatamipour et al., 2015). Spirituality also helps people find *meaning and purpose in life* in both positive and negative life events (Hatamipour et al., 2015; White, 2013).

Some people do not believe in the existence of God (**atheist**), or they believe that there is no known ultimate reality (**agnostic**). Nonetheless spirituality is important regardless of a person's religious beliefs (Hsiao et al., 2013). Atheists search for meaning in life through their work and their relationships with others. Agnostics discover meaning in what they do or how they live because they find no ultimate meaning for the way things are. They believe that people bring meaning to what they do.

Spirituality is an integrating theme. A person's concept of spirituality begins in childhood and continues to grow throughout adulthood (Bryant-Davis et al, 2012). It represents the totality of one's being, serving as the overriding perspective that unifies the various aspects of an individual. It spreads through all dimensions of a person's life, whether or not the person acknowledges or develops it.

Spiritual Well-Being. The concept of **spiritual well-being** has two dimensions. One dimension supports the transcendent relationship between a person and God or a higher power. The other dimension describes positive relationships and connections that people have with others (Petersen, 2014). Those who experience spiritual well-being feel connected to others and are able to find meaning or purpose in their lives. Those who are spiritually healthy experience joy, are able to forgive themselves and others, accept hardship and mortality, and report an enhanced quality of life (Haugan et al., 2014).

Faith. In addition to being a component of spirituality, the concept of faith has other definitions. It is a cultural or institutional religion such as Judaism, Buddhism, Islam, or Christianity. It is also a

relationship with a divinity, higher power, or spirit that incorporates a reasoning faith (belief) and a trusting faith (action). Reasoning faith provides confidence in something for which there is no proof. It is an acceptance of what reasoning cannot explain. Sometimes faith involves a belief in a higher power, spirit guide, God, or Allah. It is also the manner in which a person chooses to live. It gives purpose and meaning to an individual's life, allowing for action (Dyess, 2011). Patients who are ill often have a positive outlook on life and continue to pursue daily activities rather than resign themselves to the symptoms of their disease. Their faith becomes stronger because they view their illness as an opportunity for personal growth (Granero-Molina et al., 2014).

Religion. Religion is associated with the "state of doing," or a specific system of practices associated with a particular denomination, sect, or form of worship. It is a system of organized beliefs and worship that a person practices to outwardly express spirituality. Many people practice a faith or belief in the doctrines and expressions of a specific religion or sect such as the Lutheran church or Judaism. People from different religions view spirituality differently. For example, a Buddhist believes in Four Noble Truths: life is suffering; suffering is caused by clinging; suffering can be eliminated by eliminating clinging; and to eliminate clinging and suffering, one follows an eightfold path (i.e., right understanding, intention, speech, action, livelihood, effort, mindfulness, and concentration). A Buddhist turns inward, valuing self-control, whereas a Christian looks to the love of God to provide enlightenment and direction in life.

When providing spiritual care, it is important to understand the differences between religion and spirituality. Many people tend to use the terms interchangeably. Although closely associated, they are not synonymous. Religious practices encompass spirituality, but spirituality does not need to include religious practice. Religious care helps patients maintain their faithfulness to their belief systems and worship practices. Spiritual care helps people identify meaning and purpose in life, look beyond the present, and maintain personal relationships and a relationship with a higher being or life force.

Hope. A spiritual person's faith brings hope. When a person has the attitude of something to live for and look forward to, hope is present. It is a multidimensional concept that provides comfort while people endure life-threatening situations, hardships, and other personal challenges. It is closely associated with faith and is energizing. Hope motivates people to achieve such as adopting healthy behaviors. People express hope in all aspects of their lives to help them deal with life stressors. It is a valuable personal resource whenever someone is facing a loss (see Chapter 37) or a difficult challenge (Ruchiwit, 2012).

Spiritual Health

People gain spiritual health by finding a balance between their values, goals, and beliefs and their relationships within themselves and others. Throughout life a person often grows more spiritual, becoming increasingly aware of the meaning, purpose, and values of life. In times of stress, illness, loss, or recovery, a person uses previous ways of responding or adjusting to a situation. Often these coping styles lie within the person's spiritual beliefs.

Spiritual beliefs change as patients grow and develop. Spirituality begins as children learn about themselves and their relationships with others, including a higher power. For example, the attitude of trust in a God actually begins when a baby learns to trust in the dependability of his "God-like" parents' care and love (Neifert, 2011). Nurses who understand a child's spiritual beliefs are able to care for and comfort the child (Petersen, 2014). As children mature into adulthood, they experience spiritual growth by entering into lifelong relationships with people who share similar values and beliefs.

Beliefs among older people vary on the basis of cultural factors such as gender, past experience, religion, ethnicity, and economic status. Healthy spirituality in older adults gives peace and acceptance of the self and is often the result of a lifelong connection with a higher power. A study found that older adult women demonstrate spiritual resilience, expressed by maintaining a purpose in life and expressing gratitude, which promotes spiritual well-being (Manning, 2014). Illness and loss sometimes threaten and challenge the spiritual developmental process. Older adults often express their spirituality by turning to important relationships and giving of themselves to others (Edelman and Mandle, 2014).

Factors Influencing Spirituality

When illness, loss, grief, or a major life change occurs, people either use spiritual resources to help them cope, or spiritual needs and concerns develop. **Spiritual distress** is "a state of suffering related to the impaired ability to experience meaning in life through connections with self, others, the world, or a superior being" (Herdman and Kamitsuru, 2014). It causes people to question their identity and feel doubt, loss of faith, and a sense of being alone or abandoned. Individuals often question their spiritual values, raising questions about their way of life, purpose for living, and source of meaning. Spiritual distress also occurs when there is conflict between a person's beliefs and prescribed health regimens or the inability to practice usual rituals.

Acute Illness. Sudden, unexpected illness often creates spiritual distress. For example, both the 50-year-old patient who has a heart attack and the 20-year-old patient who is in a motor vehicle accident face crises that threaten their spiritual health. The illness or injury creates an unanticipated scramble to integrate and cope with new realities (e.g., disability). People often look for ways to remain faithful to their beliefs and value systems. Some pray, attend religious services more often, or spend time reflecting on the positive aspects of their lives. In an older study that remains relevant today, patients who experienced acute myocardial infarction found spirituality to be a life-giving force that led patients to find meaning and purpose to their lives (Walton, 1999). The researcher found that patients experienced different phases of finding meaning and purpose in life: facing mortality, releasing fear and turmoil, identifying and making lifestyle changes, seeking divine purpose, and making meaning in daily life. Anger and releasing fear are common; patients sometimes express it against God, their families, themselves, or their health care providers. The strength of a patient's spirituality influences how he or she copes with sudden illness and how quickly he or she moves to recovery. Nurses use knowledge of a person's spiritual well-being and implement spiritual interventions to maximize inner peace and healing (Yeager et al., 2010).

Chronic Illness. Many chronic illnesses threaten a person's independence, causing fear, anxiety, and spiritual distress. Dependence on others for routine self-care needs often creates feelings of powerlessness. Powerlessness and the loss of a sense of purpose in life impair the ability to cope with alterations in functioning. Spirituality is an important dimension of how patients live with advanced illness (Asgeirsdottir et al., 2013) (Box 36-1). Successful adaptation provides spiritual growth. Patients who have a sense of spiritual well-being feel connected with a higher power and others, are able to find meaning and purpose in life, and are better able to cope with and accept their chronic illness.

Terminal Illness. Terminal illness causes fears of physical pain, isolation, the unknown, and dying. It creates an uncertainty about

BOX 36-1   EVIDENCE-BASED PRACTICE

Spirituality and Chronic Illness

PICO Question: How do perceptions of spirituality affect well-being and quality of life in patients with chronic illnesses?

Summary of Evidence

All aspects of a patient's life are affected by a chronic illness. Current research supports that spirituality helps patients cope with the effects of their chronic illnesses, leading to enhanced well-being and quality of life (QOL) (Delgado-Guay, 2014). For example, existential well-being (having a purpose in life and being satisfied with life) significantly contributes to the health status of patients living with human immunodeficiency virus (HIV) (Cobb, 2012; Dalmida et al., 2012) and cancer (Delgado-Guay, 2014). Religiosity and closeness to God help patients accept death (Daaleman and Dobbs, 2010). Spiritual care (both religious and nonreligious) is a vital factor in well-being and quality of life at the end of life, and multidisciplinary supportive care is needed (Delgado-Guay, 2014). Nursing interventions, including prayer, establishing presence, establishing a caring relationship, having patients discuss spirituality in groups, and supporting patients within a faith community help patients with chronic illnesses thrive even at the end of life (Dyess and Chase, 2010; Tuck, 2012).

Application to Nursing Practice

- Pay attention to a patient's cultural and spiritual identity throughout the course of their illness (Piotrowski, 2013).
- Listen to a patient's story and angst and provide a compassionate presence (Delgado-Guay, 2014).
- Patients are not looking for answers. What is spoken as a spiritual question is most often an expression of spiritual pain (Delgado-Guay, 2014).
- Pray with your patients if they desire; prayer enhances connectedness to a higher being and often provides a source of strength, enhancing well-being and quality of life (Daaleman and Dobbs, 2010; Dyess and Chase, 2010).
- Patients should agree to interventions, and they should be tailored to their worldly perspectives to help during illness or crisis (Brown et al., 2013).
- Encourage patients with chronic illnesses to maintain connections with others and their faith community (Dyess and Chase, 2010; Tuck, 2012).

what death means, making patients susceptible to spiritual distress. However, some patients have a spiritual sense of peace that enables them to face death without fear. Spirituality helps these patients find peace in themselves and their death. Individuals experiencing a terminal illness find themselves reviewing their life and questioning its meaning. Common questions they ask include, "Why is this happening to me?" or "What have I done?" Terminal illness affects family and friends just as much as the patient. It causes members of the family to ask important questions about its meaning and how it will affect their relationship with the patient (see Chapter 37). When caring for dying patients, help them gain a greater sense of control over their illness, whether they are in a health care setting (e.g., the hospital) or at home. Dying is a holistic process encompassing a patient's physical, social, psychological, and spiritual health (Hayden, 2011; Phelps et al., 2012).

Near-Death Experience. Some nurses care for patients who have had a near-death experience (NDE). An NDE is a psychological phenomenon of people who either have been close to clinical death or have recovered after being declared dead. It is not associated with a mental disorder. Instead experts agree that NDE describes a powerfully close brush with physical, emotional, and spiritual death. For example, people who have an NDE after cardiopulmonary arrest often tell the

same story of feeling themselves rising above their bodies and watching caregivers initiate lifesaving measures. Commonly patients who experience an NDE describe feeling totally at peace, having an out-of-body experience, being pulled into a dark tunnel, seeing bright lights, and meeting people who preceded them in death. Instead of moving toward the light, they learn that it is not time for them to die, and they return to life (Agrillo, 2011; Cant et al., 2012).

Patients who have an NDE are often reluctant to discuss it, thinking family or caregivers will not understand. Isolation and depression often occur. Furthermore, not all NDEs are positive experiences. However, individuals experiencing an NDE who discuss it openly with family or caregivers find acceptance and meaning from this powerful experience. They are often no longer afraid of death, and they have a decreased desire to achieve material wealth. They also report increased sensitivity to different chemicals such as alcohol and medications. After patients have survived an NDE, promote spiritual well-being by remaining open, giving patients a chance to explore what happened. and supporting them as they share the experience with significant others (Cant et al., 2012).

CRITICAL THINKING

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require you to anticipate information, analyze the data, and make decisions regarding your patient's care. While using the nursing process, apply critical thinking in providing appropriate spiritual care (Figure 36-2).

The helping role is important in nursing practice (Benner, 1984). Patients look to nurses for help that is different than the help they seek from other health care professionals. Expert nurses acquire the ability to anticipate personal issues affecting patients and their spiritual well-being. Critical thinking and the application of knowledge and skills help nurses enhance patients' spiritual well-being and health. Nurses who are comfortable with their own spirituality often are more likely to care for their patients' spiritual needs. Beliefs of a health care provider affect the discussion of treatment options with patients and ultimately their health care choices (Delgado, 2015). Nurses feel strongly about providing spiritual care as part of their holistic practice. Nurses who foster their own personal, emotional, and spiritual health become resources for their patients and use their own spirituality as a tool when caring for themselves and their patients.

After becoming comfortable with your own spirituality, use your nursing knowledge to anticipate your patients' personal issues and the resulting effect on spiritual well-being. Your knowledge about the concept of spirituality, understanding of ethics (see Chapter 22), and knowledge of a patient's faith and belief systems help to provide appropriate spiritual care. Knowledge of a patient's values, beliefs, preferences, and needs provides insight into a person's spiritual practices. Application of therapeutic communication principles (see Chapter 24) and caring (see Chapter 7) helps you establish therapeutic trust with patients. An individual's spiritual beliefs are very personal. When you integrate patient preferences, values, and beliefs into spiritual care, you provide patient-centered care with sensitivity and respect for the diversity of human experience (QSEN Institute, 2014).

Personal experience in caring for patients in spiritual distress is valuable when helping them select coping options. You need to determine if your spirituality is beneficial in assisting patients. Nurses who sense a personal faith and hope regarding life are usually better able to help their patients. A nurse learns from his or her personal faith system and previous professional experiences with dying patients and those

Knowledge
- Therapeutic communication
- Caring practices; presencing, listening
- Loss and grief
- Concepts of spiritual health and religion

Experience
- Caring for patients who exhibit strong spiritual health
- Caring for patients who experience loss
- Personal experience whereby faith and beliefs are challenged or used in coping

ASSESSMENT
- Assess the patient's faith and beliefs
- Review the patient's view of life, self-responsibility, and life satisfaction
- Assess the extent of the patient's fellowship and community
- Review if the patient practices religion and rituals

Standards
- Demonstrate the ethic of care
- Be thorough and ensure that assessment is relevant to the patient's situation
- Follow ANA code of ethics

Attitudes
- Approach assessment with fairness and integrity so as not to let personal beliefs bias conclusions

FIGURE 36-2 Critical thinking model for spiritual health assessment. *ANA*, American Nurses Association.

with chronic disease or severe loss how to provide spiritual care comfortably (Delgado, 2015).

Because each person has a unique spirituality, you need to know your own beliefs so you are able to care for each patient without bias (Tiew and Creedy, 2010). Use critical thinking when assessing each patient's reaction to illness and loss and determining if spiritual intervention is necessary. Humility is essential, especially when caring for patients from diverse cultural backgrounds. Recognize personal limitations in knowledge about patients' spiritual beliefs and religious practices. Effective nurses show genuine concern as they assess their patients' beliefs and determine how spirituality influences their patients' health. You demonstrate integrity by refraining from voicing your opinions about religion or spirituality when your beliefs conflict with those of your patients.

The application of intellectual standards helps you make accurate clinical decisions and helps patients find meaningful and logical ways to acquire spiritual healing. Critical thinking ensures that you obtain significant and relevant information when making decisions about patients' spiritual needs. The nature of a person's spirituality is complex and individualized. Avoid making assumptions about his or her religion and beliefs. Significance and relevance are standards of critical thinking that allow you to explore the issues that are most meaningful to patients and most likely to affect spiritual well-being.

In setting standards for quality health care, The Joint Commission (TJC) (2015) requires health care organizations to assess patients' denomination, beliefs, and spiritual practices and acknowledge their rights to spiritual care. However, TJC does not specify what to include in an assessment. A health care organization must define the content and scope of spiritual assessment and provide for patients' spiritual needs through pastoral care or others who are certified, ordained, or lay individuals.

The American Nurses Association *Code of Ethics for Nurses* (2015) requires nurses to practice nursing with compassion and respect for the inherent dignity, worth, and uniqueness of every person. It is essential to promote an environment that respects patients' values, customs, and spiritual beliefs. Routinely implementing standard nursing interventions such as prayer or meditation is coercive and unethical. Therefore determine which interventions are compatible with your patient's beliefs and values before selecting them. An ethic of caring (see Chapter 7) provides a framework for decision making and places the nurse as the patient's advocate.

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to use to develop and implement an individualized plan of care. Understanding a patient's spirituality and then appropriately identifying the level of support and resources needed require a broad perspective and an open mind. As a nurse you make a commitment to meet the spiritual needs of your patients; thus it is essential to respect each patient's personal beliefs. People experience the world and find meaning in life differently. Application of the nursing process from the perspective of a patient's spiritual needs is not simple. It goes beyond assessing his or her religious practices. Caring for your patients' spiritual needs requires you to be compassionate and remove any personal biases or misconceptions. Be willing to share and discover their meaning and purpose in life, illness, and health. Identify common values and respect unique commitments and values with your patients by having quiet conversations, listening effectively, and communicating using presence and touch (Delgado, 2015).

◆ Assessment

During the assessment process thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care. Convey caring and openness to successfully promote honest discussion about each patient's spiritual beliefs. Taking a faith history reveals patient's beliefs about life, health, and a Supreme Being.

Through the Patient's Eyes. It is essential to take the time to assess a patient's viewpoints and establish a trusting relationship. As you and your patients reach a point of learning together, spiritual caring occurs. Because completing a spiritual assessment takes time, conduct an ongoing assessment over the course of a patient's stay in the health care setting if possible. Establish trust and rapport and make the opportunity to conduct meaningful discussions with patients a priority. Once you establish a trusting relationship with a patient, you and the patient reach a point of learning together, and spiritual caring occurs (Bailey et al., 2009). Focus your assessment on aspects of spirituality most likely to be influenced by life experiences, events, and questions in the case of illness and hospitalization. Be sure that you discuss what is meaningful and relevant to the patient. Conducting an assessment is therapeutic for you and your patient because it conveys a level of caring and support.

Assessment Tools. Listening to a patient's story is an essential method for obtaining a spiritual assessment. However, you can assess your patients' spiritual health in several different ways, using open-ended questions to prompt them to tell their story or asking them direct questions (Box 36-2). Asking direct questions requires you to feel comfortable asking others about their spirituality. Some health care agencies and researchers have created assessment tools to clarify values and assess spirituality. For example, the spiritual well-being (SWB) scale has 20 questions that assess a patient's relationship with God and his or her sense of life purpose and life satisfaction (Life Advance, 2009). The FICA assessment tool (Borneman et al., 2010) evaluates spirituality and is closely correlated to quality of life. FICA stands for the following criteria:

F—**F**aith or belief
I—**I**mportance and Influence
C—**C**ommunity
A—**A**ddress (Interventions to address)

Effective assessment tools such as the SWB scale and FICA help you remember important areas to assess. Patient responses to the assessment items on the tools indicate areas that you need to investigate further. For example, if, after using the FICA tool with a patient who is having difficulty accepting a new diagnosis of prostate cancer, you find out that he does not want you or his pastor to help him address this issue, you need to spend time understanding how the patient plans to manage this new illness. Remember, when using any spiritual assessment tool, do not impose your personal values on your patient. This is difficult, especially when a patient's values and beliefs are similar to

yours, because it is very easy for you to make false assumptions. When you understand the overall approach to spiritual assessment, you are able to enter into thoughtful discussions with patients, gain a greater awareness of the personal resources they bring to a situation, and incorporate the resources into an effective plan of care.

Faith/Belief. Assess the source of authority and guidance that patients use in life to choose and act on their beliefs. Determine if a patient has a religious source of guidance that conflicts with medical treatment plans and affects the option that nurses and other health care providers are able to offer patients. For example, if a patient is a Jehovah's Witness, blood products are not an acceptable form of treatment. Christian Scientists often refuse any medical intervention, believing that their faith heals them. It is also important to understand a patient's philosophy of life. Your assessment should reveal the basis of the patient's belief system regarding meaning and purpose in life and the patient's spiritual focus. This information often reflects the impact that illness, loss, or disability has on the person's life. Considerable religious diversity exists in the United States. A patient's religious faith and practices, views about health, and the response to illness often influence how nurses provide support (Table 36-1).

Life and Self-Responsibility. Spiritual well-being includes life and self-responsibility. Individuals who accept change in life, make decisions about their lives, and are able to forgive others in times of difficulty have a higher level of spiritual well-being. During illness patients often are unable to accept limitations or do not know how to regain a functional and meaningful life. Their sense of helplessness reflects spiritual distress. However, they often use their spiritual well-being as a resource for adapting to changes and dealing with limitations. Assess the extent to which a patient understands the limitations or threats posed by an illness (e.g., activity restriction, ability to have sexual intimacy with a partner, risk of medical complications) and the manner in which he or she chooses to adjust to them.

Connectedness. People who are connected to themselves, others, nature, and God or another Supreme Being cope with the stress brought on by crisis and chronic illness. In a study involving Muslim patients with chronic diabetic foot ulcers, a positive relationship was found between connectedness and health-related quality of life (Alzahrani and Sehlo, 2013). One way patients remain connected with their God is by praying (Figure 36-3). Prayer is personal communication with one's god. It provides a sense of hope, strength, security, and well-being; and it is a part of faith. Help patients become or remain connected by respecting each patient's unique sense of spirituality. Assess whether the patient loses the ability to express a sense of relatedness to something greater than the self.

Life Satisfaction. Spiritual well-being is tied to a person's satisfaction with life and what he or she has accomplished, even in the case of children (Chlan et al., 2011). When people are satisfied with life and how they are using their abilities, more energy is available to deal with new difficulties and resolve problems. You assess a patient's satisfaction with life by asking questions such as, "How happy or satisfied are you with your life?" or "Tell me how satisfied you feel about what you have accomplished in life."

Culture. Spirituality is a personal experience within a cultural context. It is important to know a patient's cultural background and assess his or her values about the health care problem and impending treatment (see Chapter 9). It is common in many cultures for individuals to believe that they have led a worthwhile and purposeful

TABLE 36-1	**Religious Beliefs About Health**		
Religious or Cultural Group	**Health Care Beliefs**	**Response to Illness**	**Implications for Health and Nursing**
Hinduism	Accepts modern medical science.	Past sins cause illness. Prolonging life is discouraged.	Allow time for prayer and purity rituals. Allow use of amulets, rituals, and symbols.
Sikhism	Accepts modern medical science.	Females are to be examined by females. Removing undergarments causes great distress.	Provide time for devotional prayer. Allow use of religious symbols.
Buddhism	Accepts modern medical science.	Followers sometimes refuse treatment on Holy Days. Nonhuman spirits invading body cause illness. Followers may want a Buddhist priest. Followers usually accept death as last stage of life and permit withdrawal of life support. Followers do not practice euthanasia. They often do not take time off from work or family responsibilities when sick.	Health is an important part of life. Good health is maintained by caring for self and others. Medications are not always accepted because of belief that chemical substances in body are harmful.
Islam	Must be able to practice Five Pillars of Islam. Sometimes has fatalistic view of health.	Muslims use faith healing. Family members are comfort. Group prayer is strengthening. They often permit withdrawal of life support. They do not practice euthanasia. They believe that time of death is predetermined and cannot be changed. They maintain sense of hope and often avoid discussions of death.	Women prefer female health care providers. During month of Ramadan Muslims do not eat until after sun goes down. Health and spirituality are connected. Family and friends visit during time of illness. They usually do not consider organ transplantation or donation and postmortem examinations.
Judaism	Believes in sanctity of life. Balance between God and medicine. Observance of Sabbath important. Treatments sometimes refused on Sabbath.	Visiting sick is obligation. There is an obligation to seek care, exercise, sleep, eat well, and avoid drug and alcohol abuse. Euthanasia is forbidden. Life support is discouraged.	They believe that it is important to stay healthy. Jews expect a nurse to provide competent health care. Allow patients to express their feelings. Allow family to stay with dying patient.
Christianity	Accepts modern medical science. Complementary or alternative medicine often followed (see Chapter 33).	Followers use prayer, faith healing. They appreciate visits from clergy. Some use laying on of hands. Holy Communion is sometimes practiced. Anointing of the sick is given when patient is ill or near death (Catholic).	Christians usually in favor of organ donation. Health is important to maintain. Allow time for patients to pray by themselves or with family or friends.
Navajos	Concepts of health have fundamental place in their concept of humans and their place in the universe.	Blessingway is practice that attempts to remove ill health by means of stories, songs, rituals, prayers, symbols, and sand paintings.	Navajos prefer holistic approach to health care. They often are not on time for appointments. Promote physical, mental, spiritual, and social health of people, families, and communities. Allow family members to visit. Provide teaching about wellness, not disease prevention, when possible.
Appalachians	External locus of control. Nature controls life and health. Accept folk healers.	They dislike hospitals. Tend to not follow medical regimens but expect to be helped directly when seeking episodic treatment.	They become anxious in unfamiliar settings. Encourage communication with family and friends when ill.

life. Remaining connected with their cultural heritage often helps patients define their place in the world and express their spirituality. Asking them about their faith and belief systems is a good beginning for understanding the relationship between culture and spirituality (Box 36-3).

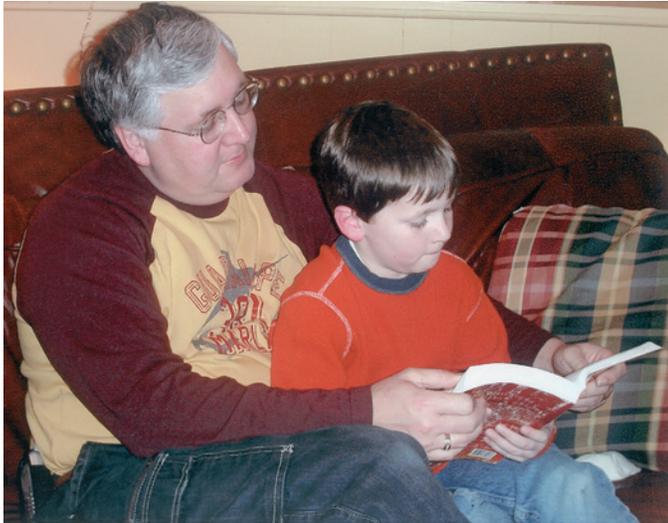
Fellowship and Community. Fellowship is one kind of relationship that an individual has with other people, including immediate family, close friends, associates at work or school, fellow members of a church, and neighbors. More specifically this includes the extent of the community of shared faith between people and their support networks. Many times social support from faith-based groups helps patients cope with illness (Heiney et al., 2011) and participate in health promotion behaviors (Newlin et al., 2012). To assess a patient's supportive community, ask questions such as, "With whom do you bond?" "Who do you find to be the greatest source of support in times of difficulty?" or "When you've faced difficult times in the past, who has been your greatest resource?"


FIGURE 36-3 Praying or reading a bible together enhances the connectedness between parents and their children.

⊕ BOX 36-3   CULTURAL ASPECTS OF CARE

Spirituality and Culture

Spirituality and spiritual health vary among cultures. Remember that a person's culture is defined by his or her age, gender, political association, religion, or other variables such as ethnicity and educational background. One way to assess a patient's spirituality through a cultural lens is to first understand his or her definition of health, wellness, and illness. For example, ask questions such as, "What do you call your health problem? What do you think has caused it? What do you think your sickness does to you? How do you find strength to cope with this problem?"

You want to assess how a patient's spirituality is affected by his or her culture. If your focus is on a patient's ethnicity, know the unique characteristics of that ethnic group's spiritual values. For example, spiritual aspects of life are frequently important to Latinos. *Personalismo* is a cultural value that indicates warmth, closeness, and empathy in relationships with other people and a universal being. *Familismo*, another Latino cultural value, indicates commitment and loyalty to immediate and extended family (Campesino et al., 2009).

Implications for Patient–Centered Care

- Explore the spirituality of patients from different cultural backgrounds; assess the meaning of health and how patients achieve balance, stability, peace, or comfort in their lives.
- Offer a universal and holistic approach when assessing patients' needs; demonstrate caring and use therapeutic communication techniques.
- During assessment respect patients' human rights, values, customs, and spiritual beliefs (see Chapter 9).
- Spiritual assessment should be interdisciplinary. If you feel uncomfortable with religion or spirituality, respectfully identify if a patient wishes referral to an appropriate professional chaplain or clergy.
- Avoid use of language that alienates or discriminates among different cultures.

Explore the extent and nature of a person's support networks and their relationship with the patient. It is unwise to assume that a given network offers the kind of support that a patient desires. For example, calling a patient's pastor to request a visit is inappropriate if the patient has little fellowship with the pastor or the pastor's faith community.

Does the patient have one significant fellowship or several? What level of support does the community give? Do they visit, say prayers, or support the patient's immediate family? Learn whether openness exists between a patient and the people with whom a fellowship has formed.

Ritual and Practice.   Assessing the use of rituals and practices helps you understand a patient's spirituality. Rituals include participation in worship, prayer, sacraments (e.g., baptism, Holy Eucharist), fasting, singing, meditating, scripture reading, and making offerings or sacrifices. Different religions have different rituals for life events. For example, Buddhists practice baptism later in life and find burial or cremation acceptable at death. Muslims wash the body of a dead family member and wrap it in white cloth with the head turned toward the right shoulder. Orthodox and conservative Jews circumcise their newborn sons 8 days after birth. Determine whether illness or hospitalization has interrupted a patient's usual rituals or practices. A ritual often provides the patient with structure and support during difficult times. If rituals are important to a patient, use them as part of nursing intervention.

Vocation.   Individuals express their spirituality on a daily basis in life routines, work, play, and relationships. It is often a part of a person's identity and vocation. Determine if illness or hospitalization alters the ability to express some aspect of spirituality as it relates to the person's work or daily activities. Expression of spirituality includes showing an appreciation for life in the variety of things people do, living in the moment and not worrying about tomorrow, appreciating nature, expressing love toward others, and being productive. When illness or loss prevents patients from expressing their spirituality, understand the psychological, social, and spiritual implications and provide appropriate guidance and support.

QSEN   **QSEN: BUILDING COMPETENCY IN PATIENT-CENTERED CARE.**   You are caring for Grace, a 52-year-old who experienced multiple fractures following a motor vehicle crash. Grace is experiencing difficulties with mobility, and she is not going to be able to go back to work for at least 6 months. Currently she is having extensive rehabilitation to help her complete activities of daily living. When you walk into Grace's room, she will not look at you. You can tell that she has been crying. She has a flat affect and states, "I just don't know why God did this to me. How am I going to go on from here?"

Identify at least three questions you will ask Grace to assess her spiritual well-being and plan effective, evidence-based care.

ⓔ *Answers to QSEN Activities can be found on the Evolve website.*

◆ Nursing Diagnosis

A spiritual assessment allows a nurse to learn a great deal about the patient and the extent that spirituality plays in his or her life. Exploring the patient's spirituality sometimes reveals responses to health problems that require nursing intervention or the existence of a strong set of resources that allow the patient to cope effectively. Analyze data to find risk factors or patterns of defining characteristics and select appropriate nursing diagnoses (Box 36-4). In identifying diagnoses, recognize the significance that spirituality has for all types of health problems. Be sure that each problem-focused nursing diagnosis has an accurate related factor to guide the selection of individualized, purposeful, and goal-directed interventions. Potential nursing diagnoses for spiritual health include the following:

- *Anxiety*
- *Ineffective Coping*

BOX 36-4 Nursing Diagnostic Process

Readiness for Enhanced Spiritual Well-Being

Assessment Activities	Defining Characteristics
Ask patient to describe personal source of faith and hope.	Patient expresses inner strength and source of guidance.
Have patient describe level of satisfaction with life.	Life has purpose and meaning; patient finds satisfaction while providing community service as a volunteer.
Determine who provides greatest source of strength and support to patient during times of difficulty.	Patient pursues interactions with friends and family.

- *Complicated Grieving*
- *Hopelessness*
- *Powerlessness*
- *Readiness for Enhanced Spiritual Well-Being*
- *Spiritual Distress*
- *Risk for Spiritual Distress*
- *Risk for Impaired Religiosity*

Three nursing diagnoses accepted by NANDA International (Herdman and Kamitsuru, 2014) pertain specifically to spirituality. *Readiness for Enhanced Spiritual Well-Being* is based on defining characteristics that show a person's ability to experience and integrate meaning and purpose in life through connectedness with self and others. A patient with this nursing diagnosis has potential resources on which to draw when faced with illness or a threat to well-being.

The nursing diagnoses of *Spiritual Distress* and *Risk for Spiritual Distress* create different clinical pictures. Defining characteristics from a nurse's assessment reveal patterns that reflect a person's actual or potential dispiritedness (e.g., expressing lack of hope, meaning, or purpose in life; anger toward God; or verbalizing conflicts about personal beliefs). Patients likely to be at risk for spiritual distress include those who have poor relationships, have experienced a recent loss, or are suffering some form of mental or physical illness.

Accurate selection of diagnoses requires critical thinking. Review and analyze all concrete data (e.g., religious rituals and sources of fellowship), your assessment of previous patient experiences, your own spirituality, and your appraisal of the patient's spiritual well-being. Commonly patients have multiple nursing diagnoses.

◆ Planning

During the planning step of the nursing process, develop a plan of care for each of the patient's nursing diagnoses. Critical thinking at this step is important because you reflect on previous experiences and apply knowledge and critical thinking attitudes and standards in selecting the most appropriate nursing interventions (Figure 36-4). Prior experience with other patients is valuable when selecting interventions to support spiritual well-being. Integrate assessment data with knowledge about resources and therapies available for spiritual care to develop an individualized plan of care (see the Nursing Care Plan). Match the patient's needs with evidence-based interventions that are supported and recommended in the clinical and research literature. Use a concept map (Figure 36-5) to organize patient care and show how the patient's medical diagnosis, assessment data, and nursing diagnoses are interrelated.

Confidence, an important critical thinking attitude, builds trust, enabling you and a patient to enter into a healing relationship together.

Knowledge
- Caring practices in the individualization of an approach with a patient
- Available services offered by health care providers and community agencies
- Nursing interventions that instill hope and provide spiritual support

Experience
- Previous patient responses to nursing interventions designed to support the patient's spiritual well-being

PLANNING
- Collaborate with the patient and family on choice of interventions
- Consult with pastoral care or other clergy or spiritual leaders as appropriate
- Incorporate spiritual rituals and observances

Standards
- Support the patient's autonomy to make choices
- Promote self-determination

Attitudes
- Exhibit confidence in your skills and knowledge to develop a trusting relationship with the patient

FIGURE 36-4 Critical thinking model for spiritual health planning.

Attempting to meet or support patients' spiritual needs is not simple; frequently you need additional resources. For example, sometimes a nurse's skills in helping patients interpret and understand the meaning of illness and loss are limited. Because spiritual care is so personal, standards of autonomy and self-determination are critical in supporting the patient's decisions about the plan of care.

Goals and Outcomes. A spiritual care plan includes realistic and individualized goals along with relevant outcomes. It is very important to collaborate closely with patients when setting goals for spiritual support and growth and choosing related interventions. Setting realistic goals requires you to know a patient well. When spiritual care requires helping patients adjust to loss or stressful life situations, goals are long term. However, short-term outcomes such as renewing participation in religious practices help patients progressively reach a more spiritually healthy situation. In establishing a plan of care, an example of a goal and associated outcomes follows:

The patient will improve personal harmony and connections with members of his or her support system.

- The patient expresses an acceptance of illness.
- The patient reports the ability to rely on family members for support.
- The patient initiates social interactions with family and friends.

◎ NURSING CARE PLAN

Readiness for Enhanced Spiritual Well-Being

ASSESSMENT

Lisa Owens is a 61-year-old female who was diagnosed with stage IV breast cancer over 2 years ago. She has undergone numerous rounds of chemotherapy treatment. Her husband, Richard, is 59 years old and a financial assistant at a local bank. The Owens have two children, both adults, with one daughter who is unmarried and living only 2 miles away. The other child, a son, lives out of town. The son is married; he and his wife are about to have their first child. Lisa has numerous side effects from her advancing disease and chemotherapy. She has ongoing hip pain from the cancer having spread to the bone. She also has reduced sensation in her feet, chronic fatigue, and difficulty sleeping at night. Her husband provides most of her support at home, but this sometimes interferes with his ability to do the work that he brings home. Lisa is coming to the outpatient chemotherapy infusion center to begin yet another course of chemotherapy. The nurse who has been seeing Lisa in the center knows that the patient regularly attends church with her husband.

Assessment Activities	*Findings/Defining Characteristics**
Ask Lisa to describe what it is about her cancer that frightens her most.	Lisa explains, "I have found it makes me appreciate what I have with my family. That being said, I worry that I will not see my grandchild born, **but I hope the chemotherapy will give me some time and it will make me feel a bit better."**
Have Lisa tell you who she finds to be the greatest source of support since she has been taking chemotherapy.	Lisa has received support from her husband and daughter. **She wants to be able to show them her love, "I still want to be there for them."**
Ask Lisa if she feels satisfaction with her life.	Lisa responds, "We always want more, don't we? **I have been blessed, but I think God gave me this illness so I can show others what life means**."

*__Defining characteristics__ are shown in bold type.

NURSING DIAGNOSIS: Readiness for Enhanced Spiritual Well-Being

PLANNING

Goals	*Expected Outcomes (NOC)[†]*
	Hope
Lisa will express her will to live with family members.	Lisa participates in worship with her family and shares spiritual readings.
	Lisa connects with members of her church.
	Lisa interacts with family members and discusses their future.
	Spiritual Health
Lisa will describe a feeling of peacefulness to her family.	Lisa engages in regular prayer and meditation.
Lisa will express a personal sense of spiritual well-being.	Lisa expresses her feelings through writing.

[†]Outcome classification labels from Moorhead S et al: *Nursing outcomes classification (NOC),* ed 5, St Louis, 2013, Mosby.

INTERVENTIONS (NIC)[‡]	**RATIONALE**
Spiritual Growth Facilitation	
Plan discussions with Lisa during treatment and listen, allowing her to sort out concerns she might have about her future. Include Lisa's husband if she desires.	Listening provides support or comfort in spiritual care (Delgado, 2015). Family caregivers engage in "meaning making" activities by expressing important values such as hope, dignity, and togetherness (Delgado-Guay, 2014).
Offer to pray with Lisa as she describes what she hopes for.	One study found that cancer patients commonly used prayer and meditation to reduce their side effects (Huebner et al., 2014)
Introduce Lisa to journaling. Encourage her to begin by writing what is meaningful to her about her illness and family	Use of journaling helps individuals facing a crisis deal with the unknown; find meaning and spiritual connection; and physically, emotionally, and spiritually heal (Harvey et al., 2013; Sealy, 2013).
Spiritual Support	
Discuss with Lisa the likely times that her chemotherapy will affect her most and how she can schedule involvement in church activities around those times.	Chemotherapy can cause severe fatigue. Faith communities such as a church play an important role in fostering belief systems of compassion (Delgado-Guay, 2014).
Teach Lisa methods of relaxation, meditation, and guided imagery.	Relaxation methods help promote quality of life and enhance serenity and dignity. Relaxation responses have been associated with improved physiological (blood pressure, exercise capacity, and cardiac symptoms) and psychological (depression and anxiety) outcomes (Horowitz, 2010; Sheeba et al., 2013).

[‡]Intervention classification labels from Bulechek GM et al: *Nursing interventions classification (NIC),* ed 6, St Louis, 2013, Mosby.

EVALUATION

Nursing Actions	*Patient Response/Finding*	*Achievement of Outcome*
Ask Lisa to describe in what way relaxation exercises have helped her.	Lisa reported using relaxation daily after being at clinic. She states, "I feel calm. It allows me to connect with God, and know I have my loving family to help me."	Lisa's story reflects spiritual well-being and peacefulness. She needs to share with family.
Have Lisa review her discussions with family and/or church members.	Lisa reports, "We have been talking more. My family knows that I see each day as a blessing and that my hope is to see my son's baby. My church really keeps me connected."	Lisa is connecting with family and church members. She is able to express a sense of hope.

CONCEPT MAP

Nursing diagnosis: Readiness for enhanced spiritual well-being
- Desires to enhance love
- Desires to enhance meaning of life
- Expresses hope

Interventions
- Be an attentive listener, encourage Lisa to tell her story
- Offer to pray with Lisa
- Coach Lisa in use of relaxation exercises

Nursing diagnosis: Risk for caregiver role strain
- Husband is source of support, but caregiving can conflict with work activities
- Lisa's future condition may affect ability to give care

Interventions
- Encourage husband and daughter to verbalize feelings about Lisa's health
- Plan care activities so Lisa can continue being involved and helpful
- Have husband set realistic activity goals each day with Lisa
- Offer respite care resources

Primary health problem: Stage IV breast cancer with metastasis to lung
Priority assessments: Comfort, spiritual health, coping strategies, effects on family members and family system

Nursing diagnosis: Activity intolerance
- Severe fatigue from chemotherapy treatment
- Becoming less able to perform regular activities
- Patient's disease is terminal

Interventions
- Have daughter or friends from church assist with basic care as patient's condition worsens (if family and Lisa accept)
- Encourage regular, short walks
- Provide frequent rest periods

—— Link between medical diagnosis and nursing diagnosis   - - - - Link between nursing diagnoses

FIGURE 36-5 Concept map for Lisa Owens.

Setting Priorities. Spiritual care is very personalized. Your relationship with a patient allows you to understand the patient's priorities in the context of his or her spiritual life. When establishing a mutually agreed-on plan with the patient, he or she is able to identify what is most important. Spiritual priorities do not need to be sacrificed for physical care priorities. For example, when a patient is in acute distress, focus care to provide him or her a sense of control to minimize powerlessness. When a patient is terminally ill, spiritual care often is the most important nursing intervention (see Chapter 37).

Teamwork and Collaboration. If a patient participates in a formal religion, involve members of the clergy or church, temple, mosque, or synagogue in the plan of care when appropriate. In a hospital setting the pastoral care department is a valuable resource. These spiritual care professionals offer insight about how and when to best support patients and their families. Spiritual care providers provide direct support in the form of actively addressing spiritual or religious needs of a patient and family, having discussions about family members' feelings and patient values, and reminiscing with families about a patient (Johnson et al., 2014). Significant others such as spouses, siblings, parents, and friends need to be involved in the patient's care as appropriate. This means that you learn from an assessment which individuals or groups have formed a relationship with the patient. These individuals sometimes become involved in all levels of the plan of care. They often assist in giving physical care, providing emotional comfort, and sharing spiritual support.

◆ **Implementation**

Establish caring relationships with patients to discover their beliefs about the meaning of illness or loss and the effects on the meaning and purpose of their lives. This level of understanding enables you to deliver care in a sensitive, creative, and appropriate manner.

Health Promotion.   Spiritual care needs to be a central theme in promoting an individual's overall well-being because of its importance in health promotion (Kemppainen et al., 2011). In settings where health promotion activities occur, patients often need information, counseling, and guidance to make the necessary choices to remain healthy.

Establishing Presence.   Nurses contribute to a sense of well-being and provide hope for recovery when they spend time with their patients. Establishing presence by sitting with a patient to attentively listen to his or her feelings and situation, talking with the patient, crying with the patient, and simply offering time are powerful spiritual care approaches (Bowers and Rieg, 2014). Presence is part of the art of nursing (Milligan, 2011). Benner (1984) explains that presence involves "being with" a patient versus "doing for" a patient. It is being able to offer closeness with a patient physically, psychologically, and spiritually. It helps to prevent emotional and environmental isolation (see Chapter 7).

When health promotion is the focus of care, your presence gives patients the confidence needed to discuss ways to remain healthy. Show your caring presence by listening to patients' concerns and willingly involving family in discussions about patients' health. Show self-confidence when providing health instruction and support patients as they make decisions about their health. The patient who seeks health care is often fearful of experiencing an illness that threatens loss of control and looks for someone to offer competent direction. Encouraging words of support and a calm, decisive approach establish a presence that builds trust and well-being.

Supporting a Healing Relationship.   Learn to look beyond isolated patient problems and recognize the broader picture of a patient's holistic needs. For example, do not just look at a patient's back pain as a problem to solve with quick remedies; rather look at how the pain influences his or her ability to function and achieve goals established in life. A **holistic** view enables you to establish a helping role and a healing relationship. Three factors are evident when a healing relationship develops between nurse and patient:

1. Realistically mobilizing hope for the nurse and patient
2. Finding an interpretation or understanding of the illness, pain, anxiety, or other stressful emotion that is acceptable to the patient
3. Helping the patient use social, emotional, and spiritual resources (Benner, 1984)

Mobilizing a patient's hope is central to a healing relationship. Hope motivates people with strategies to face challenges in life (Yeager et al., 2010). Help patients find things for which to hope. For example, a patient newly diagnosed with diabetes wants to learn how to manage the disease to continue a productive and satisfying way of life. An adult daughter who has decided to become caregiver to her older adult parent hopes to be able to protect the parent from injury or worsening disability. Hope helps patients work toward recovery. To help patients achieve hope, work together to find an explanation for their situation that is acceptable to them. Help a patient realistically exercise hope by supporting positive attitudes toward life or the desire to be informed and make decisions.

Remain aware of a patient's spiritual resources and needs. It is always important for patients to be able to express and exercise their beliefs and find spiritual comfort. When life stressors or illness create confusion or uncertainty, recognize the possible effect on a patient's well-being. How do you use and strengthen spiritual resources? Begin by encouraging a patient to discuss the effect that illness has had on personal beliefs and faith, thus giving the chance to clarify any misconceptions or inaccuracies in information. Having a clear sense of what illness will be like for an individual helps the person apply all resources toward recovery.

Acute Care.   Within acute care settings patients experience multiple stressors that threaten their sense of control. Ongoing assessment of spiritual needs is essential because a patient's needs often change rapidly. Support and enhancement of a patient's spiritual well-being are challenges when the focus of health care seems to be on treatment and cure rather than care (Tiew and Creedy, 2010). To meet these challenges display a soothing presence and supportive touch when providing care. The artful use of hands, encouraging words of support, promotion of connectedness, and a calm and decisive approach establish a presence that builds trust.

Support Systems.   Use of support systems is important in any health care setting. They provide patients with the greatest sense of well-being during hospitalization and serve as a human link connecting the patient, the nurse, and the patient's lifestyle before an illness. Part of a patient's caregiving environment is the regular presence of supportive family and friends. Provide privacy during visits and plan care with the patient and the patient's support network to promote the interpersonal bonding that is needed for recovery. The support system is a source of faith and hope and an important resource in conducting meaningful religious rituals.

When patients look to family and friends for support, encourage them to visit the patient regularly. Help family members feel comfortable in the health care setting and use their support and presence to promote the patient's healing. For example, including family members in prayer is a thoughtful gesture if it is appropriate to the patient's religion and if family members are comfortable participating. Having the family bring meaningful religious symbols to the patient's bedside offers significant spiritual support.

Other important resources to patients are spiritual advisors and members of the clergy. Many hospitals have pastoral care departments. Professional spiritual care providers have expertise in understanding how an illness influences a person's beliefs and how these beliefs influence the patient's responses to illness, recovery, or preparation for death. Ask if patients desire to have a member of the clergy visit during their hospitalization. When requested by patients or families, keep clergy informed of any physical, psychosocial, or spiritual concerns affecting the patient. A spiritual care provider is especially helpful in discussing patient and family wishes about end-of-life care (Johnson et al., 2014). Respect patients' spiritual values and needs by allowing time for pastoral care members to provide spiritual care and facilitating the administration of sacraments, rites, and rituals.

Diet Therapies.   The intake of food satisfies and promotes a sense of comfort. Food and nutrition are important aspects of patient care and often an important component of some religious observances (Table 36-2). Food and the rituals surrounding the preparation and serving of food are sometimes important to a person's spirituality. Consult with a dietitian to integrate patients' dietary preferences into daily care. In the event that a hospital or other health care agency cannot prepare food in the preferred way, ask the family to bring meals that fit into dietary restrictions posed by the patient's condition.

Supporting Rituals.   Nurses provide spiritual care by supporting patients' participation in spiritual rituals and activities. Plan care to allow time for religious readings, spiritual visitations, or attendance at religious services. Allow family members to plan a prayer session or an organized reading of scriptures on a regular basis. Make arrangements with spiritual care professionals for the patient and family to participate in religious practices (e.g., receiving sacraments). Clergy often visit people who are unable to attend religious services. Taped meditations, classical or religious music, and televised religious services

TABLE 36-2 Religious Dietary Regulations Affecting Health Care

Religion	Dietary Practices
Hinduism	Some sects are vegetarians. The belief is not to kill *any* living creature.
Buddhism	Some are vegetarians and do not use alcohol. Many fast on Holy Days.
Islam	Consumption of pork and alcohol is prohibited. Followers fast during the month of Ramadan.
Judaism	Some observe the kosher dietary restrictions (e.g., avoid pork and shellfish, do not prepare and eat milk and meat at same time).
Christianity	Some Baptists, Evangelicals, and Pentecostals discourage use of alcohol and caffeine. Some Roman Catholics fast on Ash Wednesday and Good Friday. Some do not eat meat on Fridays during Lent.
Jehovah's Witnesses	Members avoid food prepared with or containing blood.
Mormonism	Members abstain from alcohol and caffeine.
Russian Orthodox Church	Followers observe fast days and a "no-meat" rule on Wednesdays and Fridays. During Lent all animal products, including dairy products and butter, are forbidden.
Native Americans	Individual tribal beliefs influence food practices.

BOX 36-5 FOCUS ON OLDER ADULTS

Spirituality and Spiritual Health

- There is an association between an older adult's spirituality and his or her ability to adjust or cope with illness and other life stressors (Manning, 2014).
- Older adults achieve spiritual resilience through frequent expressions of gratitude (e.g., via prayer, meditation, or discussions with friends) and finding ways to maintain purpose in life (e.g., helping family, volunteering) (Manning, 2014).
- Patients use spiritual rituals, exercise, and complementary medicine to cope with pain and chronic illness.
- Feelings of connectedness are important for the older adult (Anderberg and Berglund, 2010). Enhance connectedness by helping older patients find meaning and purpose in life by listening actively to concerns and being present.
- Beliefs in the afterlife increase as adults age. Make visits from clergy, social workers, lawyers, and financial advisors available so patients feel as though they have completed all unfinished business. Leaving a legacy (e.g., oral history, art, photographs) to loved ones prepares an older adult to leave the world with a sense of meaning and maintains a way to continue connection for the one left behind (Touhy and Jett, 2012).
- Older-adult caregivers use their spirituality and spiritual behaviors or practices to help them deal with crisis and conflict (Strudwick and Morris, 2010).

BOX 36-6 PATIENT TEACHING

Meditation Techniques

Objective
- The patient will verbalize feelings of relaxation and self-transcendence after meditation.

Teaching Strategies
- Give patient a brief description of information and a printed teaching guide that describes how to meditate.
- Help patient identify a quiet room in the home that has minimal interruptions.
- Explain that peaceful music or the quiet whirring of a fan blocks out distractions.
- Teach steps of meditation (i.e., sit in a comfortable position with the back straight; breathe slowly; and focus on a sound, prayer, or image).
- Encourage patient to meditate for 10 to 20 minutes twice a day.
- Answer questions and reinforce information as needed.

Evaluation
- Have patient describe feelings following meditation.

provide other effective options. Always respect the icons, medals, prayer rugs, or crosses that a patient brings to a health setting and ensure that they are not accidentally lost, damaged, or misplaced. Supporting spiritual rituals is especially important for older adults (Box 36-5).

Restorative and Continuing Care. For patients who are recovering from a long-term illness or disability or who suffer chronic or terminal disease, spiritual care becomes especially important. Many of the nursing interventions applicable in health promotion and acute care apply to this level of health care as well.

Prayer. The act of prayer gives an individual the opportunity to renew personal faith and belief in a higher being in a specific, focused way that is either highly ritualized and formal or quite spontaneous and informal. Prayer is an effective coping resource for physical and psychological symptoms (Oliver and Dutney, 2012). Patients pray in private or participate in group prayer with family, friends, or clergy. Some pray while listening to music. Be supportive of prayer by giving the patient privacy if desired, learning if the patient wishes to have you participate, and suggesting prayer when you know that it is a coping resource for the patient. Delgado (2015) has found that nurses tend to pray for patients rather than with patients; sharing the fact that prayer has been offered gives patients comfort and support. If prayer is not suitable for a patient, alternatives include listening to calming music or reading a book, poetry, or inspirational texts selected by the patient.

Meditation. Meditation creates a relaxation response that reduces daily stress. Patients who meditate often state that they have an increased awareness of their spirituality and of the presence of God or a Supreme Being. Meditation exercises give patients relief from pain,

insomnia, anxiety, and depression and increase coping and the ability to relax (Cole et al., 2012; Williams-Orlando, 2012). Meditation involves sitting quietly in a comfortable position with eyes closed and repeating a sound, phrase, or sacred word in rhythm with breathing while disregarding intrusive thoughts. Individuals who meditate regularly (twice a day for 10 or 20 minutes) experience decreased metabolism and heart rate, easier breathing, and slower brain waves (Box 36-6). Chapter 33 addresses relaxation approaches.

Supporting Grief Work. Patients who experience terminal illness or who have suffered permanent loss of body function because of a

Knowledge
- Coping theory
- Behaviors reflecting spiritual health

Experience
- Previous patient responses to spiritual care interventions

EVALUATION
- Review the patient's self-perceptions regarding spiritual health
- Review the patient's view of his or her purpose in life
- Discuss with family and close associates the patient's connectedness
- Ask if the patient's expectations are being met

Standards
- Use established expected outcomes to evaluate the patient's response to care
- Demonstrate ethics of care

Attitudes
- Demonstrate integrity; be open to any possible conflict between the patient's opinion and yours; decide how to proceed to reach mutually beneficial outcomes

FIGURE 36-6 Critical thinking model for spiritual health evaluation.

disabling disease or injury require a nurse's support in grieving and coping with their loss. Your ability to enter into a caring, therapeutic, and spiritual relationship with patients supports them during times of grief (see Chapter 37).

◆ Evaluation

Through the Patient's Eyes. The evaluation of a patient's spiritual care requires you to think critically in determining if efforts at restoring or maintaining the patient's spiritual health were successful (Figure 36-6). Include the patient in your evaluation of care. Outcomes established during the planning phase serve as the standards to evaluate the patient's progress. Ask him or her if you and the health care team met their expectations and if there is anything else you can do to enhance their spiritual well-being or enable them to practice important religious rituals. In addition, evaluate ethical concerns that arise in the course of the patient's spiritual care and support. Apply critical thinking attitudes and use therapeutic communication techniques to ensure sound nursing judgments.

Patient Outcomes. Attaining spiritual health is a lifelong goal. In evaluating outcomes, compare the patient's level of spiritual health with the behaviors and perceptions noted in the nursing assessment. Evaluation data related to spiritual health are usually subjective. For example, if your assessment finds the patient losing hope, the follow-up evaluation involves asking him or her if feelings of hope have been restored. Include family and friends when gathering evaluative information. Successful outcomes reveal the patient developing an increased or restored sense of connectedness with family; maintaining, renewing,

or reforming a sense of purpose in life; and for some a confidence and trust in a Supreme Being or power. When outcomes are not met, ask questions to determine appropriate continuing care. Examples of questions to ask include the following:
- Do you feel the need to forgive someone or to be forgiven by someone?
- Which spiritual activities such as prayer or meditation were helpful to you?
- Would you like for me to ask a friend, family member, or someone from pastoral care to talk with you?
- What can I do to help you feel more at peace?
- Sometimes people need to give themselves permission to feel hope when they experience difficult events. What can you do to allow yourself to feel hope again?

KEY POINTS

- Spirituality is an inherent human characteristic that gives individuals the energy needed to discover themselves, cope with difficult situations, and maintain health.
- Nurses need to be aware of their own spirituality to provide appropriate and relevant spiritual care to others.
- Research shows that spirituality positively affects and enhances physical and psychological health, quality of life, health promotion behaviors, and disease prevention activities.
- Spirituality is important regardless of a person's religious beliefs.
- Spiritual well-being has two dimensions: support of the transcendent relationship between a person and a higher power and the positive relationships and connections that people have with others.
- Nurses who are comfortable with their own spirituality often are more likely to care for their patients' spiritual needs.
- After establishing a trusting relationship with a patient, you and the patient reach a point of learning together, and spiritual caring occurs.
- Nursing assessment of a patient's spiritual needs includes a review of the patient's faith, connectedness, life and self-responsibility, life satisfaction, and fellowship and community.
- It is important to know a patient's cultural background and assess his or her values about his or her health care problem and impending treatment.
- Nurses need to determine if a patient's religious beliefs conflict with medical treatment.
- Establishing presence involves attentive listening, talking with patients and answering questions, crying with patients, and simply offering your time.
- Spiritual care providers provide direct support in the form of actively addressing spiritual or religious needs of a patient and family and having discussions about family members' feelings and patient values.
- Prayer is an effective coping resource for physical and psychological symptoms.
- During evaluation successful outcomes reveal a patient developing an increased or restored sense of connectedness with family and maintaining, renewing, or reforming a sense of purpose in life.

CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

Lisa is coming to the oncology center regularly. Her hip pain is increasing, and she continues having fatigue. Her doctor has told her that this will likely be the last chemotherapy treatment protocol she will be able

to have. Magnetic resonance imaging (MRI) shows that the cancer has spread to Lisa's lung. It is 1 month from the time that her son's wife is to have their baby. Her husband has been helping to care for Lisa at home because she is becoming less physically able to do normal daily activities. Her daughter tries to help, but her job sometimes takes her out of town for short trips.

1. The nurse chooses to assess the extent to which Lisa now understands the limitations or threats posed by her cancer. This is an example of which assessment category to cover in a spiritual assessment? Explain its importance.
2. Give three examples of assessment questions the nurse might ask to determine the level of support available to Lisa from members of her church.
3. Because Lisa has a terminal illness, what common reactions might she express in dealing with death?

ⓔ *Answers to Clinical Application Questions can be found on the Evolve website.*

REVIEW QUESTIONS

1. A student nurse is telling a faculty member that her patient talked about gaining spiritual comfort from being focused on her inner self, including her values and principles. The instructor explains that this is an example of:
   1. Faith.
   2. Community.
   3. Interpersonal connection.
   4. Self-transcendence.
2. Health care agencies often have assessment tools to use in clarifying patient values and assess spirituality. Using the FICA assessment tool, match the criteria on the left with the appropriate assessment question on the right.
   1. F—Faith ___
   2. I—Importance of spirituality ___
   3. C—Community ___
   4. A—Interventions to address spiritual needs ___

   a. Tell me if you have a higher power or authority that helps you act on your beliefs
   b. Describe which activities give you comfort spiritually?
   c. To whom do you go for support in times of difficulty?
   d. Your illness has kept you from attending church. Is that a problem for you?
3. A nurse is caring for a 78-year-old patient with chronic multiple sclerosis. The patient has severe fatigue, muscle weakness, severe muscle spasms, and difficulties with coordination and balance. Her disease will likely worsen. The nurse has gained the patient's trust and wants to assess her life satisfaction. Which of the following questions should the nurse ask? (Select all that apply.)
   1. How often are you able to attend your synagogue?
   2. What about your family makes you proudest?
   3. What does your husband do for you at home?
   4. Looking back, what is your greatest accomplishment?
   5. How has your illness affected the way you live your life spiritually at home?
4. You are caring for a hospitalized patient who is Muslim and has diabetes. Which of the following items do you need to remove from the meal tray when it is delivered to the patient?
   1. Small container of vanilla ice cream
   2. A dozen red grapes
   3. Bacon and eggs
   4. Garden salad with ranch dressing

5. A 44-year-old male patient has just been told that his wife and child were killed in an auto accident while coming to visit him in the hospital. Which of the following statements are defining characteristics that support a nursing diagnosis of *Spiritual Distress related to loss of family members*? (Select all that apply.)
   1. "I need to call my sister for support."
   2. "I have nothing to live for now."
   3. "Why would my God do this to me?"
   4. "I need to pray for a miracle."
   5. "I want to be more involved in my church."
6. A patient has just learned she has been diagnosed with a malignant brain tumor. She is alone; her family will not be arriving from out of town for an hour. You have cared for her for only 2 hours but have a good relationship with her. What might be the most appropriate intervention for support of her spiritual well-being at this time?
   1. Make a referral to a professional spiritual care advisor
   2. Sit down and talk with the patient; have her discuss her feelings and listen attentively
   3. Move the patient's bible from her bedside cabinet drawer to the top of the over-bed table
   4. Ask the patient if she would like to learn more about the implications of having this type of tumor
7. A nurse is preparing to teach an older adult who has chronic arthritis how to practice meditation. Which of the following strategies are appropriate? (Select all that apply.)
   1. Encourage family members to participate in the exercise.
   2. Have patient identify a quiet room in the home that has minimal interruptions.
   3. Suggest use of a quiet fan running in the room.
   4. Explain that it is best to meditate about 5 minutes 4 times a day.
   5. Show the patient how to sit comfortably with the limitation of his arthritis and focus on a prayer.
8. A student nurse is developing a plan of care for a 74-year-old female patient who has spiritual distress over losing a spouse. As the nurse develops appropriate interventions, which characteristics of older adults should be considered? (Select all that apply.)
   1. Older adults do not routinely use complementary medicine to cope with illness.
   2. Older adults dislike discussing the afterlife and what might have happened to people who have passed on.
   3. Older adults achieve spiritual resilience through frequent expressions of gratitude.
   4. Have the patient determine if her husband left a legacy behind.
   5. Offer the patient her choice of rituals or participation in exercise.
9. A patient states that he does not believe in a higher power but instead believes that people bring meaning to what they do. This patient most likely is an:
   1. Academic.
   2. Atheist.
   3. Agnostic.
   4. Anarchist.
10. A nurse begins a night shift, assuming care for a critically ill patient who was resuscitated earlier in the day from cardiac arrest. He survived and is physically stable, alert, oriented, and responding appropriately to the nurse's questions. Knowing that the patient experienced a period when his heart stopped beating, what would be the best approach for the nurse to use with him?
    1. Have family come to visit and focus discussion about their gratitude that the patient survived

2. Change the subject when the patient begins talking about entering a dark tunnel when the doctors were resuscitating him

3. Sit and encourage the patient to share what he experienced during resuscitation

4. Provide the patient the opportunity to have passages from the bible read to him

11. A nurse is caring for a patient with a seriously advanced infection who asks to have a spiritual care provider come who can offer Blessingway, a practice that attempts to remove ill health. This patient is likely a member of which religion or culture?
    1. Hinduism
    2. Navajo
    3. Sikhism
    4. Judaism

12. Evaluation of spiritual care is necessary to determine if a patient's level of spiritual health has changed following intervention. If the use of rituals was part of a nurse's care plan, which of the following questions is most appropriate to evaluate its efficacy?
    1. Do you feel the need to forgive your wife over your loss?
    2. What can I do to help you feel more at peace?
    3. Were prayer or meditation helpful to you?
    4. Should we plan on having your family try to visit you more often in the hospital?

13. A patient who is recovering from a bilateral amputation of the legs below the knee shows transcendence when she states:
    1. "My pain medicine helps me feel better."
    2. "I know I'll get better if I just keep trying."
    3. "I see God's grace and become relaxed when I watch the sun set at night."
    4. "I have had a great life and a good marriage. My husband has been so helpful in my healing."

14. The nurse is caring for a 50-year-old woman visiting the outpatient medicine clinic. The patient has had type 1 diabetes since age 13. She has numerous complications from her disease, including reduced vision, heart disease, and severe numbness and tingling of the extremities. Knowing that spirituality helps patients cope with their chronic illness, which of the following principles should the nurse apply in practice? (Select all that apply.)
    1. Pay attention to the patient's spiritual identity throughout the course of her illness
    2. Select interventions that you know scientifically support spiritual well-being
    3. Listen to the patient's story each visit to the clinic and offer a compassionate presence
    4. When the patient questions the reason for her long-time suffering, try to provide answers
    5. Consult with a spiritual care advisor and have the advisor recommend useful interventions

15. Select the three factors that are evident when a healing relationship develops between nurse and patient.
    1. The nurse being able to realistically mobilize hope for the patient
    2. The patient being able to share fears of loss with significant others
    3. Finding an interpretation or understanding of the patient's illness that is acceptable to the patient
    4. Understanding your own beliefs about spirituality
    5. Helping the patient use spiritual resources that he or she chooses

The Experience of Loss, Death, and Grief

Loss is an inevitable part of life. Accompanying each loss are feelings of grief and sadness. Whether a patient is facing infertility or an amputation, an unwanted diagnosis or impending death, you are in a position to offer both the patient and family support to cope with the loss and provide comfort when continued life is not possible. Regardless of the practice setting, you will provide care for those in grief. Like grief, death is as inescapable in practice as it is in life. Although palliative care and hospice use have increased, nurses in all practice settings and specialties provide care for a majority of the dying.

Although people agree that death is a part of life, many are hesitant to talk about it because of feelings of fear, uncertainty, and not wanting to upset others. Talking openly about death is discouraged in American society (i.e., in our everyday lives, our language, and even our thinking) (Matzo and Sherman, 2015). An example is our avoidance of the word "died" and instead the use of words such as "passed away" or "gone." Many health care professionals feel uncomfortable about discussing and providing end-of-life care (Parker et al., 2012). You need to learn how to become comfortable discussing such sensitive topics and providing patients with the opportunity to express their desires for care

at the end of life. Historically health care professionals waited until it was too late to discuss end-of-life wishes. With the Self-Care Determination Act of 1990, nurses and other health care providers are starting these conversations earlier, but there is more work left to do. You have the opportunity to advocate for patients and the high quality of care deserved at the end of life.

As a student you need to know that you are capable of providing what patients and families need most at the end of life: compassion, attentiveness, and patient-centered care. As with other nursing situations, the more experience you have caring for the grieving and the dying, the more confident, courageous, and compassionate you will become when caring for patients and families at this intimate and meaningful time. Your skills and knowledge base will develop quickly if you have the desire and willingness to learn, be present, and seek the help needed to learn how to give excellent care at the end of life. Whether it is educating patients and families about advance directives, managing patients' symptoms, or simply holding a hand, nurses care for the dying every day. It is the caring actions of nursing that help the patient and family during these times (see Chapter 7).

SCIENTIFIC KNOWLEDGE BASE

Loss

Life provides each person with multiple opportunities to grieve a loss or change. Sometimes the change is welcomed (marriage, birth of a child), and sometimes not (divorce, loss of a job, death). The loss can be of tangible things such as a body part or function, relationship, or possession. They can also be intangible such as the loss of self-esteem, confidence, or a dream.

The experience of loss starts early in life and continues until death. Children develop independence from the adults who raise them and as they begin and leave school, change friends, begin careers, and form new relationships. From birth to death people form attachments and experience loss. Illness can also be a source of loss. It can change his or her functioning and therefore his or her job, family role, income level, and overall quality of life (Table 37-1). How one grieves depends on cultural norms, belief systems, support systems, and personal faith (AACN and CHNMC, 2014).

Life changes are normal, expected, and often positive. As people age they learn that change always involves a **necessary loss**. They learn to expect that most necessary losses eventually are replaced by something different or better. However, some losses cause them to undergo permanent changes in their lives that threaten their sense of belonging and security. The death of a loved one, divorce, or loss of independence changes life forever and often significantly disrupts a person's physical, psychological, and spiritual health.

A **maturational loss** is a form of necessary loss and includes all normally expected life changes across the life span. A toddler experiences separation anxiety from mom when starting preschool. A grade school child does not want to lose her favorite teacher and classroom. A college student does not want to leave his campus community. Maturational losses associated with normal life transitions help people develop coping skills to use when they experience unplanned, unwanted, or unexpected loss.

Other losses seem unnecessary and are not part of expected maturation experiences. Sudden, unpredictable external events bring about

situational loss. For example, a person in an automobile accident sustains an injury with physical changes that make it impossible to return to work or school, leading to loss of function, income, life goals, and self-esteem.

Losses may be actual or perceived. An **actual loss** occurs when a person can no longer feel, hear, see, or know a person or object. Examples include the loss of a body part, death of a family member, or loss of a job. Lost valued objects include those that wear out or are misplaced, stolen, or ruined. A **perceived loss** is uniquely defined by the person experiencing the loss and is less obvious to other people. For example, some people perceive rejection by a friend to be a loss, which creates a loss of confidence or changes their status in the social group. How an individual interprets the meaning of the perceived loss affects the intensity of the grief response. Perceived losses are easy to overlook by others because they are experienced so internally and individually, but they are as painful as an actual loss and grieved in the same way.

Each person responds to loss differently. The type of loss and the person's perception of it influence the depth and duration of the grief response. In addition, a person's previous experience with loss also affects how he or she responds to a new loss. For some individuals the loss of an object (e.g., home or treasured gift) generates the same level of distress as the loss of a person, depending on the value the person places on the object. Chronic illnesses, disabilities, and hospitalization produce multiple losses. When entering an institution for care, patients lose access to familiar people and environments, privacy, and control over body functions and daily routines. A chronic illness or disability adds financial hardships for most people and often brings about changes in lifestyle and dependence on others. Even brief illnesses or hospitalizations cause temporary changes in family role functioning, daily activities, and relationships.

Death is the ultimate loss. Although it is an expected part of life, death represents the unknown and can generate anxiety, fear, and uncertainty for many people. It creates a permanent separation of people and can cause fear, sadness, and regret for the dying person, family members, friends, and caregivers. A person's culture, spirituality, personal beliefs, and values; previous experiences with death; and degree of social support influence the way he or she approaches death.

Grief

Grief is a "normal but bewildering cluster of ordinary human emotions arising in response to a significant loss, intensified and complicated by the relationship to the person or the object lost" (Mitchell and Anderson, 1983) (see Chapters 9 and 36). Grief cannot be prevented (Brohard, 2014). It is very personal. No two people grieve the same loss the same way, nor do they journey through grief in the same way. Grief work is very hard and requires enormous amounts of energy from the griever. It is rarely orderly and predictable. Because objects, memories, and anniversaries can cause a surge in feelings of loss, grief work is never fully completed. However, grief can diminish, and healing can occur when the pain of loss is less (AACN and CHNMC, 2014).

Coping with grief involves a period of **mourning,** the outward, social expressions of grief and the behavior associated with loss (AACN and CHNMC, 2014). Most mourning rituals are culturally influenced, learned behaviors. For example, the Jewish mourning ritual of *Shivah* is a time period when normal life activities come to a stop. Those mourning welcome friends into the home as a way of honoring the dead and receive support during the mourning period.

The term **bereavement** encompasses both grief and mourning and includes the emotional responses and outward behaviors of a person experiencing loss. The bereaved should be encouraged to talk about the loss and reassured that the feelings are normal and that

TABLE 37-1 **Types of Loss**	
Definition	**Implications of Loss**
Loss of possessions or objects (e.g., theft, deterioration, misplacement, or destruction)	Extent of grieving depends on value of object, sentiment attached to it, or its usefulness.
Loss of known environment (e.g., leaving home, hospitalization, new job, moving out of a rehabilitation unit)	Loss occurs through maturational or situational events or by injury/illness. Loneliness in an unfamiliar setting threatens self-esteem, hopefulness, or belonging.
Loss of a significant other (e.g., divorce, loss of friend, trusted caregiver, or pet)	Close friends, family members, and pets fulfill psychological, safety, love, belonging, and self-esteem needs.
Loss of an aspect of self (e.g., body part, job, psychological or physiological function)	Illness, injury, or developmental changes result in loss of a valued aspect of self, altering personal identity and self-concept.
Loss of life (e.g., death of family member, friend, co-worker, or one's own death)	Loss of life grieves those left behind. Dying people also feel sadness or fear pain, loss of control, and dependency on others.

major decisions should be postponed (AACN and CHNMC, 2014). Recognizing that there are different types of grief can help nurses plan and implement appropriate care.

Normal Grief. **Normal (uncomplicated) grief** is a common and universal reaction characterized by complex emotional, cognitive, social, physical, behavioral, and spiritual responses to loss and death. Some normal feelings of grief are disbelief, yearning, anger, and depression. Although manner of death (violent, unexpected, or traumatic) increases risk to the survivors' normal grief response, it does not always determine how an individual will actually grieve. Helpful coping mechanisms for grieving people include hardiness and resilience, a personal sense of control, and the ability to make sense of and identify positive possibilities after a loss.

Anticipatory Grief. A person experiences **anticipatory grief** before the actual loss or death occurs, especially in situations of prolonged or predicted loss such as caring for patients diagnosed with dementia or amyotrophic lateral sclerosis (ALS). Family members often grieve the impending loss of companionship, control, and sense of freedom and the mental and physical changes to be experienced by their loved one. Ultimately they grieve the impending death (Chan et al., 2013).

When grief extends over a long period of time, people absorb loss gradually and begin to prepare for its inevitability. They experience intense responses to grief (e.g., shock, denial, and tearfulness) before the actual death occurs and often feel relief when it finally happens. Another way to think about anticipatory grief is that it is a forewarning or cushion that gives people time to prepare or complete the tasks related to the impending death. However, this idea may not apply in every situation. Although forewarning is a buffer for some individuals, it increases stress for others, creating an emotional roller coaster of highs and lows.

Disenfranchised Grief. People experience **disenfranchised grief** when their relationship to the deceased person is not socially sanctioned, cannot be shared openly, or seems of lesser significance. The person's loss and grief do not meet the norms of grief acknowledged by his or her culture, thereby cutting the grieving person off from social support and the sympathy given to people with more socially acceptable losses. Examples include the death of a former spouse, a married lover, or an incarcerated person or a terminated pregnancy (AACN and CHNMC, 2014).

Ambiguous Loss. Sometimes people experience losses that are marked by uncertainty. **Ambiguous loss**, a type of disenfranchised grief, can occur when the lost person is physically present but not psychologically available, as in cases of severe dementia or brain injury. Other times the person is gone (e.g., after a kidnapping, prisoner of war, or when there is no body found such as on 9/11/01 or a missing hiker), but the grieving person maintains an ongoing, intense psychological attachment, never sure of the reality of the situation. Ambiguous losses are particularly difficult to process because of the lack of finality and unknown outcomes (Walter and McCoyd, 2009).

Complicated Grief. Some people do not experience a normal grief process. In **complicated grief** a person has a prolonged or significantly difficult time moving forward after a loss. He or she experiences a chronic and disruptive yearning for the deceased; has trouble accepting the death and trusting others; and/or feels excessively bitter, emotionally numb, or anxious about the future. Complicated grief occurs more often when a person had a conflicted relationship with the deceased, prior or multiple losses or stressors, mental health issues, or

lack of social support. Loss associated with homicide, suicide, sudden accidents, or the death of a child has the potential to become complicated. Specific types of complicated grief include chronic, exaggerated, delayed, and masked grief.

Chronic Grief. A person with chronic grief experiences a normal grief response, except that it extends for a longer period of time. This can include years to decades of intense grieving.

Exaggerated Grief. A person with an exaggerated grief response often exhibits self-destructive or maladaptive behavior, obsessions, or psychiatric disorders. Suicide is a risk for these individuals.

Delayed Grief. A person's grief response is unusually delayed or postponed because the loss is so overwhelming that the person must avoid the full realization of the loss. A delayed grief response is frequently triggered by a second loss, sometimes seemingly not as significant as the first loss.

Masked Grief. Sometimes a grieving person behaves in ways that interfere with normal functioning but is unaware that the disruptive behavior is a result of the loss and ineffective grief resolution (AACN and CHNMC, 2014).

Theories of Grief and Mourning

Knowledge of grief theories and normal responses to loss and bereavement helps you to better understand these complex experiences and how to help a grieving person. Grief theorists describe the physical, psychological, and social reactions to loss. Remember that people who vary from expected norms of grief or theoretical descriptions are not abnormal. The variety of theories supports the complexity and individuality of grief responses. Although most grief theories describe how people cope with death, they also help to understand responses to other significant losses (Table 37-2).

Criticism exists for the stages and task theories because they fail to capture the complexity and diversity of the experience (Hall, 2014). The more recent grief theories take into consideration that human beings construct their own experiences and truths differently and make their own meanings when confronted with loss and death. Differences in social and historical context, family structure, and cognitive capacities shape an individual's truths and grief experiences. No one's grief follows a predetermined path, nor is it linear. Grief is cyclical, with movement forward and backward (Figure 37-1). Educating grievers about the cyclical pattern of grief work prepares them for difficult days among the better days. Consider a widow several months after the death of her husband. She may have had several weeks of feeling less sad and depressed. If unprepared for the cyclical nature of grief, she may be taken off guard by her strong grief reaction to a phone call for her husband or a commercial advertising his favorite candy. Knowing that these feelings will come and go help the griever to be prepared for them and allow for the necessary self-care.

NURSING KNOWLEDGE BASE

Nurses develop plans of care to help patients and family members who are undergoing loss, grief, or death experiences. On the basis of nursing research, practice evidence, nursing experience, and patient and family preferences, nurses implement plans of care in acute care, nursing home, hospice, home care, and community settings. Extensive nursing education programs support the improvement of end-of-life care. The End-of-Life Nursing Education Consortium (ELNEC) provides nurses with basic and advanced curricula to care for patients and families experiencing loss, grief, death, and bereavement (AACN and CHNMC, 2014). In conjunction with the Hospice and Palliative Care Nurses Association, the American Nurses Association (ANA) has developed the Scope and Standards of Hospice and Palliative Nursing Practice

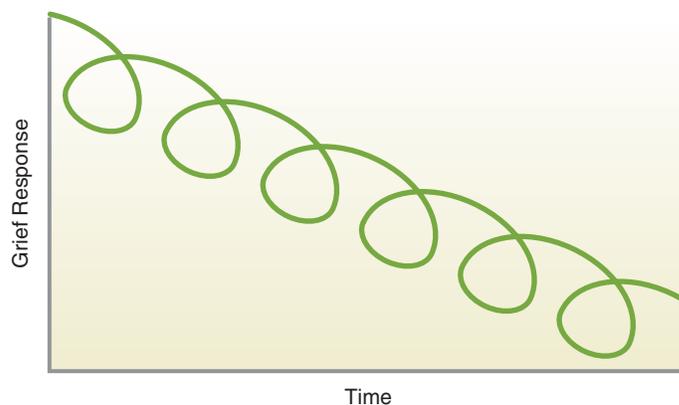
TABLE 37-2	**Theories of Grief and Mourning**
Stages of Dying Kübler-Ross (1969)	**Denial** The person cannot accept the fact of the loss. It is a form of psychological protection from a loss that the person cannot yet bear. **Anger** The person expresses resistance or intense anger at God, other people, or the situation. **Bargaining** The person cushions and postpones awareness of the loss by trying to prevent it from happening. **Depression** The person realizes the full impact of the loss. **Acceptance** The person incorporates the loss into life.
Attachment Theory Bowlby (1980)	**Numbing** Protects the person from the full impact of the loss **Yearning and Searching** Emotional outbursts of tearful sobbing and acute distress; common physical symptoms in this stage: tightness in chest and throat, shortness of breath, a feeling of lethargy, insomnia, and loss of appetite **Disorganization and Despair** Endless examination of how and why the loss occurred or expressions of anger at anyone who seems responsible for the loss **Reorganization** Accepts the change, assumes unfamiliar roles, acquire new skills, builds new relationships, and begins to separate himself or herself from the lost relationship without feeling that he or she is lessening its importance
Grief Tasks Model Worden (2008)	Accepts the reality of the loss Experiences the pain of grief Adjusts to a world in which the deceased is missing Emotionally relocates the deceased and moves on with life
Rando's "R" Process Model Rando (1993)	**Recognizing** the loss **Reacting** to the pain of separation **Reminiscing** **Relinquishing** old attachments **Readjusting** to life after loss **Reminiscence** of the relationship by mentally or verbally anecdotally reliving and remembering the person and past experiences
Dual Process Model Stroebe and Schut (1999)	**Loss-Oriented** activities: (e.g., grief work, dwelling on the loss, breaking connections with the deceased person, and resisting activities to move past the grief) **Restoration-Oriented** activities: attending to life changes, finding new roles or relationships, coping with finances, and participating in distractions, which provide balance to the loss-oriented state
Trajectories of Bereavement Bonanno et al. (2002)	**Common Grief** **Chronic Grief** **Chronic Depression** **Depression Followed by Improvement** **Resilience**


FIGURE 37-1 Cyclical nature of a normal grief response over time.

(ANA, 2014). Professional nursing organizations such as the American Society of Pain Management Nurses and the American Association of Critical Care Nurses offer evidence-based practice guidelines for managing clinical and ethical issues at the end of life in many health care settings.

Factors Influencing Loss and Grief

Multiple factors influence the way a person perceives and responds to loss. They include developmental factors, personal relationships, the nature of the loss, coping strategies, socioeconomic status, and cultural and spiritual influences and beliefs.

Human Development. Patient age and stage of development affect the grief response. For example, toddlers cannot understand loss or death but often feel anxiety over the loss of objects and separation from parents. Common expressions of grief include changes in eating and sleeping patterns, bowel and bladder disturbances, and increased fussiness (AACN, 2014). School-age children understand the concepts of permanence and irreversibility but do not always understand the causes of a loss. Some have intense periods of emotional expression and experience changes in eating, sleeping, and level of social engagement (AACN and CHNMC, 2014).

Young adults undergo many necessary developmental losses related to their evolving future. They leave home, begin school or a work life, or form significant relationships. Illness or death disrupts the young adult's future dreams and establishment of an autonomous sense of self. Midlife adults also experience major life transitions such as caring for aging parents, dealing with changes in marital status, and adapting to new family roles (Walter and McCoyd, 2009). For older adults the aging process leads to necessary and developmental losses. Some older adults experience age discrimination, especially when they become dependent or are near death; but they show resilience after a loss as a result of their prior experiences and developed coping skills (Box 37-1).

Personal Relationships. When loss involves another person, the quality and meaning of the lost relationship influence the grief response. When a relationship between two people was very rewarding and well connected, the survivor often finds it difficult to move forward after the death. Grief work is hampered by regret and a sense of unfinished business, especially when people are closely related but did not have a good relationship at the time of death. Social support and the ability to accept help from others are critical variables in recovery from loss and grief. Grievers experience less depression when they have

BOX 37-1 FOCUS ON OLDER ADULTS

Grief Considerations in Older Adults

- There is little evidence that grief experiences differ because of age alone. Responses to loss are more likely related to the nature of the specific loss experience and individual differences.
- Increased age increases the likelihood that older adults have faced multiple losses (i.e., loved ones, friends, valued objects, a child, or declining health). Older adults residing in communal living situations experience many losses as friends die.
- Many older adults exhibit resilience. Others around them can learn from their courage and ability to respond to life challenges graciously, accepting life with integrity and wholeness (Walter and McCoyd, 2009).
- Older adults are at risk for complicated grieving as a result of multiple losses, potential for cognitive impairment, or decreased physical resources. The risks include depression, loneliness, and accompanying functional decline.
- Physical decline caused by chronic illness sometimes leads to grief over lost health, function, and roles.
- Pain is often undertreated in older adults, particularly in people with dementia or cognitive impairments. Side effects of pain medications are usually more pronounced in older adults (Matzo and Sherman, 2015; Reynolds et al., 2013).
- Older adults benefit from the same therapeutic techniques as people in other age-groups. Evidence indicates that positive reappraisal (cognitive restructuring) helps older adults adapt to significant losses (e.g., seeing a cardiac diagnosis as the opportunity to become healthy by eating nutritiously and exercising regularly) (Brohard, 2014). Relieving depression and maintaining physical function are therapeutic goals for grieving older adults.

highly satisfying personal relationships and friends to support them in their grief (de Vries et al., 2014).

Nature of the Loss. Exploring the nature of a loss will help you understand the effect of the loss on the patient's behavior, health, and well-being. Was the loss avoidable? Is it permanent or temporary? Is it actual or imagined? Encouraging patients to share information about the loss will help you better develop appropriate interventions that meet the individualized needs of your patients.

Highly visible losses generally stimulate a helping response from others. For example, the loss of one's home from a tornado often brings community and governmental support. A more private loss such as a miscarriage brings less support from others. A sudden and unexpected death poses challenges different from those of a person in a debilitating chronic illness. When the death is sudden and unexpected, the survivors do not have time to say good-bye. In chronic illness survivors have memories of prolonged suffering, pain, and loss of function. Death by violence or suicide or multiple losses by their very nature complicate the grieving process in unique ways (Walter and McCoyd, 2009).

Coping Strategies. The losses that patients face from the time they were children formulate the coping skills they will use when faced with larger and more painful losses in adulthood. These coping strategies such as talking, journaling, and sharing their emotions with others may be healthy and effective. They may also be unhealthy and ineffective such as increased use of alcohol, drugs, and violence. Nurses provide support by assessing a patient's coping strategies, educating about new and healthy strategies, and encouraging use of these strategies.

Socioeconomic Status. Socioeconomic status influences a person's grief process in direct and indirect ways. Because of role changes, a newly widowed mom finds herself working several jobs to make ends meet and does not find time to initiate self-care or allow herself to grieve the loss of her husband. With limited resources, activities that support healthy grief work such as buying a tree to plant in honor of the deceased or travel to a support group may be unrealistic. Practical implications also exist when there are limited resources. A patient with limited finances is not able to replace a car demolished in an accident and pay for the associated medical expenses.

Culture. During times of loss and grief patients and families draw on the social and spiritual practices of their culture to find comfort, expressions, and meaning in the experience (Walter and McCoyd, 2009). To provide the best care possible, it is necessary for us to ask about cultural beliefs and practices. Patients and families will rarely offer this information without prompting. Expressions of grief in one culture do not always make sense to people from a different culture (see Chapter 9). Try to understand and appreciate each patient's cultural values related to loss, death, and grieving (Fiorelli and Jenkins, 2012). For example, many people in western European and American cultures hold back their public displays of emotion. In other cultures behaviors such as public wailing and physical demonstrations of grief, including survivor body mutilation, show respect for the dead. Core American cultural values of individualism and self-determination stand in contrast with communal, family, or tribal ways of life. Even urban and rural settings provide a framework of culture in which people draw strength from traditional practices

Culture extends beyond the geographic location of a person. Consider the influence of sexual orientation, socioeconomic status, and family make-up (blended versus nuclear) when assessing cultural influence on grief practices and death rituals.

Spiritual and Religious Beliefs. Like cultural influences, spirituality and/or religious practices and beliefs provide a framework to navigate, understand, and heal from loss, death, and grief (see Chapter 36). Patients' faith may influence the way they respond to an illness, treatment, advanced life-support options, autopsy, organ donation, and what happens to the body and spirit after death. Patients draw on their spiritual beliefs to provide comfort and seek understanding at times of loss. You must remain open to the varying views and beliefs that are in contrast to your own to best support and care for your patients' and their families (Bauer-Wu et al., 2007; Dose et al., 2014). To never offend a patient and to offer high quality care, you must assess your patient's beliefs and practices and encourage expression of them whenever possible. You should encourage patients to draw on their spiritual resources (e.g., faith in a higher power, communities of support, friends, a sense of hope and meaning in life, and religious practices). Spirituality affects the patient's and family members' ability to cope with loss as well. Caring for the patient in a holistic approach, which includes the spirit, ensures that you are providing patients with the best possible individualized care.

Hope, a multidimensional concept considered to be a component of spirituality, energizes and provides comfort to individuals experiencing personal challenges. Hope gives a person the ability to see life as enduring or having meaning or purpose. With hope a patient moves from feelings of weakness and vulnerability to living as fully as possible. Maintaining a sense of hope depends in part on a person having strong relationships and emotional connectedness to others. On the other hand, spiritual distress often arises from a patient's inability to feel hopeful or foresee any favorable outcomes. Spirituality and

hope play a vital role in a patient's adjustment to loss and death (see Chapter 36).

CRITICAL THINKING

To provide appropriate and responsive care for the grieving patient and family, use critical thinking skills to synthesize scientific knowledge from nursing and nonnursing disciplines, professional standards, evidence-based practice, patient assessments, previous caregiving experiences, and self-knowledge. Critical thinking informs all steps of the nursing process (see Chapter 15).

During assessment consider all elements that build toward making an appropriate nursing diagnosis (Figure 37-2). To understand a patient's subjective experiences of loss, form assessment questions on the basis of your theoretical and professional knowledge of grief and loss but then listen carefully to the patient's perceptions. A culturally competent nurse also uses culture-specific understanding of grief to explore the meaning of loss with a patient.

Being familiar with commonly experienced responses to loss enables you to better understand a patient's emotions and behaviors. Some patients ignore, lash out, plead with, or withdraw from other people as part of a normal response to loss. Instead of "taking things personally," a critically thinking nurse integrates theory, prior experience, appreciation of subjective experiences, and self-knowledge to respond to the patient's emotions with patience and understanding. In designing plans of care, use professional standards, including the Nursing Code of Ethics (see Chapter 22), the dying person's bill of rights (Box 37-2), the ANA Scope and Standards of Hospice and Palliative Nursing Practice (2014), and the American Society of Pain Management Nurses' position for pain management at the end of life (Reynolds et al., 2013).

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care.

◆ Assessment

During the assessment process thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care. A trusting, helping relationship with grieving patients and family members is essential to the assessment process. A caring nurse encourages a patient to tell his or her story. Look for opportunities to invite patients to share their experiences, being aware that attitudes about self-disclosure; sharing emotions; or talking about illness, fears, and death are shaped by an individual's personality, coping style, and culture. This information is invaluable to understanding the unique and individual needs of each patient.

Knowledge
- Grief process
- Pathophysiology of related illness threatening a loss
- Therapeutic communications principles
- Cultural perspectives on the meaning of loss/death
- Family dynamics in offering social support
- Concepts of caring
- Concepts of stress and coping

Experience
- Caring for a patient who experienced a physical or emotional loss
- Caring for a patient who died
- Personal experience with loss or death of a significant other

ASSESSMENT
- Assess meaning of loss for this patient
- Observe behaviors and other symptoms indicative of grief response
- Note quality and extent of patient's family support

Standards
- Apply principles outlined in professional and clinical standards (e.g., American Society of Pain Management Nursing guidelines for assessing pain in nonverbal patient)(ANA, 2014)
- Demonstrate the ethical principles of health care
- Apply intellectual standards of significance; know what is important to the patient

Attitudes
- Take risks if necessary to develop a close relationship with the patient to understand loss
- Be willing to be open minded
- Demonstrate empathetic approach

FIGURE 37-2 Critical thinking model for loss, death, and grieving assessment.

BOX 37-2 A Dying Person's Bill of Rights

I have the right to be treated as a living human being until I die.

I have the right to maintain a sense of hopefulness, however changing its focus may be.

I have the right to be cared for by those who can maintain a sense of hopefulness, however changing this may be.

I have the right to express my feelings and emotions about my approaching death in my own way.

I have the right to participate in decisions about my care.

I have the right to expect continuing medical and nursing attention even though "cure" goals must be changed to "comfort" goals.

I have the right not to die alone.

I have the right to be free of pain.

I have the right to have my questions answered honestly.

I have the right to retain my individuality and not be judged for my decisions that may be contrary to beliefs of others.

I have a right to expect that the sanctity of my human body will be respected after death.

I have the right to be cared for by caring, sensitive, knowledgeable people who will try to understand my needs and be able to gain some satisfaction in helping me face my death.

Modified from Barbus AJ: The dying person's bill of rights, *Am J Nurs* 75:99, 1975.

Through the Patient's Eyes. One of the best things that you can do for patients and families is to be present. By using the skills of active listening, silence, and therapeutic touch, you can establish a trusting relationship with your patients. This trusting relationship will help you explore with patients their unique responses to grief or their preferences for end-of-life care, which may include advance directives. Patient perceptions and expectations influence how we prioritize our nursing diagnoses. To assess patient perceptions, ask, "What is the most important thing I can do for you right now?" You usually gather information from patients first, but with advanced illness and as death approaches, patients often rely on family members to communicate for them. Encourage family members to share their goals and perceptions with you. Most often they provide valuable information about patient preferences and clarify misunderstandings or identify overlooked information. Assess patients' and family members' understanding of treatment options to implement a mutually developed care plan. Assessment of grief responses extends throughout the course of an illness into the bereavement period following a death. During this time you can work to normalize the grief response (AACN and CHNMC, 2014). Patients with advanced chronic illness and their families eventually face end-of-life care decisions and should discuss the content of any advance directives together. Because most deaths are now "negotiated" among patients, family members, and the health care team, discuss end-of-life care preferences early in the assessment phase of the nursing process. If you feel uncomfortable in assessing a patient's wishes for end-of-life care by yourself, ask a health care provider experienced in discussing these issues to help you. Communicate what you have learned about patient preferences during any registered nurse (RN) hand-off, at health care team conferences, in written care plans, and through ongoing consultation (see Chapter 26).

Speak to patients and family members using honest and open communication, remembering that cultural practices influence how much information the patient shares. Keep an open mind, listen carefully, and observe the patient's verbal and nonverbal responses. Facial expressions, voice tones, and avoided topics often disclose more than words. Anticipate common grief responses, but allow patients to describe their experiences in their own words. Open-ended questions such as, "What do you understand about your diagnosis?" or "You seem sad today. Can you tell me more?" may open the door to a patient-centered discussion. Many people find it difficult to talk about loss, fear, death, or grief. The use of pauses, gentle questioning, and silence honors the patient's privacy and readiness to talk. Talk to patients and family members in a private, quiet setting. Many times a patient wants to have family members present so everyone hears the same thing and has an opportunity to add to the conversation. However, some people want their concerns and questions addressed privately. Ask patients and family members about their preferences. As you gather assessment data, summarize and validate your impressions with the patient or family member. Information from the medical record and other members of the health care team, physicians, social workers, and spiritual care providers contributes to your assessment data.

Because of the importance of symptom management and priority of comfort in end-of-life care, prioritize your initial assessment to encourage patients to identify any distressing symptoms. Completing a thorough assessment is difficult when patients are in pain, anxious, depressed, or short of breath.

Grief Variables. Conversations about the meaning of loss to a patient often leads to other important areas of assessment, including the patient's coping style, the nature of family relationships, social support systems, the nature of the loss, cultural and spiritual beliefs, life goals, family grief patterns, self-care, and sources of hope

---

BOX 37-3 Nursing Assessment Questions

Nature of Relationships
- How long have you known _____ (the deceased person)?
- What role did (name person) play in your life?
- Tell me about your relationship with (name person).

Social Support Systems
- Who is "there for you?" Absent? Who provides support?
- What do others do for you that is most meaningful or helpful?
- Are family/friends available when needed? Which friends or relatives do you wish were here?

Nature of the Loss
- What does this loss mean to you?
- What other losses have you experienced?
- Was this loss expected or unexpected?

Cultural and Spiritual Beliefs
- What is your belief about death? Meaning of life?
- Which rituals/practices are important to you at the end of life?
- How do members of your culture or religious group respond to this loss?

Life Goals
- What are your life goals at this time?
- How have your goals changed because of this experience?
- Are you able to envision what you will do in the future?

Family Grief Patterns
- How have you/your family dealt with loss in the past?
- What are your family's strengths?
- How have family relationships changed as a result of your loss?
- What role do you assume in your family during stressful situations?

Self-Care
- Tell me how you're feeling.
- What are you doing to take care of yourself now?
- What helps you when you feel this sad? What doesn't help?
- What can I do for you?

Hope
- What do you hope for right now?
- What helps you to remain hopeful? What causes you to lose hope?

(Box 37-3). Use skills appropriate for assessing a patient's culture, family, self-concept, or spiritual beliefs (see Chapters 9, 10, 34, and 36) to acquire a deeper understanding of his or her loss.

Knowing the commonly experienced reactions to grief and loss and grief theories guides your critical thinking and assessment skills. A single behavior can occur in all types of grief. If a grieving patient describes loneliness and difficulty falling asleep, consider all factors surrounding the loss in context. What was the loss? When did it occur? What was the meaning of the loss to the patient? For example, when your patient exhibits signs of a normal grief reaction, but you learn that the loss occurred 2 years ago, the patient's response most likely indicates a complicated, chronic grief experience. Focus your assessment on how a patient is reacting to loss or grief and not on how *you* believe that patient should be reacting.

Grief Reactions. Use psychological and physical assessment skills to assess a patient's unique grief responses. Most grieving people show some common outward signs and symptoms (Box 37-4).

BOX 37-4 Symptoms of Normal Grief

Feelings
- Sorrow
- Fear
- Anger
- Guilt or self-reproach
- Anxiety
- Loneliness
- Fatigue
- Helplessness/hopelessness
- Yearning
- Relief

Cognitions (Thought Patterns)
- Disbelief
- Confusion or memory problems
- Problems making decisions
- Inability to concentrate
- Feeling the presence of the deceased

Physical Sensations
- Headaches
- Nausea and appetite disturbances

- Tightness in the chest and throat
- Insomnia
- Oversensitivity to noise
- Sense of depersonalization ("Nothing seems real")
- Feeling short of breath, choking sensation
- Muscle weakness
- Lack of energy
- Dry mouth

Behaviors
- Crying and frequent sighing
- Distancing from people
- Absentmindedness
- Dreams of the deceased
- Keeping the deceased's room intact
- Loss of interest in regular life events
- Wearing objects that belonged to the deceased

BOX 37-5 Nursing Diagnostic Process

Hopelessness Related to Deteriorating Physiological Condition

Assessment Activities	Defining Characteristics
Ask patient to discuss her understanding of her health situation.	Patient sighs and offers a negative view of her future; turns away from health care professionals.
Observe patient's nonverbal behavior.	Patient sighs, keeps eyes closed; decreased verbalization.
Observe patient's responses to care options.	Patient does not want scheduled test. "There is nothing they can do."
Assess activity level.	Patient states that she has no energy and reports pain; can't sleep, wants to stay in bed.
Observe patient's interactions with others.	Patient shows lack of interest, communicates minimally, and does not want to contact daughter yet.

Analyze assessment data and identify possible related causes for the signs and symptoms that you observe. For example, after a significant loss a person has a sad affect, withdrawn behaviors, headaches, upset stomach, and decreased ability to concentrate. You associate these symptoms with several potential causes, including anxiety, gastrointestinal disturbances, medication side effects, or impaired memory. Careful analysis of the symptoms in context leads you to an accurate nursing diagnosis. Ask: How are the symptoms related to one another when they occur? When did they begin? Were they present before the loss? To what does the person attribute them?

Loss takes place in a social context; thus family assessment is a vital part of your data gathering. If a father of a young family is dying, he will not be able to fulfill certain roles, causing a change in family structure. When a person develops a disability, the patient and family members realign their roles and responsibilities to meet new demands. Family members also experience a variety of physical and psychological symptoms. Assess the family's response to loss and recognize that sometimes they are dealing with their grief at a different pace.

◆ Nursing Diagnosis

Use critical thinking to cluster assessment data cues, identify defining characteristics, draw conclusions regarding the patient's actual or potential needs or resources, and identify nursing diagnoses applicable to the patient's situation (Box 37-5). In addition to numerous diagnoses related to physical symptoms at the end of life, additional nursing diagnoses relevant for patients experiencing grief, loss, or death include:
- *Compromised Family Coping*
- *Death Anxiety*
- *Grieving*
- *Complicated Grieving*
- *Risk for Complicated Grieving*
- *Hopelessness*

- *Pain (Acute or Chronic)*
- *Spiritual Distress*

You cannot make accurate nursing diagnoses on the basis of just one or two defining characteristics. Carefully review your patient's assessment data to consider if more than one diagnosis applies. For example, a dying patient who cries often, has angry outbursts, and reports nightmares gives evidence of several possible nursing diagnoses: *Pain (Acute or Chronic), Ineffective Coping, Grieving,* or *Spiritual Distress.* Examine the available data, validate assumptions with the patient, and look for other validating behaviors and symptoms before making a diagnosis.

As part of the diagnostic process, identify the appropriate "related to" factor for each diagnosis. Clarification of the related factors ensures that you select appropriate interventions. For example, a nursing diagnosis of *Complicated Grieving related to the permanent loss of mobility* requires different interventions than a diagnosis of *Complicated Grieving related to infertility after an ectopic pregnancy.*

When identifying nursing diagnoses related to a patient's grief or loss, you sometimes identify other related diagnoses. Some patients experiencing grief or impending death have nursing diagnoses such as *Disturbed Body Image* or *Impaired Physical Mobility.* A patient entering the phase of active dying often has diagnoses related to physical changes, including *Impaired Urinary Elimination, Bowel Incontinence, Acute Pain, Nausea, Disturbed Sensory Perception,* and *Ineffective Breathing Pattern.*

◆ Planning

Nurses provide holistic, physical, emotional, social, and spiritual care to patients experiencing grief, death, or loss. Figure 37-3 illustrates the interrelatedness of critical thinking factors during the planning phase of the nursing process. The use of critical thinking ensures a well-designed care plan that supports a patient's self-esteem and autonomy by including him or her in the planning process. A care plan for the dying patient focuses on comfort; preserving dignity and quality of life; and providing family members with emotional, social, and spiritual support (see the Nursing Care Plan).

Goals and Outcomes. During planning establish realistic goals and expected outcomes on the basis of the nursing diagnoses. Consider a patient's own resources such as physical energy and activity tolerance,

◎ **NURSING CARE PLAN**

Hopelessness

ASSESSMENT

Mrs. Allison, an 80-year-old woman, was brought to the hospital after a neighbor found her lying on the floor. She was unable to get up after falling down 4 hours earlier. She was admitted to the hospital with low blood pressure, dehydration, and weakness. She reports having severe pain in her back and toes, making it difficult for her to walk. In addition, she has experienced recent weight loss and a poor appetite and reports being too tired to cook or enjoy activities. Blood tests and physical examination reveal that she has a more serious health problem, likely a form of leukemia, for which she needs a bone marrow biopsy to make a medical diagnosis. Mrs. Allison lives alone since her husband's death 2 years earlier. She has the support of her neighbors and church community and one daughter who lives out of town. On entering the room the nurse notes that Mrs. Allison appears withdrawn and tearful. The nurse talks to her to gather more information.

Assessment Activities	*Findings/Defining Characteristics**
Ask open-ended questions. "It looks like you're having a difficult time. What do you understand about your situation right now?"	"The doctors say that **I might have cancer. Shrugging her shoulders,** she states, **"There's nothing they can do. I don't want the test."**
Observe Mrs. Allison's behaviors and nonverbal communication.	Mrs. Allison **appears sad and keeps her eyes closed**. She **cries and sighs frequently**.
Assess Mrs. Allison's pain and energy level.	Mrs. Allison's **great toes are swollen and red** and sore to the touch. Reports **constant back pain**. She has "**no energy for anything."**
Observe Mrs. Allison's interactions and interest in others.	Mrs. Allison **does not look at people and does not want to talk to her daughter yet.**
Assess meaning of recent events with Mrs. Allison and invite her to talk about her situation.	Mrs. Allison states that "**It's time to quit on life and be with my late husband."**

***Defining characteristics** are shown in bold type.

NURSING DIAGNOSIS: Hopelessness related to declining physical condition

PLANNING

Goals	*Expected Outcomes (NOC)*[†]
	Hopelessness
Mrs. Allison will discuss two care priorities and preferences within 1 day.	Mrs. Allison identifies the concerns causing the greatest amount of suffering or distress.
Mrs. Allison will communicate with one support person within next 12 hours.	Daughter, church community, and neighbors provide supportive care.
Mrs. Allison will identify at least three tasks with which she needs help to live at home by discharge from the hospital.	Mrs. Allison identifies ways she can live at home with the help of others.

[†]Outcome classification labels from Moorhead S et al: *Nursing outcomes classification (NOC),* ed 5, St Louis, 2013, Mosby.

INTERVENTIONS (NIC)[‡]	**RATIONALE**
Presence	
Develop an open and caring relationship through active listening and emotional support.	Individuals approaching the end of life often experience fragmented care delivery. Therapeutic communication supports patient- and family-centered care at the end of life and helps to ensure that patient needs are communicated among all health care professionals (Meghani et al., 2015).
Provide frequent conversations with patient and family regarding patient's symptom management and grief.	Frequent conversations with patient and family provide opportunity to discuss end-of-life care values, goals, and preferences (Meghani et al., 2015).
Pain Management	
Provide pharmacological and nonpharmacological relief for chronic back and foot pain.	Anxiety, pain, and suffering are reduced with effective pain management; and quality of life is improved (Paice, 2015).
Grief Work Facilitation	
Help Mrs. Allison identify her personal goals, desires, and priorities. Evaluate effectiveness and promote goal achievement as appropriate.	Allowing the patient to direct care decisions helps the patient and family select priority of care and increases patient and family understanding of current and proposed treatments (Brohard, 2014; Coyle, 2015).
Help Mrs. Allison identify available resources. Initiate discussions with interdisciplinary team as appropriate.	Hope is strengthened when one finds realistic possibilities and can adapt to life challenges (McDonald and McCallin, 2010).
Discuss Mrs. Allison's spiritual beliefs, practices, needs, and resources.	Inclusion of spiritual assessment and spiritual care practices at the end of life increases patient's sense of connectedness and overall quality of life (Dose et al., 2014).

[‡]Intervention classification labels from Bulechek GM et al: *Nursing interventions classification (NIC),* ed 6, St Louis, 2013, Mosby.

EVALUATION

Nursing Actions	*Patient Response/Finding*	*Achievement of Outcome*
Validate Mrs. Allison's experience: "It must be difficult to face such a big life change."	Mrs. Allison responds, "My life has changed, but I have good friends and a good daughter."	Mrs. Allison shows beginning acceptance of her changed health condition.
Use open-ended question: "Tell me how you're feeling now."	Mrs. Allison explains, "I'm not sure what will happen. I may not be able to take care of myself much longer, but I'll try."	She is able to express normal grieving behaviors and feelings of uncertainty resulting from loss of her life as she knew it.
Observe Mrs. Allison's planning activities and behavior with her daughter and friends.	Mrs. Allison and daughter discuss what they can do so she can stay at home longer.	She indicates ability to make plans for a change of care location. Daughter supports revised plans.

Knowledge
- Spirituality as a resource for dealing with loss
- Role other health professions play in helping patients deal with loss
- Services provided by community agencies
- Principles of providing comfort
- Principles of grief support

Experience
- Previous patient responses to planned nursing interventions for pain and symptom management or loss of a significant other

PLANNING
- Select communication strategies that assist the patient/family in accepting and adapting to loss
- Select interventions designed to maintain the patient's dignity and self-esteem
- Provide skills/knowledge for the family to manage and understand care for the dying patient

Standards
- Provide privacy for the patient and family
- Apply ethical principles of autonomy in supporting the patient's choice regarding treatment
- Individualize therapies for the patient's self-esteem
- Apply appropriate professional standards for end-of-life care (e.g., American Nurses Association: Scope and Standards of Hospice or Palliative Nursing)

Attitudes
- Be responsible for delivering high-quality supportive care
- Demonstrate an openness to participate in experiencing the loss
- Demonstrate empathetic approach

FIGURE 37-3 Critical thinking model for loss, death, and grief planning.

family support, and coping style. A nursing diagnosis of *Powerlessness related to experimental cancer therapy* with a goal of "Patient will be able to describe the expected course of disease" is realistic for a patient who frequently asks for clarification about the treatment plan and participates in educational discussions. In contrast, an expected outcome of "Patient will identify a minimum of three effective coping skills" is appropriate for a patient with the same nursing diagnosis who is experiencing depression from feeling powerless about having experimental cancer treatment.

The goals of care for a patient experiencing loss are either short or long term, depending on the nature of the loss and the patient's condition. Some nursing care goals for patients facing loss or death include accommodating grief, accepting the reality of a loss, or maintaining

meaningful relationships. A possible goal for a young woman with advanced breast cancer is "Will maintain a sense of control," with the following potential expected outcomes:
- Patient participates in all treatment decisions.
- Patient identifies a minimum of three ways to maintain a parental role in the care of her young child.
- Patient communicates a minimum of three treatment side effects or concerns to the health care team.

Setting Priorities. Encourage patients and family members to share their priorities for care at the end of life. Patients at the end of life or with advanced chronic illness are more likely to want their comfort, social, or spiritual needs met rather than pursuing medical cures. Give priority to a patient's most urgent physical or psychological needs while also considering his or her expectations and priorities. If a terminally ill patient's goals include pain control and promoting self-esteem, pain control takes priority when the patient experiences acute physical discomfort. When comfort needs have been met, you address other issues important to the patient and family. When it is realistic for the patient to remain independent, strategies that foster his or her sense of autonomy and ability to function independently take priority. A patient's condition at the end of life often changes quickly; therefore maintain an ongoing assessment to revise the plan of care according to patient needs and preferences.

When a patient has multiple nursing diagnoses, it is not possible to address them all simultaneously. Figure 37-4 illustrates a concept map developed for Mrs. Allison, an elderly patient with a medical diagnosis of advanced cancer (leukemia). In conjunction with her recent medical diagnosis, she experiences associated health problems identified in the nursing diagnoses *Chronic Pain, Imbalanced Nutrition: Less Than Body Requirements, Fatigue,* and *Hopelessness.* In such a situation determine which of the four diagnoses should take priority. The chronic pain experienced by the patient is often the first focus. Until her pain is under control, it will not be possible for her to feel more energized, eat well, or regain her sense of hopefulness.

Teamwork and Collaboration. As described previously, grief, loss, and death affect people physically, emotionally, spiritually, and culturally. No one is able to address all of these dimensions alone. A team of nurses, physicians, social workers, spiritual care providers, nutritionists, pharmacists, physical and occupational therapists, patients, and family members works together to provide palliative care, grief care, and care at the end of life. Massage or music/art therapists who provide alternative therapies are sometimes part of the team (see Chapter 33). As a patient's care needs change, team members take a more or less active role, depending on the patient's shifting priorities. Team members communicate with one another on a regular basis to ensure coordination and effectiveness of care.

QSEN **QSEN: BUILDING COMPETENCY IN TEAMWORK AND COLLABORATION** You are caring for Mrs. Allison, an older patient who has recently been diagnosed with a terminal illness and is preparing for discharge home. She has lost strength as a result of decreased activity, depression, and back pain. Her greatest desire is to be able to attend weekly services at her church; but, because of the weakness, pain, and fatigue, she is afraid that she will be unable to do so. She believes that her feelings of depression will improve if she can again participate in church activities. How can you, with the help of the interprofessional team, help Mrs. Allison respond to her spiritual needs and desire to be involved within her faith community?

ⓔ *Answers to QSEN Activities can be found on the Evolve website.*

CONCEPT MAP

Nursing diagnosis: Hopelessness
- Frequent sighing
- Negative view of future
- Ready to give up and be with her deceased husband
- Eyes closed; shows no facial or voice expression

▼

Interventions
- Treat chronic pain
- Identify sources of social support
- Set appropriate goals
- Encourage expression of positive life elements

Nursing diagnosis: Chronic pain
- Toes red, swollen, and painful
- Grimaces when moving
- Reports severe back pain; unable to walk well lately

▼

Interventions
- Give oral medications for chronic pain
- Use around-the-clock pain management; treat breakthrough pain
- Recommend massage, supportive chair, heating pads
- Monitor for side effects of pain medications
- Identify sources of social support

Primary health problem: Advanced leukemia
Priority assessments: Chronic pain; sense of hopelessness

Nursing diagnosis: Fatigue
- States she does not want to go on
- Has no energy; prefers to stay in bed
- Has chronic arthritis pain
- States she feels hopeless

▼

Interventions
- Treat chronic pain
- Schedule rest periods
- Arrange for physical and occupational therapy consultation
- Encourage patient to talk about feelings related to fatigue
- Determine adequacy of nutrition and sleep

Nursing diagnosis: Imbalanced nutrition: less than body requirements
- Reduced appetite
- Lack of energy to cook/eat alone
- Feelings of giving up
- Recent weight loss

▼

Interventions
- Plan social activities with friends that involve eating
- Identify easily prepared meals
- Identify food preferences
- Arrange for home meal delivery
- Encourage patient to eat smaller meals more often in the day

——— Link between medical diagnosis and nursing diagnosis   - - - - - Link between nursing diagnoses

FIGURE 37-4 Concept map for Mrs. Allison.

◆ **Implementation**

Health Promotion. Health promotion in serious chronic illness or death focuses on facilitating successful coping and optimizing physical, emotional, and spiritual health. Many people continue to look for and find meaning even in difficult life circumstances. They often find personal growth and spiritual insights that they have not previously experienced and need family and nurse support as they strive to maintain a degree of normalcy; live with loss; make health care decisions; prepare for death; and adjust to disappointments, frustration, and anxieties along the way (Box 37-6).

Palliative Care. Patients and families can benefit greatly from the specialized approach of palliative care. This holistic method to prevent and reduce symptoms promotes quality of life and whole-person well-being through care of the mind, body, and spirit.

Palliative care focuses on the prevention, relief, reduction, or soothing of symptoms of disease or disorders throughout the entire course of an illness. It can also include, but is not solely, care of the dying. The primary goal of palliative care is to help patients and families achieve the best possible quality of life (Mariano, 2015). Although it is especially important in advanced or chronic illness, palliative care is appropriate for patients of any age, with any diagnosis, at any time, and in any setting.

A large misconception concerning palliative care is that it is used only when curative treatments are no longer pursued. However, it is appropriate both for patients still receiving aggressive treatment with hope of achieving a cure and for patients who have forgone any life-extending treatment (Coyle, 2015). It is important that you help patients and their families understand the distinction because often

BOX 37-6 PATIENT TEACHING

Maintaining Self-Care

Objective
- The patient will participate in activities to manage symptoms.

Teaching Strategies
- Encourage patient to set realistic goals and identify ways to achieve them.
- Identify ways that patient can maintain usual daily routines that provide comfort and sense of normalcy.
- Demonstrate forms of complementary therapy that patient can use for symptom management.
- Discuss ways that patient can maintain a sense of control over end-of-life planning and maintain a realistic outlook (advance directives, funeral planning, and preferred location of death).
- Discuss patient's needs for presence of particular support people or for solitude.
- Identify methods to facilitate safety and ease in managing activities of daily living as patient's abilities change (assistive devices, in-home caregivers).

Evaluation
- Ask patient to describe symptom-management methods used and rate their effectiveness.

misunderstanding the purpose of palliative care causes patients to refuse it.

The World Health Organization (2015) summarizes palliative care philosophy as follows:
- Affirms life and regards dying as a normal process.
- Neither hastens or postpones death.
- Integrates psychological and spiritual aspects of patient care.
- Offers a support system to help patients live as actively as possible until death.
- Enhances the quality of life.
- Uses a team approach to meet the needs of patients and families.

Because the focus of palliative care is comfort and improved quality of life, it is a valuable approach to caring for patients with a complex illness. A variety of therapies are used to provide patients with a holistic approach to symptom management and ultimately improved quality of life. Kraft (2012) reports that activities such as yoga, acupuncture, massage, and aromatherapies have shown to have a positive effect on feelings of depression. In addition, music therapy, mindfulness-based stress-reduction techniques, and aromatherapy have successfully treated some patient's anxiety. Fatigue, a common symptom reported by the palliative care patient, responds to acupuncture and exercise. Massage has also been shown to reduce the symptoms of pain, anxiety, nausea, shortness of breath, stress and increase relaxation and peacefulness (Trumble et al., 2014).

When the goals of care change and cure for illnesses becomes less likely, the focus shifts to more palliative care strategies and ideally transition to hospice care, a more specialized form of palliative care for the dying.

Hospice Care. **Hospice** care is a philosophy and model for the care of terminally ill patients and their families at the end of life. It gives priority to managing a patient's pain and other symptoms; comfort; quality of life; and attention to physical, psychological, social, and spiritual needs and resources. Patients accepted into a hospice program usually have less than 6 months to live. Hospice services are available in home, hospital, extended care, and nursing home settings.

The cornerstone of hospice care is a trusting relationship between the hospice team and the patient and family. Knowing expectations, desired location of care, and family dynamics helps the hospice team provide individualized care at the end of life. Unlike traditional care, hospice patients are active participants in all aspects of care, and caregivers prioritize care according to patient wishes. Patient care goals are mutually set, and all participants fully understand the patient's care preferences and try to honor them. Hospice services provide bereavement visits made by the staff after the death of the patient to help the family move through the grieving process. Hospice programs are built on the following core beliefs and services:
- Patient and family are the unit of care
- Coordinated home care with access to inpatient and nursing home beds when needed
- Symptom management
- Physician-directed services
- Provision of an interdisciplinary care team
- Medical and nursing services available at all times
- Bereavement follow-up after patient's death
- Use of trained volunteers for visitation and respite support

To be eligible for home hospice services, a patient must have a family caregiver to provide care when the patient is no longer able to function alone. Home care aides offer help with hygienic needs, and a nurse is available to coordinate and manage symptom relief. Nurses providing hospice care use therapeutic communication, offer psychosocial care and expert symptom management, promote patient dignity and self-esteem, maintain a comfortable and peaceful environment, provide spiritual comfort and hope, protect against abandonment or isolation, offer family support, help with ethical decision making, and facilitate mourning. Hospice team members offer 24-hour accessibility and coordinate care between the home and inpatient setting. A patient receiving home hospice care may enter an inpatient hospice unit for stabilization of symptoms or caregiver respite. As a patient's death comes closer, the hospice team provides intensive support to the patient and family (Hospice Foundation of America, 2014).

Use Therapeutic Communication. The heart of nursing care is the establishment of a caring and trusting relationship with your patient. This patient-focused approach allows you to respond to patients rather than react and encourages the sharing of important information. Open-ended questions invite patients to elaborate on their thoughts and encourage them to tell their stories. Patients usually give short answers (yes or no) when you use closed-ended questions, which limit what we can learn about their situation. Use active listening, learn to be comfortable with silence, and use prompts (e.g., "go on," "tell me more") to encourage continued conversation. Empathizing, touching, and offering self are also effective ways to therapeutically communicate with our patients. Specifically, empathizing allows the patient to see that their feelings are normal and that as the nurse you understand. Sometimes questioning a patient feels uncomfortable; thus stating an observation such as, "You look worried" or "You didn't eat much lunch" invites patients to respond without feeling pressure to answer (see Chapter 24).

Feelings of sadness, numbing, or anger make talking about these situations especially difficult. For example, a patient may experience anger during grief and lash out at caregivers. Some patients even become demanding and accusing. Remain supportive by letting patients and family members know that feelings such as anger are normal by saying, "I see that you're upset right now, and that's understandable. I just want you to know I'm here to talk with you if you want." Encourage patients to share the emotions and concerns of greatest importance to them and then acknowledge their feelings and concerns in a nonjudgmental manner. If a patient chooses not to share

feelings or concerns, express a willingness to be available at any time. Some patients do not discuss emotions for personal or cultural reasons, and others hesitate to express their emotions for fear that people will abandon or judge them. If you are reassuring and respectful of a patient's privacy, a therapeutic relationship likely develops. Sometimes patients need to begin resolving their grief privately before they discuss their loss with others, especially strangers.

Do not avoid talking about a topic. When you sense that a patient wants to talk about something, make time to do so as soon as possible. This may be very challenging if you are in a busy acute care setting; however, it is a necessary part of quality nursing care and should be made a priority. Above all, remember that a patient's emotions are not something you can "fix." Instead view emotional expressions as an essential part of the patient's adjustment to significant life changes and development of effective coping skills. Help family members access other professional resources. Social workers, chaplains, and case managers can offer additional information and support to families and patients in grief.

Provide Psychosocial Care. Patients at the end of life experience a range of psychological symptoms, including anxiety, depression, powerlessness, uncertainty, and isolation. They can experience anguish from the unknown surroundings, treatment options, health status, and the dying process. Worry or fear is common in many patients and often heightens their perception of discomfort and suffering. You can alleviate some of it by providing information to them about their condition, the course of their disease, and the benefits and burdens of treatment options.

Manage Symptoms. Managing the multiple symptoms commonly experienced by chronically ill or dying patients remains a primary goal of palliative care nursing. Uncontrolled symptoms cause patients' and families' distress, discomfort, and suffering, which often complicates the dying experience. Despite the availability of effective treatment options for pain, many patients suffer with avoidable pain at the end of life because of misconceptions by the nurse or family (see Chapter 44). Maintain an ongoing assessment of the patient's pain and response to interventions. Reassure the family repeatedly of the need for pain control even if the patient does not appear in pain. Discuss pain control with the family frequently and dispel any myths regarding dependence on narcotics. You are responsible to advocate for change if the patient does not obtain relief from the prescribed regimen. It is imperative that you assess dying patients' nonverbal cues because they often are unable to communicate their intentions. During the dying process patients' renal and liver function decline, decreasing metabolism and rate of drug clearance, which might require modification to the dosage of medication. Also be aware that advancing disease pathology, anxiety, or delirium sometimes requires the use of higher doses or different drug therapies.

Remain alert to the potential side effects of opioid administration: constipation, nausea, sedation, respiratory depression, or myoclonus. Family members often worry about potential addiction to opioid medications. Not only is the incidence of true addiction very low, but a patient's need for pain relief at the end of life takes priority. Education is necessary to help families understand the need for appropriate use of opioid medications. Table 37-3 provides a basic overview of nursing care for common symptoms experienced at the end of life.

Promote Dignity and Self-Esteem. A sense of dignity includes a person's positive self-regard, the ability to find meaning in life and feel valued by others, and treatment by caregivers. Nurses promote a patient's self-esteem and dignity by respecting him or her as a whole person (i.e., as a person with feelings, accomplishments, and passions independent of the illness experience), not just as a diagnosis. Respecting and valuing the things that a patient cares about validates the person and at the same time strengthens communication among the patient, family members, and the nurse. Sharing time with patients as they share their life stories helps you know them and facilitates the development of individualized interventions.

Attending to the patient's physical appearance also promotes dignity and self-esteem. Cleanliness, absence of body odors, and attractive clothing give patients a sense of worth. When caring for a patient's bodily functions, show patience and respect, especially after the patient becomes dependent on others. Remember that patients are directing care at the end of life. Allow them to make decisions such as how and when to administer personal hygiene, diet preferences, and timing of nursing interventions. Keep the patient and family members informed about daily activities, tests, or therapies; their purposes; and anticipated effects. Provide privacy during nursing care procedures and be sensitive to when the patient and family need time alone together.

Maintain a Comfortable and Peaceful Environment. A comfortable, clean, pleasant environment helps patients relax, promotes good sleep patterns, and minimizes symptom severity. Keep a patient comfortable through frequent repositioning, making sure that bed linens are dry, and controlling extraneous environmental noise and offensive odors. Pictures, cherished objects, and cards or letters from family members and friends create a familiar and comforting environment for the patient dying in an institutional setting. When possible, allow patients to wear their own pajamas or lounging clothes to promote a sense of comfort and familiarity. Consider nonpharmacological interventions such as massage therapy to increase patient comfort (Paice, 2015). Family members are often able to provide these interventions, increasing their sense that they are making a positive contribution. Use patient-preferred music in the background, provide guided-imagery exercises, and dim the lights to provide a soothing environment for the patient and family. Patient-preferred forms of complementary therapies offer noninvasive methods to increase comfort and well-being at the end of life (Mariano, 2015) (see Chapter 33).

Promote Spiritual Comfort and Hope. Patients are comforted when they have assurance that some aspect of their lives will transcend death; therefore helping patients make connections to their spiritual practice or cultural community can be a useful intervention. Draw on the resources of spiritual care providers in an institutional setting or collaborate with the patient's own spiritual or religious leaders and communities. Making an audiotape or videotape for the family, writing letters, or keeping a journal assures patients that something of their essence will survive past their death.

The spiritual concept of hope takes on special significance near the end of life. Nursing strategies that promote hope are often quite simple: be present and provide whole-person care. Patients perceive the love of family and friends, faith, goal setting, positive relationships with professional caregivers, humor, and uplifting memories as hope promoting. Circumstances that hinder the preservation of hope include abandonment or isolation, uncontrolled symptoms, or being devalued as a person. Patients and their families hope for different things over the course of their experience with illness and death. Balancing each perspective is imperative to quality patient care at the end of life. Some hope to live for an anniversary, sit outdoors for a meal, see an important person one last time, gain pain relief, or have a peaceful death. Listen for shifts in patients' hopes and find ways to help them meet their desired goals.

Protect Against Abandonment and Isolation. Many patients with terminal illness fear dying alone. Patients feel more hopeful when others are near to help them. Nurses in institutional settings need to answer call lights promptly and check on patients often to reassure them that someone is close at hand. If family members plan to stay

TABLE 37-3 Promoting Comfort in the Terminally Ill Patient

Symptoms	Characteristics or Causes	Nursing Implications
Pain	Pain has multiple causes, depending on patient diagnosis.	Collaborate with team members to identify and implement appropriate pharmacological and nonpharmacological interventions to reduce pain and promote comfort (see Chapter 44 for further discussion on pain management).
Skin discomfort	Any source of skin irritation increases discomfort.	Keep skin clean, dry, and moisturized. Monitor for incontinence.
Mucous membrane discomfort	Mouth breathing or dehydration leads to dry mucous membranes; tongue and lips become dry or chapped.	Provide oral care at least every 2 to 4 hours. Apply a light film of lip balm for dryness. Apply topical analgesics to oral lesions prn.
Corneal irritation	Blinking reflexes diminish near death, causing drying of cornea.	Optical lubricants or artificial tears reduce corneal drying.
Fatigue	Metabolic demands, stress, disease states, decreased oral intake, and heart function cause weakness and fatigue.	Provide periods of rest and educate patient about energy conservation.
Anxiety	Physical, social, or spiritual distress causes anxiety; causes may be situational or event specific.	Provide opportunity for patient to express feelings though active listening. Provide calm, supportive environment. Consult members of health care to determine if pharmacological interventions are appropriate.
Nausea	Nausea is caused by medications, pain, or decreased intestinal blood flow with impending death.	Determine the cause of nausea and work to reduce nausea triggers such as strong smells. Administer antiemetics or promotility agents. Encourage patients to lie on their right side. Provide oral care at least every 2 to 4 hours.
Constipation	Opioids, medications, and immobility slow peristalsis. Lack of bulk in diet or reduced fluid is a cause.	Increase fiber in diet if appropriate. Administer stool softeners or laxatives as needed. If possible encourage increased liquid intake and regular periods of ambulation.
Diarrhea	Disease processes, treatment or medications, and gastrointestinal (GI) infections are causes.	Consult with members of the health are to determine the cause and make appropriate changes. Provide skin care and easy accessibility to the toilet or bedside commode.
Urinary incontinence	Progressive disease and decreased level of consciousness are causes.	Provide good skin care and frequent assessment for incontinent urine. Place Foley catheter as appropriate.
Altered nutrition	Medications, depression, decreased activity, and decreased blood flow to GI tract are causes. Nausea produces anorexia.	Encourage patient to eat small, frequent meals of preferred foods. Patients should never be forced to eat.
Dehydration	Patient is less willing or able to maintain oral fluid intake; has fever.	Reduce discomfort from dehydration; give mouth care at least every 2 to 4 hours; offer ice chips or moist cloth to lips. Keep lips and tongue moist.
Ineffective breathing patterns (e.g., dyspnea, shortness of breath)	Anxiety; fever; pain; increased oxygen demand; disease processes; and anemia, which reduces oxygen-carrying capacity, are causes.	Treat or control underlying cause. Use nonpharmacological interventions such as elevating the head of the bed to promote lung expansion. Provide oxygen as needed. Keeping the air cool provides ease and comfort for the terminal patient. Using narcotic to treat tachypnea is sometimes appropriate.
Noisy breathing ("death rattle")	Noisy breathing is the sound of secretions moving in the airway during inspiratory and expiratory phases caused by thick secretions, decreased muscle tone, swallow, and cough.	Elevate head to facilitate postural drainage. Turn patient at least every 2 hours. Provide oral care and maintain hydration as tolerated.

with the patient at all times or if you have assessed high privacy needs for the patient and family, a private room is best.

Some family members who have a difficult time accepting a patient's impending death cope by making fewer visits. When family members do visit, inform them of the patient's status and share meaningful insights or encounters that you have had with the patient. Find simple and appropriate care activities for the family to perform such as offering food, cooling the patient's face, combing hair, or filling out a menu. Nighttime can be particularly lonely for the patient. Suggest that a family member stay through the night if possible. Make exceptions to visiting policies, allowing family members to remain with patients who are dying at any time. Family members appreciate having open access or closeness to their loved one through their experiences at the end of life. Record contact information for them so you can reach them at any time.

Support the Grieving Family. In palliative and hospice care patients and family members constitute the unit of care. When a patient becomes debilitated or approaches the end of life, family members also suffer. They describe caregiving at the end of life as unpredictable, frightening, and anguishing. Yet many family members find meaning in providing practical and simple care to their loved one. In these extremely intimate and emotionally challenging times, offer holistic, family-centered support, compassion, and education that incorporates the uniqueness of each patient. Often family members face challenging and complex situations long before their loved one is actively dying. Family members caring for people with serious life-limiting illness

BOX 37-7 EVIDENCE-BASED PRACTICE

Use of Antimuscarinic Drugs to Control Respiratory Secretions

PICO Question: In patients who are terminally ill, what is the effect of antimuscarinic drugs to reduce excess respiratory secretions compared to no intervention?

Evidence Summary

Many symptoms occur when the body is slowly shutting down. One of the most fearful and troublesome is excess respiratory tract secretions, also known as the *death rattle*. For loved ones and caregivers at the bedside the sound of secretions in the respiratory tract is unnerving and distressing. However, patients most likely are not suffering from these secretions. Because end-of-life care is concerned with the family unit, treatment is often initiated to reduce the amount of secretions and therefore reduce and hopefully eliminate the distressing sound. Health care providers use different antimuscarinic drugs such as scopolamine, glycopyrronium (Robinul), hyoscine butylbromide (Buscopan), atropine, and octreotide (Sandostatin) in hopes of preventing or managing the excess secretions. The question remains if these treatments are effective. A systematic review of the research literature was completed; and 39 studies, published between 1988 and 2012, were identified. The researchers concluded that no evidence exists to support the claim that these drugs are better at reducing the amount of secretions in the terminal patient when compared to no treatment (Lokker et al., 2014).

Application to Nursing Practice

- Provide education about the occurrence of the death rattle to reduce the anxiety and distress often experienced by loved ones (Lokker et al., 2014).
- Help family position loved one to reduce secretion and improve breathing.
- Teach family member how to use oral suction devices to control excess secretions.

BOX 37-8 Physical Changes Hours or Days Before Death

- Increased periods of sleeping/unresponsiveness
- Coolness and color changes in extremities, nose, fingers (cyanosis, pallor, mottling) (see Figure 37-5)
- Bowel or bladder incontinence
- Decreased urine output; dark-colored urine
- Restlessness, confusion, or disorientation
- Decreased intake of food or fluids; inability to swallow
- Congestion/increased pulmonary secretions; noisy respirations (death rattle)
- Altered breathing (apnea, labored or irregular breathing, Cheyne-Stokes pattern)
- Decreased muscle tone, relaxed jaw muscles, sagging mouth
- Weakness and fatigue

FIGURE 37-5 Skin mottling. (From Adams J et al: *Emergency medicine,* Philadelphia, 2009, Saunders.)

need attention and support early and consistently throughout the experience of illness and death.

Educate family members in all settings about the symptoms that the patient will likely experience and the implications for care (Box 37-7). For example, patients in the last days of life often develop anorexia or feel nauseated by food. Illness, excessive respiratory secretions, decreased activity, treatments, and fatigue decrease a patient's caloric needs and appetite. Family members, distressed with the decline, often believe that they need to encourage the patient to eat. Because the goal of palliative care is comfort, we do not want to force the patient to do anything that is causing discomfort. Eating in the last days of life often causes the patient pain and discomfort. In addition, as the body is shutting down, the nutrients in food are not able to be absorbed. Therefore forcing patients to eat serves no beneficial purpose for the patient. Help families shift their focus to other helping activities during this time.

Family members who have limited prior experience with death do not know what to expect. They may need personal time with the nurse to share their concerns, ask about treatment options, validate perceived changes in the patient's status, or explore the possible meaning of patient behaviors. Whenever possible, communicate news of a patient's declining condition or impending death when family members are together so they can support one another. Provide information privately and stay with the family as long as needed or desired. Reduce family member anxiety, stress, or fear by describing what to expect as death approaches. Become familiar with common manifestations of impending death (Box 37-8), remembering that patients usually

experience some but not all of these changes. Do not try to predict the time of death; instead use your assessments to help family members anticipate what is happening. Be compassionate and sensitive in how you share information. "Mottling is an expected sign as a body begins shutting down" instead of "when a person gets closer to death we see mottling" (Figure 37-5). Share your observations and through your role modeling encourage a sense of patience, compassion, and comfort throughout the dying process.

During the dying process check frequently on families, offering support, information, and, if appropriate, encouragement to continue touching and talking with their loved ones. In the time immediately following death determine the family's needs. Some families will want to touch or hold the deceased, others will not. Make the deceased accessible by lowering side rails, having hands exposed, and a chair close to the bedside. Depending on facility policies allow the family the necessary time to be with their loved one.

After death help the family make decisions such as notification of a funeral home, transportation of family members, and collection of the patient's belongings. Nurses are a primary source of family support. Remember that, because of differing responses to grief, some family members prefer to be alone at the time of and after the death, whereas others want to be surrounded by a support community. When uncertain about what a family member prefers for support, pose simple questions and offer suggestions for assistance.

With the death of a patient, family members benefit from the many resources of the health care team. When the patient chooses to die at home, family members provide direct care, which is often emotionally

stressful and physically exhausting. In the home setting fatigued family caregivers benefit from respite care. During respite care a patient temporarily receives care from others so family members are able to get away to rest and relax. Hospice program benefits include some days of respite care. Inform family members of home care, hospice, and community service options so they can access the best resources for their situation.

Assist with End-of-Life Decision Making. Patients and family members often face complex treatment decisions at the end of life. Patients and families must decide which treatments to continue and which to forgo; to enroll in hospice or stay in the hospital; or to transfer to a nursing home, in-patient unit, or home. Even after the decision to enroll in hospice, questions arise about symptom management, artificial nutrition and hydration, and the desired location for death. You are able to support and educate patients and families as they identify, contemplate, and ultimately decide how to best journey to the end of life.

Difficult ethical decisions at the end of life complicate a survivor's grief, create family divisions, or increase family uncertainty at the time of death (see Chapter 22). When ethical decisions are handled well, survivors achieve a sense of control and experience a meaningful conclusion to their loved one's death. Suggest to patients that they clearly communicate their wishes for end-of-life care so family members are able to act as faithful surrogates when the patient can no longer speak for himself or herself. Some patients and family members rely on the nurse and other members of the health care team to initiate discussions regarding end-of-life care. Nurses often provide options that family members do not know are available and are advocates for patients and family members making decisions at the end of life in the form of an advanced directive. Over the last decade there has been a 25% increase in completion of advance directives. Although this has increased patients' level of autonomy, it has not reduced the number of deaths that occur in the hospital (Silveira et al., 2014).

Facilitate Mourning. Nurses who work with grieving family members often provide bereavement care after the patient's death. Helpful strategies for assisting grieving persons include the following:

- Help the survivor accept that the loss is real. Discuss how the loss or illness occurred or was discovered, when, under what circumstances, who told him or her about it, and other factual topics to reinforce the reality of the event and put it in perspective.
- Support efforts to adjust to the loss. Use a problem-solving approach. Have survivors make a list of their concerns or needs, help them prioritize, and lead them step-by-step through a discussion of how to proceed. Encourage survivors to ask for help.
- Encourage establishment of new relationships. Reassure people that new relationships do not mean that they are replacing the person who has died. Encourage involvement in nonthreatening group social activities (e.g., volunteer activities or church events).
- Allow time to grieve. "Anniversary reactions" (e.g., renewed grief around the time of the loss in subsequent years) are common. A return to sadness or the pain of grief is often worrisome. Openly acknowledge the loss, provide reassurance that the reaction is normal, and encourage the survivor to reminisce.
- Interpret "normal" behavior. Being distractible, having difficulty sleeping or eating, and thinking that they have heard the deceased's voice are common behaviors following loss. These symptoms do not mean that an individual has an emotional problem or is becoming ill. Reinforce that these behaviors are normal and will resolve over time.

- Provide continuing support. Survivors need the support of a nurse with whom they have bonded for a time following a loss, especially in home care or hospice nursing. The nurse has filled an important role in the deceased's life and death and has helped survivors through some very intimate and memorable times. Attachment for a period of time after the death is appropriate and healing for both the survivor and the nurse. However it is imperative that professional boundaries always be maintained.
- Be alert for signs of ineffective, potentially harmful coping mechanisms such as alcohol and substance abuse or excessive use of over-the-counter analgesics or sleep aids.

Care After Death. Federal and state laws require institutions to develop policies and procedures for certain events that occur after death: requesting organ or tissue donation, performing an autopsy, certifying and documenting the occurrence of a death, and providing safe and appropriate postmortem care. In accordance with federal law, a specially trained professional (e.g., transplant coordinator or social worker) makes requests for **organ and tissue donation** at the time of every death. The person requesting organ or tissue donation provides information about who can give consent legally, which organs or tissues can be donated, associated costs, and how donation affects burial or cremation.

In extremely stressful circumstances created by the loss of a loved one, grieving survivors usually cannot remember all they were told. Nurses provide support and reinforce or clarify explanations given to them during the request process. In addition, understanding the physiology of organ donation is often difficult for family members. Even though a patient who is brain dead is legally declared dead, he or she remains on life support to provide the vital organs with blood and oxygen before transplant. The appearance of a live-looking body confuses the family, and they need help to understand that the life support is only preserving the vital organs. Nonvital tissues such as corneas, skin, long bones, and middle ear bones are taken at the time of death without artificially maintaining vital functions. If the deceased has not left behind instructions concerning organ and tissue donation, the family gives or denies consent at the time of death. Review your state organ retrieval laws and institutional policy and procedure regarding the formal consent process. Be aware that the laws governing who to approach for organ donation may not be acceptable in other cultures.

Family members give consent for an **autopsy** (i.e., the surgical dissection of a body after death) to determine the exact cause and circumstances of death or discover the pathway of a disease (see Chapter 23). In most cases a coroner or medical examiner determines the need to perform an autopsy. Law sometimes requires that an autopsy be performed when death is the result of foul play; homicide; suicide; or accidental causes such as motor vehicle crashes, falls, the ingestion of drugs, or deaths within 24 hours of hospital admission.

Usually the physician or other designated health care provider asks for autopsy permission while the nurse answers questions and supports the family's choices. Inform family members that an autopsy does not deform the body and that all organs are replaced in the body. Family members are often comforted to know that others may be helped by either the gift of organ and tissue donation or autopsy. Respect and honor family wishes and final decisions.

Documentation of a death provides a legal record of the event. Follow agency policies and procedures carefully to provide an accurate and reliable medical record of all assessments and activities surrounding a death. Physicians or coroners sign some medical forms such as a request for autopsy, but the RN gathers and records much of the remaining information surrounding a death. Nurses also usually witness or delegate the signing of forms (e.g., release of body or

personal belongings forms). Nursing documentation becomes relevant in risk management or legal investigations into a death, underscoring the importance of accurate, legal reporting. Documentation also validates success in meeting patient goals or provides justification for changes in treatment or expected outcomes. Box 37-9 lists important documentation elements for end-of-life care.

Family members deserve and expect a clear description of what happened to their loved one, especially in cases of sudden, unusual, or unexpected circumstances. Give *only* factual information in a nonjudgmental, objective manner and avoid sharing your opinions. State law and agency policy govern the sharing of the written medical record information, which usually involves a written request. Follow legal guidelines for documentation and sharing of medical records (see Chapter 23).

BOX 37-9   Documentation of End-of-Life Care

- Time and date of death and all actions taken to respond to the impending death
- Name of health care provider certifying the death
- People notified of the death (e.g., health care providers, family members, organ request team, morgue, funeral home, spiritual care providers) and person who comes to declare time of death
- Name of person making request for organ or tissue donation
- Special preparations of the body (e.g., desired or required religious/cultural rituals)
- Medical tubes, devices, or lines left in or on the body
- Personal articles left on and secured to the body
- Personal items given to the family with description, date, time, to whom given
- Location of body identification tags
- Time of body transfer and destination
- Any other relevant information or family requests that help clarify special circumstances
- Verify with health care agency

When a patient dies in an institutional or home care setting, nurses provide or delegate **postmortem care,** the care of a body after death. Above all, a deceased person's body deserves the same respect and dignity as that of a living person and needs to be prepared in a manner consistent with the patient's cultural and religious beliefs. Death produces physical changes in the body quite quickly; thus you need to perform postmortem care as soon as possible to prevent discoloration, tissue damage, or deformities.

Maintaining the integrity of cultural and religious rituals and mourning practices at the time of death gives survivors a sense of fulfilled obligations and promotes acceptance of the patient's death (Box 37-10). The ability of families to mourn in a manner consistent with cultural values helps survivors experience some predictability and control in an otherwise uncertain and confusing time. Some cultures consider "family" as more than a nuclear biological unit. Health care providers need to understand the makeup of a family network and know which individuals to involve in end-of-life decisions and care.

The nurse coordinates patient and family care during and after a death. Become familiar with applicable policies and procedures for postmortem care because they vary across settings or institutions. See the procedural guideline (Box 37-11) for standard activities for care of the body after death.

◆ Evaluation

Through the Patient's Eyes. The success of the evaluation process depends partially on the bond that you have formed with the patient and family. Through a trusting relationship patients are more likely to share personal expectations or their wishes, especially if encouraged through appropriate questioning. Refer back to the goals and expected outcomes established during the planning phase to determine the effectiveness of nursing interventions. A patient's responses and perceptions of the effectiveness of the interventions determine if the existing plan of care is effective or if different strategies are necessary. For example, if the goal is to have the patient communicate a sense of hope to family members, evaluate verbal and nonverbal communication and behaviors for cues related to expressions of hope. Continue

---

⊕ BOX 37-10   CULTURAL ASPECTS OF CARE

Care of the Body After Death

Loved ones use cultural-specific rituals and mourning practices to achieve a sense of acceptance and inner peace and participate in socially accepted expressions of grief. One's culture greatly influences which behaviors and rituals are expected at the time of death. Institutional guidelines and end-of-life care procedures for patients from all cultures provide standards based on compassion, maintaining privacy and dignity, and respect for patients' and family members' cultural beliefs and practices. Expert end-of-life care allows time for patients and their families to make private and public preparations and complete unfinished communication. Understanding the uniqueness of cultural expectations at the end of life helps a nurse know which questions to ask. The following cultural or religious practices are not necessarily exclusive to the culture named but are offered to give you an idea of some cultural-specific concerns that you may encounter in end-of-life care.

Implications for Patient-Centered Care
African-American: Care of the body after death depends on the African-American's country of origin and degree of American acculturation. The presence of large extended family groups, including the church family, is common at time of death. The mourning period is relatively short, with a memorial

service and a public viewing of the body or a wake before burial. Organ donation and autopsy are allowed.

Chinese: Death is regarded as a negative life event, and there is no concept of an afterlife. The dead are treated with the same respect as the living and may be buried with food and other artifacts. Members of an extended family usually stay with the deceased for up to 8 hours after death. The oldest son or daughter bathes the body under direction of an older relative or a temple priest. They often believe the body should remain intact; thus organ donation and autopsy are uncommon (Xu, 2007).

Hispanic or Latino: Honoring family values and roles is essential in providing care and making decisions at the end of life. People in Hispanic and Mexican-American cultures often use special objects such as amulets or rosary beads, alternative healing practices (folk medicine), and prayer. Grief is expressed openly. Religious and spiritual rituals (predominantly Catholic) are essential at the end of life. Death is often believed to be the will of God (Owen et al., 2012; Taxis et al., 2008).

Native American: Native Americans encompass diverse tribal groups with differing practices, traditions, and ceremonies. Traditional Navajos do not touch the body after death. Care of the body in the large Navajo tribe includes

---

⊕ BOX 37-10 **CULTURAL ASPECTS OF CARE**

Care of the Body After Death—cont'd

cleansing the body, painting the deceased's face, dressing in clothing, and attaching an eagle feather to symbolize a return home. Mourners also have a ritual cleansing of their bodies. The dead are buried on the deceased's homeland (Hanley, 2012).

Islamic: The deceased's body is ritualistically washed, wrapped, cried over, prayed for, and buried as soon as possible after death. The eyes and mouth are closed, and the face of the deceased is turned toward Mecca. Muslims of the same gender prepare the body for burial. Bodies are buried, not cremated. Autopsies interfere with a quick burial; make autopsy requests with sensitivity and only if necessary. The proximity of loved ones after death is important since it is believed that the soul stays with the body until it is buried. Organ donation is permissible by some Qur'an interpretations (Gatrad and Sheikh, 2008).

Buddhist: Buddhists believe in an afterlife in which humans manifest in different forms. Death is preferred at home, and a person's state at the time of death is important. Individuals usually minimize emotional expressions and

maintain a peaceful, compassionate atmosphere. Male family members prepare the body. Buddhists recommend not touching the body after death to give the deceased a smoother transition to the afterlife. People often say prayers while touching and standing at the head of the deceased. The body is not left alone after death. Family and friends pay respects after death and before cremation of the body (Bauer-Wu et al., 2007).

Hindu: The body is placed on the floor with the head facing north. People of the same gender handle the body after death. There are no general prohibitions against autopsy. Bodies are cremated after death to purify by fire (Gatrad and Sheikh, 2008).

Jewish: If the family practices Orthodox Judaism, determine if members from the Jewish Burial Society are coming to the facility before preparing the body. A family member often stays with the body until burial. Usually the burial occurs within 24 hours but not on the Sabbath. Some but not all types of Judaism avoid cremation, autopsy, and embalming (Bauer-Wu et al., 2007).

BOX 37-11 **PROCEDURAL GUIDELINES**

Care of the Body After Death

Delegation Considerations

The skill of care of the body after death can be delegated to nursing assistive personnel (NAP). Nurses often find it meaningful to help care for a patient after death and assist the NAP whenever possible. Instruct the NAP to:

- Contact the nurse for all questions and procedures related to organ/tissue donation and autopsy requests.
- Alert nurse to family members' questions related to manner of death or after-death activities.

Equipment

Bath towels, washcloths, washbasin, scissors, shroud kit with name tags, bed linen, documentation forms.

Steps

1. Confirm that the health care provider certified the death and documented the time of death and actions taken.
2. Determine if the health care provider requested an autopsy. An autopsy is required for deaths that occur under certain circumstances.
3. Validate the status of request for organ or tissue donation. Given the complex and sensitive nature of such requests, only specially trained personnel make the requests. Maintain sensitivity to personal, religious, and cultural beliefs in this process.
4. Identify the patient using two identifiers (e.g., name and birthday or name and medical record number according to agency policy).
5. Provide sensitive and dignified nursing care to the patient and family.
   a. Elevate the head of the bed as soon as possible after death to prevent discoloration of the face.
   b. Collect ordered specimens.
   c. Ask if the family wishes to participate in preparation of the body. Offer to make arrangements for supportive company for the family (patient/family religious leader, spiritual care personnel, or bereavement specialist) during body preparation.
   d. Ask about family requests for body preparation such as wearing special clothing or religious artifacts. Be aware that personal, religious, or

cultural practices determine whether or not to shave male facial hair. Get permission before shaving a beard.
   e. Remove all equipment, tubes, and indwelling lines. Note that autopsy or organ donation often poses exceptions to removal; thus consult agency policy in these situations.
   f. Cleanse the body thoroughly, maintaining safety standards for body fluids and contamination when indicated. Comb patient's hair or apply personal hairpieces.
   g. Cover body with a clean sheet, place head on a pillow, and leave arms outside covers if possible. Close eyes by gently holding them shut; leave dentures in the mouth to maintain facial shape; cover any signs of body trauma.
   h. Prepare and clean the environment, deodorize room if needed, and lower the lights.
   i. Offer family members the option to view the body and ask if they want you or other support people to accompany them. Honor and respect individual choices.
   j. Encourage grievers to say good-bye in their own way: words, touch, singing, religious rituals, or prayers.
   k. Provide privacy and an unrushed atmosphere. Assess family members' need or desire for your presence at this time. If you leave, tell them how to reach you.
   l. Determine which personal belongings stay with the body (e.g., wedding ring or religious symbol) and give other personal items to family members. Document time, date, description of the items taken, and who received them. Save any items that are left behind accidentally and contact family for further instructions.
   m. Apply identifying name tags and shroud according to agency policy before transporting the body. Follow safety procedures for body fluid precautions or contamination concerns.
   n. Complete documentation in the narrative notes section (see Box 37-9).
   o. Maintain privacy and dignity when transporting the body to another location; cover the body or stretcher with a clean sheet.

Knowledge
- Characteristics of the resolution of grief
- Clinical symptoms of an improved level of comfort (applicable for terminally ill)
- Principles of palliative care

Experience
- Previous patient responses to planned nursing interventions for symptom management or loss of a significant other

EVALUATION
- Evaluate signs and symptoms of the patient's grief
- Evaluate family member's ability to provide supportive care
- Evaluate terminal patient's level of comfort and symptom relief
- Ask if the patient's/family's expectations are being met

Standards
- Use established expected outcomes to evaluate the patient's response to care (e.g., ability to discuss loss, participation in life review)
- Evaluate the patient's role in end-of-life decisions and/or the grieving process

Attitudes
- Persevere in seeking successful comfort measures for the terminally ill patient

FIGURE 37-6 Critical thinking model for loss, death, and grief evaluation.

to evaluate the patient's progress, the effectiveness of the interventions, and patient and family interactions. Even when a patient is not seeking care specifically related to a loss, be alert for signs and symptoms of grief. They provide the criteria for evaluating whether a patient is coping with a loss and how he or she is moving through the grief process. Critical thinking ensures that the evaluation process accurately reflects the patient's situation and desired outcomes (Figure 37-6).

Patient Outcomes. The following questions help us validate achievement of goals and expectations:
- What is the most important thing I can do for you at this time?
- Are your needs being addressed in a timely manner?
- Are you getting the care for which you hoped?
- Would you like me to help you in a different way?
- Do you have a specific request that I have not met?

Especially in home care settings, include family members in the evaluation process. The short- and long-term outcomes that signal a family's recovery from a loss guide your evaluation. Short-term outcomes indicating effectiveness of grief interventions include talking about the loss without feeling overwhelmed, improved energy level, normalized sleep and dietary patterns, reorganization of life patterns, improved ability to make decisions, and finding it easier to be around other people. Long-term achievements include the return of a sense of humor and normal life patterns, renewed or new personal relationships, and decrease of inner pain.

KEY POINTS

- When caring for patients who have experienced a loss, facilitate the grief process by helping survivors feel the loss, express it, and move through their grief.
- Loss comes in many forms, based on the values and priorities learned within a person's sphere of influence (i.e., family, friends, religion, society, and culture).
- Death is difficult for the dying person and the person's family, friends, and caregivers.
- Survivors move back and forth through a series of stages and/or tasks many times, possibly extending over a long period of time.
- Grieving people use their own unique history, context, and resources to make meaning out of their loss experiences. Listen as patients share the experience in their own way.
- A person's development, coping strategies, socioeconomic status, personal relationships, nature of loss, and cultural and spiritual beliefs influence the way he or she perceives and responds to grief.
- Assess the terminally ill patient and family wishes for end-of-life care, including the preferred place for death, desired level of intervention, and expectations for pain and symptom management.
- Establish a caring presence and use effective communication strategies to encourage patients to share to the degree they are comfortable.
- Palliative care focuses on improving quality of life through an illness or death experience.
- Hospice is a philosophy of family-centered, whole-person care at the end of life.

CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

1. Mrs. Allison is exhibiting signs of grief over her situation and possible cancer diagnosis. In her withdrawn state how might you encourage her to share her feelings? Provide specific statements that would illicit robust responses from Mrs. Allison.
2. Mrs. Allison will be staying in the hospital for the next week until her family can make the necessary arrangements to transfer her home. Describe ways to ensure that Mrs. Allison is comfortable at home and in her hospital room.
3. Before being transferred home, Mrs. Allison changes her mind and is not considering curative treatment; however she would still like to receive hospice care. How could the nurse respond to Mrs. Allison?

ⓔ *Answers to Clinical Application Questions can be found on the Evolve website.*

REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. To best assist a patient in the grieving process, which of the following is most helpful to determine?
    1. Previous experiences with grief and loss
    2. Religious affiliation and denomination
    3. Ethnic background and cultural practices
    4. Current financial status.
2. Which of the following is the best intervention to help a hospitalized patient maintain some autonomy?
    1. Use therapeutic techniques when communicating with the patient.

    2. Allow the patient to determine timing and scheduling of interventions.

    3. Encourage family to only visit for short periods of time.

    4. Provide the patient with a private room close to the nurse's station.

3. Which factors influence a person's approach to death? (Select all that apply.)

    1. Culture

    2. Age

    3. Spirituality

    4. Personal beliefs

    5. Previous experiences with death

    6. Gender

    7. Level of education

    8. Degree of social support

4. A family member of a dying patient talks casually with the nurse and expresses relief that she will not have to visit at the hospital anymore. Which theoretical description of grief best applies to this family member?

    1. Denial

    2. Anticipatory grief

    3. Yearning and searching

    4. Dysfunctional grief

5. On entering a room the nurse sees the patient crying softly. What is the most therapeutic response?

    1. Using silence

    2. Asking, "Why are you crying today?"

    3. Using therapeutic touch

    4. Stating, "I see that you're crying."

6. A young mother is dying of breast cancer with bone metastasis and tells the nurse, "My body hurts so much. I can hardly move. Why is God making me suffer when I have done nothing bad in my life? I feel like giving up. How can I care for my children when I can't even care for myself?" What is the most appropriate nursing diagnosis for this patient?

    1. *Spiritual Distress related to questioning God*

    2. *Hopelessness related to terminal diagnosis*

    3. *Pain related to disease process*

    4. *Anticipatory Grief related to impending death*

7. A nurse has the responsibility of managing a deceased patient's postmortem care. What is the proper order for postmortem care?

    1. Bathe the body of the deceased.

    2. Collect any needed specimens.

    3. Remove all tubes and indwelling lines.

    4. Position the body for family viewing.

    5. Speak to the family members about their possible participation.

    6. Ensure that the request for organ/tissue donation and/or autopsy was completed.

    7. Notify support person (e.g., spiritual care provider, bereavement specialist) for the family.

    8. Accurately tag the body, including the identity of the deceased and safety issues regarding infection control.

    9. Elevate the head of the bed.

8. Which comment to a patient by a new nurse regarding palliative care needs to be corrected?

    1. "Even though you're continuing treatment, palliative care is something we might want to talk about."

    2. "Palliative care is appropriate for people with any diagnosis."

    3. "Only people who are dying can receive palliative care."

    4. "Children are able to receive palliative care."

9. A patient is receiving palliative care for symptom management related to anxiety and pain. A family member asks if the patient is dying and now in "hospice." What does the nurse tell the family member about palliative care? (Select all that apply.)

    1. Palliative care and hospice are the same thing.

    2. Palliative care is for any patient, any time, any disease, in any setting.

    3. Palliative care strategies are primarily designed to treat the patient's illness.

    4. Palliative care relieves the symptoms of illness and treatment.

    5. Palliative care selects home health care services.

10. A grieving patient complains of confusion, inability to concentrate, and insomnia. What do these symptoms indicate?

    1. These are normal symptoms of grief.

    2. There is a need for pharmacological support for insomnia.

    3. The patient is experiencing complicated grief.

    4. These are common complaints of the admitted patient.

11. When planning care for the dying patient, which interventions promote the patient's dignity? (Select all that apply.)

    1. Providing respect

    2. Viewing patients as a whole

    3. Providing symptom management

    4. Showing interest

    5. Being present

    6. Using a preferred name

12. What are the physical changes that occur as death approaches? (Select all that apply.)

    1. Unresponsiveness

    2. Erythema

    3. Mottling

    4. Restlessness

    5. Increased urine output

    6. Weakness

    7. Incontinence

13. What is the palliative care team's primary obligation for the patient with severe pain?

    1. Providing postmortem care.

    2. Teaching about grief stages.

    3. Enhancing the patient's quality of life.

    4. Supporting the family after the death.

14. A year after her husband's death, a widow visits the unit on which he died. She talks about the anniversary and how much she misses him. Which type of grief is she experiencing?

    1. Normal

    2. Complicated

    3. Chronic

    4. Disenfranchised

15. When providing postmortem care, which action is a priority for the nurse?

    1. Locating the patient's clothing

    2. Providing culturally and religiously sensitive care in body preparation

    3. Transporting the body to the morgue as soon as possible

    4. Providing postmortem care to protect the family of the deceased from having to view the body

Answers: 1. 1; **2.** 2; **3.** 1, 3, 4, 5, 8; **4.** 2; **5.** 4; **6.** 3; **7.** 6, 9, 2, 5, 7, 3, 1, 4, 8; **8.** 3; **9.** 2, 4; **10.** 1; **11.** 1, 2, 4, 5, 6; **12.** 1, 3, 4, 6, 7; **13.** 3; **14.** 1; **15.** 2.

Stress and Coping

OBJECTIVES

- Describe the three stages of the general adaptation syndrome.
- Describe characteristics of post-traumatic stress disorder.
- Discuss the integration of stress theory with nursing theories.
- Describe stress-management techniques beneficial for coping with stress.
- Discuss the process of crisis intervention.
- Develop a care plan for patients who are experiencing stress.
- Discuss how stress in the workplace affects nurses.

It is important to become familiar with stress to effectively assess and treat your patients and families suffering from the impact of stress. In the presence of physical and/or mental illness, stress affects the entire family, and both the family's and patient's health care needs must be considered in the plan of care. Equally important, health care professionals also experience stressful events in the course of clinical practice and their own lives. Nurses need to recognize the signs and symptoms of stress in the form of compassion fatigue and understand stress-management techniques to aid personal coping and design stress-management interventions for patients and families.

The term **stress** is used in many ways. Most commonly it is a term describing a process beginning with an event that evokes a degree of tension or anxiety. Such events are referred to as stressors. **Stressors** are tension-producing stimuli operating within or on any system (Neuman and Fawcett, 2011). An important element in the perception of a stressor is appraisal. **Appraisal** is how a person interprets the impact of the stressor. It is also a personal evaluation of the meaning of the event to what is happening and a consideration of the resources on hand to help manage the stressor (Lazarus, 2007). Stress emerges when an individual considers the event as a threat and the ability to respond to the demands placed on the individual by the event to be overwhelming. Thus stress is a physical, emotional, or psychological demand that can lead to personal growth or overwhelm a person and lead to illness or worsening of existing acute or chronic illnesses (Okonta, 2012; Santos, 2013). Stress refers to the consequences of the stressor and the person's appraisal of it.

People experience stress as a consequence of daily life events and experiences. It stimulates thinking processes and helps people stay alert to their environment. It can result in personal growth and facilitate development. How people react to stress depends on how they view and evaluate the impact of the stressor, its effect on their situation and support at the time of the stress, and their usual coping mechanisms. When stress overwhelms existing coping mechanisms, patients lose emotional balance, and a crisis results. If symptoms of stress persist beyond the duration of the stressor, a person has experienced a **trauma** (O'Driscoll, 2013; Stevens et al., 2013).

SCIENTIFIC KNOWLEDGE BASE

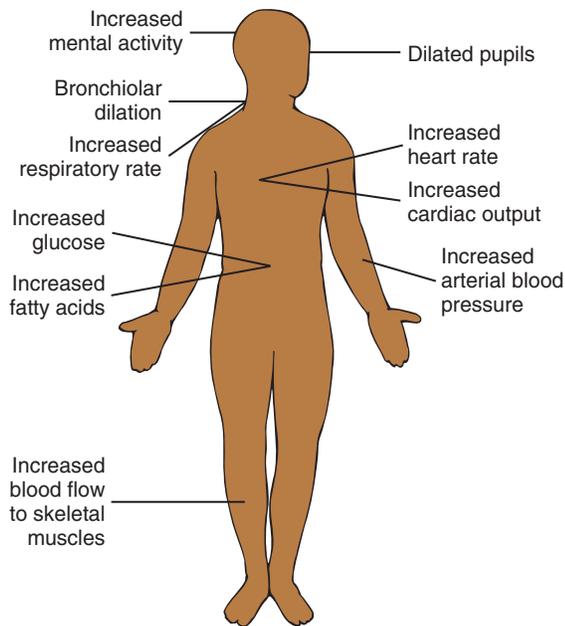
The initial response to stress involves activation of the sympathetic system, a pattern known as the **fight-or-flight response** (Figure 38-1). Neuroendocrine responses to stress function through negative feedback. The process of negative feedback senses an abnormal state such as lowered body temperature and makes an adaptive response such as


FIGURE 38-1 Fight-or-flight response.

initiating shivering to generate body heat. Three structures, the medulla oblongata, the reticular formation, and the pituitary gland, control the response of the body to a stressor.

Medulla Oblongata

The medulla oblongata located in the lower part of the brainstem controls heart rate, blood pressure, and respirations. Impulses traveling to and from the medulla oblongata increase or decrease these vital functions. For example, sympathetic or parasympathetic nervous system impulses traveling from the medulla oblongata to the heart control regulation of the heartbeat. The heart rate increases in response to impulses from sympathetic fibers and decreases with impulses from parasympathetic fibers.

Reticular Formation

The reticular formation, a small cluster of neurons in the brainstem and spinal cord, continuously monitors the physiological status of the body through connections with sensory and motor tracts. For example, certain cells within the reticular formation cause a sleeping person to regain consciousness or increase the level of consciousness when a need arises.

Pituitary Gland

The pituitary gland is a small gland immediately beneath the hypothalamus. It produces hormones necessary for adaptation to stress such as adrenocorticotropic hormone, which in turn produces cortisol. In addition, the pituitary gland regulates the secretion of thyroid, gonadal, and parathyroid hormones (Santos, 2013). A feedback mechanism continuously monitors hormone levels in the blood and regulates hormone secretion. When hormone levels drop, the pituitary gland receives a message to increase hormone secretion. When they rise, the pituitary gland decreases hormone production.

General Adaptation Syndrome

The **general adaptation syndrome (GAS),** a three-stage reaction to stress, describes how the body responds physiologically to stressors through stages of alarm, resistance, and exhaustion (Figure 38-2). The GAS is triggered either directly by a physical event or indirectly by a psychological event. It involves several body systems, especially the

neuroendocrine feedback, and responds immediately to stress (see Figure 38-2). When the body encounters a physical demand such as an injury, the pituitary gland initiates the GAS. A fundamental concept underlying this reaction is that the body will attempt to return to a state of balance, a process referred to as **allostasis** (Huether and McCance, 2012).

During the **alarm stage** the central nervous system is aroused, and body defenses are mobilized; this is the flight-or-fight reaction. During this stage rising hormone levels result in increased blood volume, blood glucose levels, epinephrine and norepinephrine amounts, heart rate, blood flow to muscles, oxygen intake, and mental alertness. In addition, the pupils of the eyes dilate to produce a greater visual field. If the stressor poses an extreme threat to life or remains for a long time, the person progresses to the second stage, resistance.

The **resistance stage** also contributes to the flight-or-fight response, and the body stabilizes and responds in an attempt to compensate for the changes induced by the alarm stage (Huether and McCance, 2012). Hormone levels, heart rate, blood pressure, and cardiac output should return to normal; and the body tries to repair any damage that occurred. However, these compensation attempts consume energy and other bodily resources.

In the **exhaustion stage** continuous stress causes progressive breakdown of compensatory mechanisms. This occurs when the body is no longer able to resist the effects of the stressor and has depleted the energy necessary to maintain adaptation. The physiological response has intensified; but the person's ability to adapt to the stressor diminishes (Huether and McCance, 2012). Even in the face of chronic demands, an ongoing state of chronic activation can occur. This chronic arousal with the presence of powerful hormones causes excessive wear and tear on bodily organs and is called **allostatic load**. A persistent allopathic load can cause long-term physiological problems such as chronic hypertension, depression, sleep deprivation, chronic fatigue syndrome, and autoimmune disorders (Diamond, 2010; Huether and McCance, 2012).

Immune Response. The immune system is integrated with other physiological processes and is sensitive to changes in central nervous system and endocrine functioning that occur during the stress response. The interactions between the neuroendocrine stress response and the immune system are complex. The stress response directly influences the immune system (Huether and McCance, 2012). Stress causes prolonged changes in the immune system, which can result in impaired immune function. As stress increases, the person is more susceptible to changes in health such as increased risk for infection, high-blood pressure, diabetes, and cancers (Janowski et al., 2014; Moreia et al., 2014).

Reaction to Psychological Stress. The GAS is activated indirectly in the face of psychological threats, which are different for each person and produce differing reactions. The intensity and duration of the psychological threat and the number of other stressors that occur at the same time affect the person's response to it. In addition, whether or not the person anticipated the stressor influences its effect. It is often more difficult to cope with an unexpected stressor. Personal characteristics that influence the response to a stressor include the level of personal control, presence of a social support system, and feelings of competence.

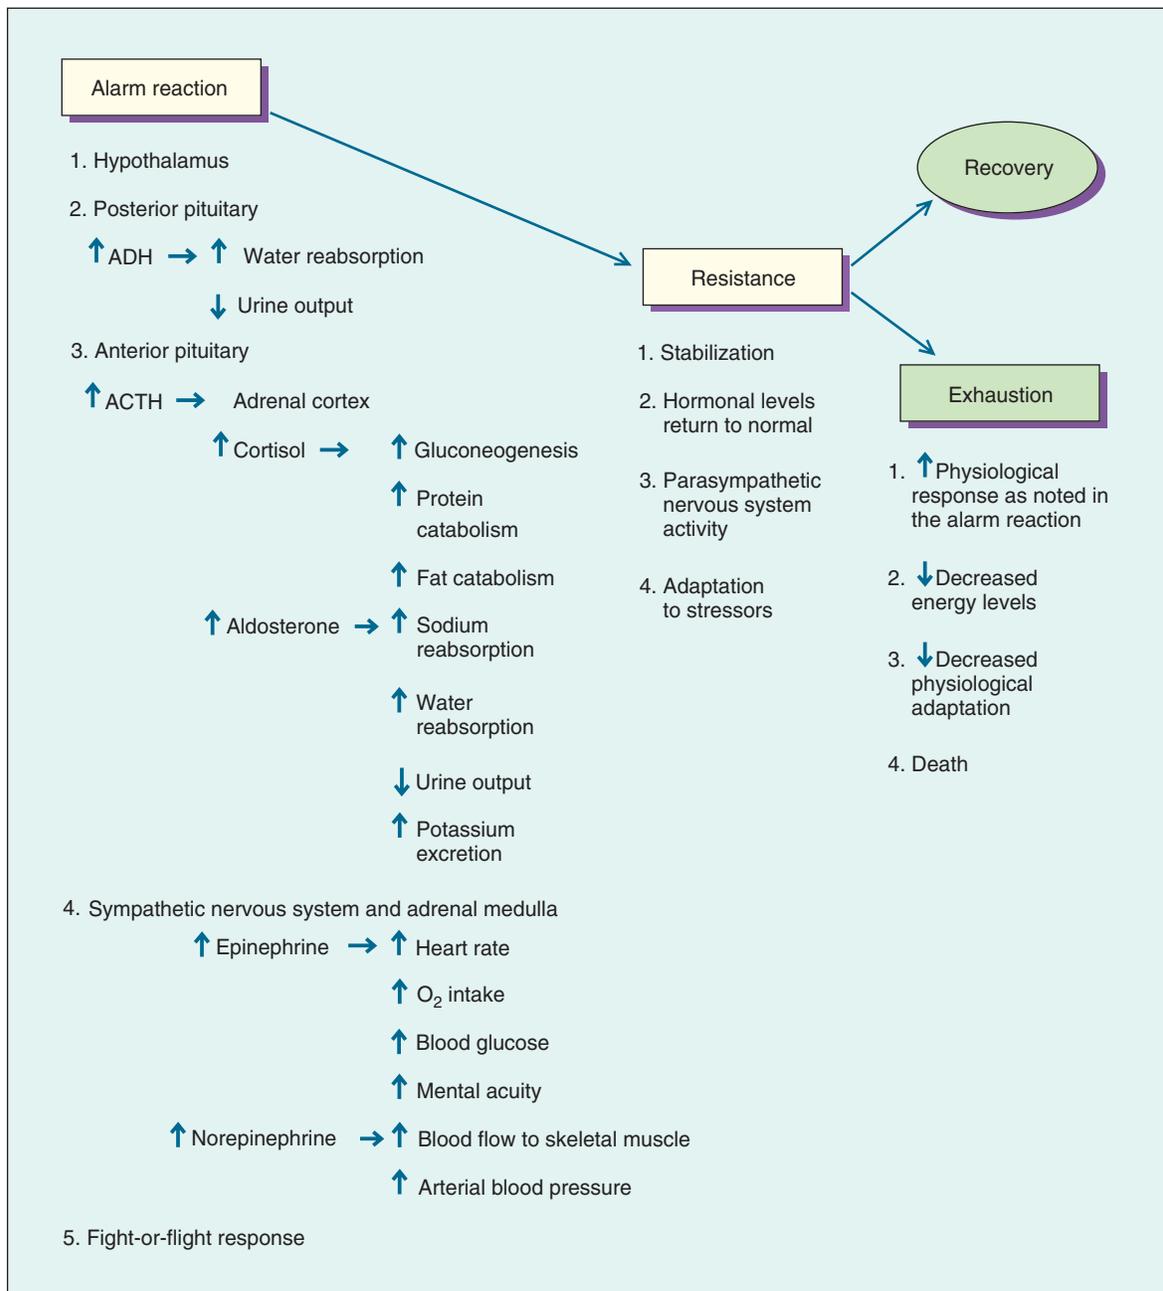
One of the many ways of viewing stress is as a transaction between the person and the environment. An event comes along and is appraised or mentally rated in terms of meaning to the person. A person experiences stress only if the event or circumstance is considered significant. Evaluating an event in terms of personal meaning is **primary appraisal**.


FIGURE 38-2 General adaptation syndrome (GAS). *ACTH,* Adrenocorticotropic hormone; *ADH,* antidiuretic hormone.

Appraisal of an event or circumstance is an ongoing perceptual process. If primary appraisal results in the person identifying the event or circumstance as a harm, loss, threat, or challenge, the person experiences stress. At the same time the person is also considering possible coping strategies or resources available to help deal with the event, a process referred to as **secondary appraisal**. If the demands placed on the person by the event exceed the ability to cope, stress occurs. Balancing factors contribute to restoring equilibrium. According to crisis theory, feedback cues lead to reappraisals of the original perception. Therefore coping behaviors constantly change as individuals perceive new information. Should they prove to be ineffective and the same attempts are repeated over and over, a state of stress can result from ineffective coping. Stress can then emerge either from an event viewed as posing a significant risk of harm or from a realization that the person is not able to cope with the demands placed by an event.

Coping is the person's cognitive and behavioral efforts to manage a stressor (Nielsen and Knardahl, 2014). It is important to physical and psychological health because stress is associated with a range of psychological and health outcomes (Doron et al., 2014). Effectiveness of coping strategies depends on the individual's needs. A person's age and cultural background influence these needs. For this reason no single coping strategy works for everyone or for every stressor. The same person may cope differently from one time to another.

In stressful situations most people use a combination of problem- and emotion-focused coping strategies. In other words, when under stress a person obtains information, takes action to change the situation (problem-focused), and regulates emotions tied to the stress (emotion-focused). In some cases people avoid thinking about the situation or change the way they think about it without changing the actual situation itself.

> ### BOX 38-1   Examples of Ego-Defense Mechanisms
>
> - Compensation: Making up for a deficiency in one aspect of self-image by strongly emphasizing a feature considered an asset (e.g., a person who is a poor communicator relies on organizational skills)
> - Conversion: Unconsciously repressing an anxiety-producing emotional conflict and transforming it into nonorganic symptoms (e.g., difficulty sleeping, loss of appetite)
> - Denial: Avoiding emotional conflicts by refusing to consciously acknowledge anything that causes intolerable emotional pain (e.g., a person refuses to discuss or acknowledge a personal loss)
> - Displacement: Transferring emotions, ideas, or wishes from a stressful situation to a less anxiety-producing substitute (e.g., a person transfers anger over an interpersonal conflict to a malfunctioning computer)
> - Identification: Patterning behavior after that of another person and assuming that person's qualities, characteristics, and actions
> - Dissociation: Experiencing a subjective sense of numbing and a reduced awareness of one's surroundings
> - Regression: Coping with a stressor through actions and behaviors associated with an earlier developmental period

The type of stress, people's goals, their beliefs about themselves and the world, and personal resources determine how people cope with stress (Nielsen and Knardahl, 2014). Resources include problem-solving skills, financial status, social skills, supportive family and friends, physical attractiveness, health and energy, and personal stress-management techniques such as optimism and mindfulness (Desiree et al., 2015; O'Driscoll, 2013).

Coping mechanisms include psychological adaptive behaviors. Such behaviors are often task oriented, involving the use of direct problem-solving techniques to cope with threats. **Ego-defense mechanisms** regulate emotional distress and thus give a person protection from anxiety and stress. They help a person cope with stress indirectly and offer psychological protection from a stressful event. Everyone uses them unconsciously to protect against feelings of worthlessness and anxiety. Occasionally a defense mechanism becomes distorted and no longer helps the person adapt to a stressor. However, people generally find them very helpful in coping and use them spontaneously (Box 38-1). Frequently short-term stressors activate ego-defense mechanisms. These usually do not result in psychiatric disorders.

Types of Stress

Stress includes work, family, daily hassles, trauma, and crisis. Stress may be acute or chronic. One person looks at a stimulus and sees it as a challenge, leading to mastery and growth. Another sees the same stimulus as a threat, leading to stagnation and loss. The individual with family responsibilities and a full-time job outside the home can experience chronic stress. It occurs in stable conditions and from stressful roles. Living with a long-term illness produces chronic stress. Conversely, time-limited events that threaten a person for a relatively brief period provoke acute stress. Recurrent daily hassles such as commuting to work, maintaining a house, dealing with difficult people, and managing money further complicate chronic or acute stress.

Post-traumatic stress disorder (PTSD) begins when a person experiences, witnesses, or is confronted with a traumatic event and responds with intense fear or helplessness. Some examples of traumatic events that lead to PTSD include motor vehicle crashes, natural disasters, violent personal assault, and military combat. Anxiety associated with PTSD is sometimes manifested by nightmares and emotional detachment. Some people with PTSD experience **flashbacks**, or recurrent and intrusive recollections of the event. Depression and PTSD commonly occur together (Stevens et al., 2013).

Secondary traumatic stress is the trauma a person experiences from witnessing other people's suffering. It is a component of compassion fatigue and is common in health care workers and first responders. Secondary traumatic stress results in intrusive symptoms in which a person takes the stress home, with nightmares and anxiety. People with this condition begin to avoid interactions and have difficulties sleeping and relating to friends or family.

A **crisis** implies that a person is facing a turning point in life. This means that previous ways of coping are not effective and the person must change. There are three types of crises: (a) maturational or **developmental crises,** (b) **situational crises,** and (c) disasters or **adventitious crises** (Varcarolis, 2013). A new developmental stage such as marriage or the birth of a child requires new coping styles. Developmental crises occur as a person moves through the stages of life. External sources such as a job change, a motor vehicle crash, or severe illness provoke situational crises. A major natural disaster, man-made disaster, or crime of violence often creates an adventitious crisis.

Patient-centered care offers a context for crisis intervention (Gillespie et al., 2013). The view of the person experiencing a crisis is the frame of reference for it. The vital questions for a person in crisis are, "What does this mean to you? How is it going to affect your life?" What causes extreme stress for one person is not always stressful to another. The perception of the event, situational supports, and coping mechanisms all influence return of equilibrium. A person either grows or regresses as a result of a crisis, depending on how he or she manages the situation (Gillespie et al., 2013; Varcarolis, 2013).

NURSING KNOWLEDGE BASE

Nurses have proposed theories related to stress and coping. Because stress plays a central role in vulnerability to disease, symptoms of stress often require nursing intervention.

Nursing Theory and the Role of Stress

Many nursing theories explain and describe stress. For example, explanation of the concepts of stress and reaction to stress are components of Betty Neuman's Neuman Systems Model. The Neuman Systems Model uses a systems approach. It helps you understand patients' individual responses to stressors and families' and communities' responses. A systems approach explains that a stressor at one place in a system affects other parts of the system; a system is a person, family, or community. Events are multidimensional and not caused or affected by only one thing. Every person develops a set of responses to stress that constitute the "normal line of defense" (Neuman and Fawcett, 2011). This line of defense maintains health and wellness. Physiological, psychological, sociocultural, developmental, or spiritual influences buffer stress. The Neuman Systems Model of nursing views a patient, family, or community as constantly changing in response to the environment and stressors.

On the other hand, Pender's Health Promotion Model focuses on promoting health and managing stress (Pender et al., 2013). In this model people want to live in ways that enable them to be as healthy as possible and capable of assessing their own abilities and assets. Interventions such as increasing physical activity, improving diet and nutrition, and using stress-management strategies help the individual become and remain healthy.

Factors Influencing Stress and Coping

Potential stressors and coping mechanisms vary across the life span (e.g., adolescence, adulthood, and old age bring different stressors).

The appraisal of stressors, the amount and type of social support, and coping strategies all balance when assessing stress and depend on previous life experiences. Furthermore, situational and social stressors place people who are vulnerable at higher risk for prolonged stress.

Situational Factors. Situational stress arises from personal, job, or family changes. Work-related stressors include promotions, transfers, downsizing, and changes in supervisors and responsibilities. Work stress manifests as burnout among health care workers. Burnout is the second component of compassion fatigue. It is defined as a chronic condition in which perceived demands (e.g., workload, difficult patients, insufficient equipment) outweigh perceived resources. It is common in emergency, oncology, and critical care settings but can occur in any setting (Ianello and Balzarotti, 2014; Mealer et al., 2014). Burnout can affect the quality of patient care. Another stressor in the health care workplace is changing work shifts, which increases fatigue. Shift work–related coping strategies vary with individuals and their situations. Some nurses often ease coping with shift work by knowing their own circadian rhythms. People who function best in the morning have the greatest difficulty with night work and changing shifts (Lin et al., 2014).

Other job-related proactive coping strategies such as resilience training for nurses working with trauma and critically ill patients prepare nurses for the critical situations, provide time to practice stress-management techniques, and better manage job-related stress (Gillespie et al., 2013; Mealer et al., 2014).

Chronic illnesses such as cancer, cardiac disease, diabetes, and depression are examples of stress-producing illnesses. Uncertainty associated with treatment and illness triggers stress in patients of all ages. Cancer survivors who made active efforts to control stress changed their physical, psychosocial, and preventive health behaviors during and following cancer treatment (Parelkar et al., 2013). Paying for treatment and limited access to providers also create stress. Although being a family caregiver for someone with a chronic illness such as Alzheimer's disease is associated with stress, the actions of competent health care providers often help minimize the stress for caregivers (see Chapter 10).

Maturational Factors. Stressors vary with life stage. Children identify stressors related to physical appearance, families, friends, and school. Preadolescents experience stress related to self-esteem issues, changing family structure as a result of divorce or death of a parent, or hospitalizations. As adolescents search for identity with peer groups and separate from their families, they experience stress. In addition, they face stressful questions about using mind-altering substances, sex, jobs, school, and career choices. Stress for adults centers around major changes in life circumstances. These include the many milestones of beginning a family and a career, losing parents, seeing children leave home, and accepting physical aging. In old age stressors include the loss of autonomy and mastery resulting from general frailty or health problems that limit stamina, strength, and cognition (Box 38-2).

Sociocultural Factors. Environmental and social stressors often lead to developmental problems. Potential stressors that affect any age-group but are especially stressful for young people include prolonged poverty and physical handicap. Children become vulnerable when they lose parents and caregivers through divorce, imprisonment, or death or when parents have mental illness or substance-abuse disorders. Living under conditions of continuing violence, disintegrated neighborhoods, or homelessness affects people of any age, especially young people (Pender et al., 2013).

BOX 38-2 FOCUS ON OLDER ADULTS

Understanding Differences in Stress and Coping Among Older Adults

- Ordinary hassles of day-to-day living are a source of stress; older people have more hassles with home maintenance and health than do younger people.
- Older adults use more passive, intrapersonal, emotion-focused forms of coping such as distancing, humor, accepting responsibility, and reappraising the stressor in a positive way.
- Life experiences and perspectives of older adults make most problems seem insignificant, especially when older adults have acquired appropriate stress-management techniques (Rayens and Reed, 2014).
- Older adults' coping improves on the basis of earlier experience with coping with traumatic situations (Yancura and Aldwin, 2008).
- Impaired coping affects overall health in older adults more than in younger adults (Rayens and Reed, 2014).
- Because of the high incidence of depression in older adults, you need to assess for suicidal thoughts and intent.
- When marital or partnership dyads are present, the perceived stress of one member has a greater effect on the other member than occurs with middle or young adults (Rayens and Reed, 2014).
- Differentiate signs of stress and crisis in older adults from dementia and acute confusion.

⊕ BOX 38-3 CULTURAL ASPECTS OF CARE

Cultural Variations in Stress Appraisal and Coping Strategies

A patient's culture defines what is stressful to the person and ways of coping with stress (Giger, 2012). Cultural context shapes the types of situations that produce stress. Culture affects how a person leaves the parental home, experiences health crises or chronic illness, cares for the family, or becomes disabled or dependent. Furthermore, how a person appraises stress also depends on his or her culture. What is perceived as a major stressor in one culture might be viewed as a minor problem in another. For example, cultures may address developmental transitions and turning points in life differently.

Coping strategies are also influenced by one's cultural background. Cultures vary in their emotion- and problem-focused coping strategies. Some stress that emotions should be controlled, whereas others believe in expressing emotion. Cultures provide different resources for coping with stress (Giger, 2012). These include the legal system for conflict resolution, advice givers or support groups, and rituals.

Implications for Patient-Centered Care
- Realize that stressors and coping styles vary with different cultures.
- Reflect on your own perceptions of stress and coping in a cultural context.
- Assess the influence of culture on a patient's appraisal of stress.
- Identify the presence of individualized cultural practices related to stress management.
- Determine resources in a patient's culture that facilitate coping.

A person's culture also influences stress and coping. Cultural variations produce stress, particularly if a person's values differ from the dominant culture in aspects of gender roles, family relationships, and religious beliefs (Giger, 2012). Other aspects of cultural variations begin with language difference, geographical location, family relationships, time orientation, access to health care programs, and disparities in health care (Box 38-3).

CRITICAL THINKING

When caring for a patient experiencing stress, use critical thinking skills to understand his or her stressor and the stress response. Integrate knowledge from nursing and other disciplines, previous experiences, and information gathered from patients to understand stress and its impact on the patient and family. Know the neurophysiological changes that occur in the patient experiencing the alarm reaction, resistance stage, and exhaustion stage of the GAS. In addition, know communication principles that contribute to assessing patient's behaviors. Give utmost attention to determining the patient's perception of the situation and his or her ability to cope with the stress. If the patient's usual coping skills have not helped or his or her support systems have failed, use crisis intervention counseling.

Experience teaches you to understand the patient's unique perspective and view each person as an individual, recognizing that no two people are exactly alike. Experience with patients also helps you to recognize responses to stress. In addition, personal experiences with stress and coping increase your ability to empathize with a patient temporarily immobilized by stress.

Be confident in the belief that you and your patients can effectively manage stress. Patients who feel overwhelmed and perceive events as beyond their capacity to cope rely on you as an expert. Patients respect your advice and counsel and gain confidence from your belief in their ability to move past the stressful event or illness. Patients overwhelmed by life events are often unable, at least initially, to act on their own behalf and require either direct intervention or guidance. Integrity is an essential attitude through which you respect the patient's perception of the stressor. Make the effort to have the patient explain his or her unique viewpoint and situation.

The practice standards for psychiatric mental health nursing (ANA, 2014) guide assessment of a patient's stress, coping mechanisms, and support system before intervening. Use linguistic and culturally effective communication skills to clearly and precisely understand a patient's perception of stress. Focus on factors relevant to his or her well-being. In addition, the patient expects you to exhibit confidence and integrity when he or she feels vulnerable. Be especially aware of the ethical responsibility in caring for someone who has diminished autonomy as a result of stress.

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care.

◆ Assessment

During the assessment process thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care.

Through the Patient's Eyes. Assessment of a patient's stress level and coping resources requires that you first establish a trusting nurse-patient relationship because you are asking a patient to share personal and sensitive information. Learn from the patient both by asking questions and by making observations of nonverbal behavior and the patient's environment. Synthesize the information and adopt a critical thinking attitude while observing and analyzing patient behavior (Figure 38-3). Often the patient has difficulty expressing exactly what is most bothersome about the situation until there is an opportunity to discuss it with someone who has time to listen.

Knowledge
- Basic stress response
- Factors influencing stress
- Physiological, emotional, and behavioral risks associated with a stressor
- Basic defense mechanisms
- Cultural influences
- Communication principles

Experience
- Caring for patients whose illness, lifestyle, family interactions, and personal/professional demands resulted in stress
- Personal experience in dealing with stressful situations

ASSESSMENT
- Identify actual or potential stressors
- Identify patient's appraisal of stressor
- Obtain data regarding the patient's previous experience with stress
- Determine the impact of illness on the patient's lifestyle

Standards
- Apply intellectual standards of completeness, relevance, precision, and accuracy when assessing the patient's stress response
- Apply ANA Standards of Care for Psychiatric Mental Health Nursing Practice (2014) by using linguistic and culturally effective communication skills and comprehensive assessment

Attitudes
- Exhibit confidence that stress can be managed
- Approach assessment with fairness and integrity to collect data in an unbiased manner and convey that patient information remains confidential

FIGURE 38-3 Critical thinking model for stress and coping assessment. *ANA*, American Nurses Association.

Begin your assessment with an open-ended question such as, "What is happening in your life that caused you to come today?" or "What happened in your life that is *different?*" This requires some focusing by the patient. Next assess the patient's perception of the event, available situational supports, and what he or she usually does when there is an unsolvable problem. Determine if a person is suicidal or homicidal by asking directly. For example, ask, "Are you thinking of hurting yourself or someone else?" If so, determine in a caring and concerned manner if the person has a plan and how lethal the means are.

Take time to understand a patient's meaning of the precipitating event and the ways in which stress is affecting his or her life. Allow time for him or her to express priorities for coping with stress. For example, in the case of a woman who has just been told that a breast mass was identified on a routine mammogram, it is important to know what the patient wants and needs most from the nurse. Although some women in this situation identify their need for information about biopsy or mastectomy as their personal priority, others need guidance

BOX 38-4   Nursing Assessment Questions

Patient Safety
- Do you have any thoughts of harming yourself or others?
- Are you having difficulty with sleeping? Falling asleep? Staying awake?
- Is there any change in eating patterns?
- Have you had any accidents at home, in the car, at school, or on the job?

Perception of Stressor
- What do you believe is stressing you right now?
- What impact does this stressor have on your lifestyle?
- How does this stressor impact you now? How will it impact you in the future?

Available Coping Resources
- Which strategies have you used in the past to deal with stress?
- Are you able to confide in friends or family?
- What is relaxing for you?

Maladaptive Coping Used
- Have you started drinking or smoking?
- Do you use any over-the-counter or herbal medications?
- Do you use any street drugs?

Adherence to Healthy Practices
- How long since you saw a health care provider?
- What is your exercise pattern?
- Which type of meals do you eat? Are your meals regular?
- Are you taking your prescribed medications as ordered?

BOX 38-5   Nursing Diagnostic Process
Ineffective Coping

Assessment Activities	Defining Characteristics
Ask patient about change in sleeping patterns.	Sleep disturbance Difficulty falling asleep at night Sighing
Ask patient to complete a sleep diary for 2 weeks.	Excessive sleeping Poor sleeping
Observe patient's behavior and response to questions during assessment.	Fatigue Inability to concentrate Inaccurate response to questions Inappropriate laugh or crying
Observe patient's appearance.	Poor grooming Lack of eye contact
Ask patient about changes in eating patterns.	Weight gain or loss Lack of interest in food

and support in discussing how to share the news with family members. In some cases, when nothing will change or improve the situation, allowing the patient to use denial as a coping mechanism is helpful. Gaining an understanding of patient expectations does not mean excluding certain types of care that are important simply because a patient does not identify them as needs. However, by inquiring about patient expectations and priorities, you are better able to ensure that you address *all* of the patient's needs in some way.

Stress also occurs in a family or a community. Stress in a family is sometimes from a critically ill family member, the sudden loss of a job, a move, or becoming homeless. An example of stress in a community is a natural disaster such as a major flood or the sudden, unexpected death of a beloved teacher or teenager. To develop appropriate and safe nursing care when caring for families or communities, ensure that you understand the meaning stress has for that group.

Subjective Findings.   When assessing a patient's level of stress and coping resources, create a nonthreatening physical environment for the interaction. Assume the same height as the patient, arranging the interview environment so you can maintain or avoid eye contact comfortably. You do this by placing chairs at a 90-degree angle or side by side to reduce the intensity of the interaction (Varcarolis, 2013). Gather information about the health status of the patient from his or her perspective and begin the process of developing a trusting relationship with him or her. Use the interview to determine the patient's view of the stress, coping resources, any possible maladaptive coping, and adherence to prescribed medical recommendations such as medication or diet (Box 38-4). If the patient is using denial as a coping mechanism, be alert to whether he or she is overlooking necessary information. As in all interactions with the patient, respect the confidentiality and sensitivity of the information shared.

Objective Findings.   Obtain objective findings related to stress and coping through observation of the appearance and nonverbal behavior of a patient. Observe grooming and hygiene, gait, characteristics of the handshake, actions while sitting, quality of speech, eye contact, and the attitude of the patient during the interview. Before the interview begins or at the end of the interview, depending on the anxiety level of the patient, obtain basic vital signs to assess for physiological signs of stress such as elevated blood pressure, heart rate, or respiratory rate. Make certain to incorporate cultural components of interpreting the patient's nonverbal communication behaviors.

◆ Nursing Diagnosis

A review of assessment data leads you to cluster data that indicate a potential or actual stressor and the patient's response. Clustering data, along with the application of your knowledge and experiences with patients in stress, leads to individualized nursing diagnoses (Box 38-5).

Nursing diagnoses for people experiencing stress generally focus on coping. Specifically, major defining characteristics of *Ineffective Coping* include verbalization of an inability to cope and an inability to ask for help. To identify defining characteristics, ask the patient what is of most concern at the time of the interview. It is important to allow him or her sufficient time to answer. Observe for nonverbal signs of anxiety, fear, anger, irritability, and tension in a patient who is experiencing ineffective coping. Other defining characteristics include the presence of life stress, an inability to meet role expectations and basic needs, alteration in societal participation, self-destructive behavior, change in usual communication patterns, high rate of accidents, excessive food intake, drinking, smoking, and sleep disturbances. Stress or the failure of coping often results in multiple nursing diagnoses. Examples of these diagnoses include but are not limited to the following:

- *Anxiety*
- *Denial*
- *Fear*
- *Ineffective Coping*
- *Powerlessness*
- *Risk for Posttrauma Syndrome*
- *Situational Low Self-Esteem*
- *Stress Overload*

◆ **Planning**

Goals and Outcomes. Desirable goals for people experiencing stress frequently include effective coping, family coping, and caregiver emotional health. Examples of outcomes might include the following: patient engages in support group, family members are able to discuss loss together, caregiver participates in respite care. A nurse often selects interventions for stress and improved coping such as coping enhancement and crisis intervention in addition to individualized interventions after considering the nursing diagnosis, the resources available to the patient, and the goals identified by the patient and nurse (Figure 38-4).

Nursing interventions are designed within the framework of primary, secondary, and tertiary prevention. At the primary level of prevention you direct nursing activities to identifying individuals and populations who may be at risk for stress. Nursing interventions at the secondary level include actions directed at symptoms such as protecting the patient from self-harm. Tertiary-level interventions help the patient readapt and can include relaxation training and time-management training. The nurse and the patient assess the level and source of the existing stress and determine the appropriate points for intervention to reduce it (Pender et al., 2013) (see the Nursing Care Plan).

A tool for planning care is a concept map (Figure 38-5). Concept maps identify multiple nursing diagnoses for a patient from the assessment database and show how they are related. In this example the nursing diagnoses are linked to the patient's medical diagnosis of depression. In addition, the concept map shows the relationship among the nursing diagnoses *Chronic Imbalanced Nutrition: Less Than Body Requirements, Ineffective Coping, Anxiety,* and *Powerlessness.* Use of a concept map requires critical thinking skills to organize patient data and helps to plan for patient-centered care.

Just as the nursing assessment of the patient's stress and coping depends on his or her perception of the problem and coping resources, the interventions focus on a partnership with the patient and support system, usually the family. In the case of a family or community stressor and impaired family or community coping, the view of the situation and resources is broader.

Setting Priorities. Consider the patient's perspective and responses to assessment questions when setting priorities for care (see the Nursing Care Plan). The patient's and family member's physical condition and perception of stressors determine which nursing diagnosis has the greatest priority. As in all areas of nursing, safety of the patient and others in his or her environment is the first priority.

If suicide or homicide is not an issue, examine other potential threats to the safety of vulnerable people who are under the care of the patient. Provide for their temporary care or supervision if necessary. Other potential threats to safety include nutritional deficits; insomnia; self-care deficits; and poor judgment and impulsiveness that may lead to unsafe decisions about sex, drugs, money, or damage to personal relationships that the person might later regret. Determine the degree of work, school, home, and family disruption in the person's life. When you have completed immediate assessment and ensured safety, begin the problem-solving process.

Teamwork and Collaboration. Sometimes nursing practice alone does not meet all of the patient's and family's needs. To effectively plan individualized care, collaborate with occupational therapists, dietitians, pastoral care professionals, and health care professionals from other clinical specialties, depending on the patient's situation.

Patients experiencing stress from medical conditions or psychiatric disorders present needs that make it necessary for you to consult with advanced practice mental health nurses, psychiatrists, psychologists, or

Knowledge
• Role of community resources in assisting patient/family adaptation
• Role of health care professionals in stress management
• Impact of diet, exercise, medication, and other health promotion indicators on stress management
• Crisis intervention skills

Experience
• Previous patient responses to planned nursing interventions for improving patient's adaptation to stress
• Previous experience in partnering with patient in goal setting

PLANNING
• Select nursing interventions to promote adaptation to stress
• Consult with mental health professionals
• Involve the patient and family
• Identify community resources accessible to the patient

Standards
• Individualize interventions to meet the patient's needs
• Apply ANA code of ethics by safeguarding the patient's right to privacy and autonomy in the selection of interventions
• Apply ANA Standards of Care for Psychiatric Mental Health Nursing Practice by developing a plan negotiated among the patient, nurse, family, and health care team and prescribing evidence-based interventions

Attitudes
• Display integrity when creating interventions for the patient's lifestyle
• Act independently to seek out resources that could benefit the patient
• Express confidence that stress can be managed

FIGURE 38-4 Critical thinking model for stress and coping planning. *ANA,* American Nurses Association.

psychiatric social workers. An interprofessional approach addresses the holistic needs of the patient. Recognize the need for collaboration and consultation; inform the patient about potential resources; and make arrangements for interventions such as consultations, group sessions, or therapy as needed. A hospital social worker shares ideas for available resources both within the hospital and in the community. A home care nurse knows community services, groups, and appropriate contacts.

In addition to maximizing use of available resources for the patient, collaborative care also benefits the nurse. While working with patients experiencing stress, you gain a broad understanding of the multitude of health care disciplines. Work becomes more satisfying.

◎ NURSING CARE PLAN

Ineffective Coping

ASSESSMENT

Sandra and John have been married only 3 years; they are both 55 years old. This is a late marriage for both of them; neither was previously married. They both work and plan on retiring at age 66. Last month John was diagnosed with stage 3 pancreatic cancer. Presently John and Sandra are in the early phase of treatment options. At this point in time they are both working. They are at the Cancer Center today to decide on some treatment options. When you greet the couple, you notice that they both look tired, Sandra is disheveled, and John is clean shaven and well groomed. John states that he is worried about Sandra as she appears "just worn out," and he is afraid that she will not be able to help him through this medical crisis.

Assessment Activities	*Findings/Defining Characteristics**
Ask Sandra how she feels about John's diagnosis.	Sandra states, **"There's so much. I just feel inadequate and overwhelmed. I don't even know how I feel. I know I feel very alone."**
Ask Sandra what she remembers about John's treatment options.	She states, "I really **can't remember anything** but stage 3 pancreatic cancer. I got on the Internet so I know this is a bad cancer.
Ask John and Sandy about friends and relatives they have for support.	Both are only children and have **no other family**; they moved to the Northwest 1 year ago for new jobs. They both work for the same company but state that they have **few close friends**.
Ask Sandy to identify people she can turn to for help.	Sandra **sobs** and **feels that she doesn't have anyone locally to whom she can turn**. They are active in their church. On further discussion Sandra mentions a close friend from the Midwest.
Ask Sandra about sleep and nutrition patterns.	She **can't get to sleep easily and awakens 3 to 4 times per night.**
	States, "Appetite **is poor; I'm just not hungry. I think I've lost weight because my clothes are loose, but I don't know."**
Assess Sandra's mood and affect by asking how she is feeling.	She states, **"I feel very tired. Everything feels overwhelming."**

***Defining characteristics** are shown in bold type.

NURSING DIAGNOSIS: Ineffective coping related to insufficient social support

PLANNING

Goals	*Expected Outcomes (NOC)[†]*
	Social Support
Sandra achieves support from her community in 1 month.	Sandra identifies at least one person in her community who can help support her in this crisis.
	Sandra participates in a local support group weekly.
	Caregiver Lifestyle Disruption
Sandra achieves a more balanced lifestyle in 1 month.	Sandra reports eating at least 2 meals a day and improved sleep within 1 month.
	Sandra develops a balanced routine that incorporates time for own rest or relaxation within 1 week.

[†]Outcome classification labels from Moorhead S et al: *Nursing outcomes classification (NOC),* ed 5, St Louis, 2013, Mosby.

INTERVENTIONS (NIC)[‡]	RATIONALE
Support System Enhancement	
Identify community-based cancer support systems for patients and family for Sandra and John.	Support systems for both patient and family are an effective intervention to cope with the stress of a cancer diagnosis and related therapies and decision making (Parelkar et al., 2013).
Help Sandra identify a person who is willing to come with Sandy and John to some of the early appointments regarding treatment decision and actual treatment.	Having another person hear some of the treatment options and treatment procedures provides opportunities to clarify the discussion. During high-stress times the patient and family may not hear the material provided by health care providers completely (Doron et al., 2014).
Explore community resources for a short-term education group for both Sandra and John for self-care tools to reduce stress.	Education groups help caregivers develop self-care tools to reduce stress, change negative self-talk, communicate more effectively, and make difficult decisions (Oken et al., 2010).
Teach Sandra and John mindfulness meditation strategies.	Mindfulness meditation, a form of cognitive therapy, reduces stress related to cancer diagnosis and treatment in patients and families (Desiree et al., 2015; Lengacher et al., 2014).

[‡]Intervention classification labels from Bulechek GM et al: *Nursing interventions classification (NIC),* ed 6, St Louis, 2013, Mosby.

EVALUATION

Nursing Actions	*Patient Response/Finding*	*Achievement of Outcome*
Ask Sandra if her fatigue and stress levels have decreased.	Sandra identified two people in her church community. One is a cancer survivor; the second is a spouse of a cancer patient currently in treatment.	Sandra falls asleep within 10 minutes and sleeps for 6 hours. She also has a 30-minute rest period during the day.
Ask Sandra and John to describe modifications they have made in their daily routine.	Both use mindfulness meditation several times a week, and both state that they are feeling much more relaxed.	Meditation is reducing stress and allowing Sandra and John to concentrate on the treatment decision.
Ask Sandra if she attended support group.	Sandra reports she has attended two sessions.	Sandra accepts support from community.

CONCEPT MAP

Nursing diagnosis: Imbalanced nutrition: less than body requirements
- Poor appetite
- Weight loss due to decreased intake

▼

Interventions
- Have Sandra do weekly meal planning of small simple meals
- Provide a cook book designed by a cancer patient and their family

Nursing diagnosis: Ineffective coping
- Crying
- Poor sleep patterns
- Inability to concentrate

▼

Interventions
- Identify support groups
- Teach mindfulness stress reduction techniques

Primary health problem: John, 55 years old, recent diagnosis of stage 3 pancreatic cancer. Sandra is having difficulty coping
Priority assessments: Impact of stress, past and current coping strategies, nutritional and sleeping patterns

Nursing diagnosis: Anxiety
- Poor sleeping
- Decreased concentration
- Difficulty maintaining eye contact

▼

Interventions
- Use mindfulness exercises to improve relaxation prior to going to bed.
- Arrange for a person to accompany John and Sandra to initial appointments to clarify information

Nursing diagnosis: Powerlessness
- Overwhelmed about husband's diagnosis
- Fatigued

▼

Interventions
- Encourage Sandra to take some alone time to relax and rest
- Provide time to repeat and clarify all treatment options and use Teach Back to verify John and Sandra's understanding of information.

——— Link between medical diagnosis and nursing diagnosis   - - - - Link between nursing diagnoses

FIGURE 38-5 Concept map for Sandra.

Contacts with other members of the interprofessional team and the community provide a feeling of contributing to the teamwork of providing holistic care.

◆ **Implementation**

Health Promotion. Three primary modes of intervention for stress are to decrease stress-producing situations, increase resistance to stress, and learn skills that reduce physiological response to stress (Pender et al., 2013). Educate patients and families about the importance of health promotion (Box 38-6).

Regular Exercise and Rest. A regular exercise program improves muscle tone and posture, controls weight, reduces tension, and promotes relaxation. In addition, exercise reduces the risk of cardiovascular disease and improves cardiopulmonary functioning. Patients who have a history of a chronic illness, are at risk for developing an illness, or are older than 35 years of age should begin a physical exercise program only after discussing the plan with a health care provider (Figure 38-6).

Regular rest and sleep are also effective in reducing stress and stress-related fatigue. When stressful situations are present, encourage

FIGURE 38-6 Regular exercise helps to cope with stress. (Courtesy Rudolph A. Furtado.)

BOX 38-6 PATIENT TEACHING

Stress Management

Objective
- Patient will report less anxiety, depression, and pain related to chronic health problems.

Teaching Strategies
- Familiarize patient with mind-body therapies that will likely benefit patient. Refer to a group or specialized practitioner when necessary (Gillespie and Gates, 2013; Okonta, 2012; Parelkar et al., 2013):
  - Meditation
  - Progressive muscle relaxation
  - Guided imagery
  - Hypnosis
  - Yoga
  - Tai Chi
- Teach patient how to incorporate 15-30 minutes of exercise into daily activities (Doron et al., 2014).
- Instruct patient to identify and use relaxation techniques such as:
  - Listen to music that you enjoy.
  - Keep a journal of your thoughts and feelings.
  - Replace unnecessary time-consuming activities with activities that are pleasurable or interesting.

Evaluation
- Use Teach Back to ask patient to explain how stress-reduction techniques help him or her to cope.
- Ask patient to report effects of the alternative therapy(ies) on anxiety, sleep, and lifestyle.
- Observe patient for signs of stress.

patients and their family members to establish bedtime and sleep routines and try to stick to the schedule (see Chapter 43). Patients and family members who are well rested are able to manage stress, problem solve, and maintain a sense of control over the situation (Akerstedt et al., 2014).

QSEN QSEN: BUILDING COMPETENCY IN EVIDENCE-BASED PRACTICE As a nurse educator for a diabetes rehabilitation program, you recognize the value of exercise for these patients. However, you are not sure about the best way to persuade the patients to increase their exercise. You've located current research articles that support types of interventions that are effective in promoting physical activity among chronically ill adults. Some of these interventions include (1) targeting physical activity exclusively, (2) using behavioral (as opposed to cognitive) strategies, and (3) encouraging self-regulation and monitoring (Park and Iacocca, 2014; Ruppar and Conn, 2010). On the basis of the evidence, which of the following interventions is (are) most likely to be successful? (Select all that apply.)

1. Develop a program that focuses on multiple behaviors, including diet, exercise, and medication compliance.
2. Develop a program that teaches tai chi.
3. Ask patients to keep a written log of the amount of physical activity they have each day.
4. Ask patients to list the ways that exercise helps them.
5. Provide patients with pedometers to record their daily steps.
6. Ask patients to set goals for exercise every day.

ⓔ *Answers to QSEN Activities can be found on the Evolve website.*

Support Systems. A support system of family, friends, and colleagues who listen, offer advice, and provide emotional support benefits a patient experiencing stress (Doron et al., 2014). Many support groups are available to individuals (e.g., those sponsored by the American Heart Association and the American Cancer Society, local hospitals and churches, and mental health organizations). Recent research shows that cancer survivors who effectively manage their stress make changes in their physical, psychosocial, and preventive health behaviors (Parelkar et al., 2013).

Time Management. Time-management techniques include developing lists of prioritized tasks. For example, help patients list tasks that require immediate attention, those that are important and can be delayed, and those that are routine and can be accomplished when time becomes available. In many cases setting priorities helps individuals identify tasks that are not necessary or can be delegated to someone else.

Guided Imagery and Visualization. Guided imagery is based on the belief that a person significantly reduces stress with imagination. It is a relaxed state in which a person actively uses imagination in a way that allows visualization of a soothing, peaceful setting. Typically the image created or suggested uses many sensory words to engage the mind and offer distraction and relaxation.

Progressive Muscle Relaxation Therapies. In the presence of anxiety-provoking thoughts and events, a common physiological symptom is muscle tension. Diminish physiological tension through a systematic approach to releasing tension in major muscle groups. Typically an individual achieves a relaxed state through deep breathing. Once the patient is breathing deeply, direct him or her to alternately tighten and relax muscles in specific groupings. Other controlled relaxation exercises such as yoga are effective in regulating stress responses and reducing blood pressure (Doron et al., 2014; Okonta, 2012).

Assertiveness Training. Assertiveness includes skills for helping individuals communicate effectively regarding their needs and desires. The ability to resolve conflict with others through assertiveness training is important for reducing stress. Teaching assertiveness in a group setting increases the benefits of the experience.

Journal Writing. For many people keeping a private, personal journal provides a therapeutic outlet for stress. Suggest that patients keep journals, especially during difficult situations. In a private journal patients are able to express a full range of emotion and vent their honest feelings without hurting anyone else's feelings and without concern for how they appear to others.

Mindfulness-Based Stress Reduction. **Mindfulness** is a moment-to-moment present awareness with an attitude on nonjudgment, acceptance, and openness (Lengacher et al., 2014). Mindfulness-based stress reduction (MBSR) meditative practices are effective in reducing psychological and physical symptoms or perceptions. They are effective in stress management and symptom control with certain chronic conditions (Box 38-7). Through mindfulness exercises people learn to self-regulate awareness and attention to feeling and implement effective changes. Patients use cognitive exercises and subjective experiences to process images or feelings (Desiree et al., 2015). These feelings are then evaluated as pleasant or unpleasant, and the patient learns strategies to enhance the pleasant experiences and replace the unpleasant experiences. Through MBSR patients can control their stress response to illnesses and treatments, employees can manage job-related stress, and students can learn to manage stress anxiety.

Stress Management in the Workplace. Stressors such as rapid changes in health care technology, diversity in the workforce, organizational restructuring, and changing work systems place stress on employees. **Burnout** occurs as a result of chronic stress. In nursing, burnout results when nurses perceive the demands of their work

Impact of Meditation Therapies on
Illness-Related Stressors

PICO Question: Does the use of meditative training such as yoga and mindfulness-based stress reduction (MBSR) help to reduce illness-related stressors?

Evidence Summary

Prolonged and recurrent stress is associated with multiple psychological and health outcomes. A person's ability to cope with these stressors impacts physical and psychological health (Doron et al., 2014). Proactive coping strategies such as exercise, rest, good nutrition, support systems, meditation, and relaxation activities demonstrate greater stress tolerance when stressors are present (Gillespie and Gates, 2013; Doron et al., 2014).

In addition, coping strategies assist in symptom management in certain chronic illnesses. For example, in hypertension yoga reduces blood pressure, blood glucose, and cholesterol levels and helps with weight control (Doron et al., 2014; Okonta, 2012). In breast cancer survivors MBSR reduced fear of recurrence, which improved physical functioning, which in turn reduced perceived stress and anxiety (Lengacher et al., 2014). Patients with advanced lung cancer and their partners also benefited from MBSR and had reduced psychological stress about the illness; the partners reported decreases in caregiver burden (Desiree et al., 2015).

Cognitive therapies such as mediation and MBSR are important interventions when dealing with illness-related stressors. These therapies are beneficial for managing symptoms and psychological distress associated with chronic conditions. However, it is important that the meditation therapy be individualized to patient needs, patient's ability to learn the therapy, and concurrent treatment.

Application to Nursing Practice

- Perform an assessment on patient's and family's stress-management experiences. This provides a baseline for proactive strategies that have worked in the past (Gillespie and Gates, 2013).
- Identify readiness to begin structured meditation therapies such as yoga or MBSR. Patients must be ready and willing to be active participants in the therapy (Desiree et al., 2015).
- Assess patient's current lifestyle practices regarding exercise, nutrition, and relaxation activities. Determine his or her perception of these activities in managing stress (Doron et al., 2014).
- Reinforce to patient and family that these stress-management techniques are an addition to, not instead of, their current treatment.

exceed perceived resources. It is manifested as emotional exhaustion, poor decision making, loss of a sense of personal identity, and feelings of failure.

It is important that nurses participate in self-care practices. For example, in oncology settings nurses experience compassion fatigue. Effective strategies for compassion fatigue and how to help nurses deal with this phenomenon are available (see Chapter 1). Other clinical settings such as critical care, trauma, and emergency departments use resilience training and clinical debriefing to manage job-related stress and reduce burnout and nursing staff turnover (Ianello and Balzarotti, 2014; Mealer et al., 2014). Recognizing the impact of shift work and changes in schedules enables some managers and nurses to use self-scheduling techniques. This reduces job-related stress and improves sleep quality, collaboration, and teamwork (Lin et al., 2014).

Recognizing the areas over which you have control and can change and those for which you do not have responsibility is a vital insight. Making a clear separation between work and home life is also crucial.

Strengthening friendships outside of the workplace, participating in creative activities for personal "recharging" of emotional energy, and spending off-duty hours in interesting activities all help reduce compassion fatigue.

Acute Care

Crisis Intervention. When stress overwhelms a person's usual coping mechanisms and demands mobilization of all available resources, it becomes a crisis. A crisis creates a turning point in a person's life because it changes the direction of his or her life in some way. The precipitating event usually occurs approximately 1 to 2 weeks before the individual seeks help, but sometimes it has occurred within the past 24 hours. Generally a person resolves the crisis in some way within approximately 6 weeks. Crisis intervention aims to return the person to a precrisis level of functioning and promote growth (Figure 38-7).

Because an individual's or family's usual coping strategies are ineffective in managing the stress of the precipitating event, the use of new coping mechanisms is necessary. This experience forces the use of unfamiliar strategies and results in either a heightened awareness of previously unrecognized strengths and resources or deterioration in functioning. Thus a crisis is often referred to as a situation of both danger and opportunity. Some individuals or families emerge from a crisis state functioning more effectively, whereas others find themselves weakened, and still others are completely dysfunctional.

Crisis intervention is a specific type of brief psychotherapy and has two specific goals. First is patient safety. Use external controls to protect the patient and others if the person is suicidal or homicidal. Second is anxiety reduction using techniques so a patient's inner resources are put into effect. It is more directive than traditional psychotherapy or counseling, and any member of the health care team who has been trained in its techniques can use it. The basic approach is problem solving, and it focuses only on the problem presented by the crisis (Varcarolis, 2013).

Help the patient make the mental connection between the stressful event and his or her reaction to it. This is crucial because he or she is sometimes unable to see the whole situation clearly. You also help the person become aware of present feelings such as anger, grief, or guilt to help him or her reduce feelings of tension. In addition, you help the patient explore coping mechanisms, perhaps identifying new methods of coping. Finally you help the person increase social contacts if he or she has been isolated and overly self-focused.

Restorative and Continuing Care. A person under stress recovers when the stress is removed or coping strategies are successful; however, a person who has experienced a crisis has changed, and the effects often last for years or for the rest of the person's life. The final stage of adapting to a crisis is acknowledgment of its long-term implications. If a person has coped with a crisis and its consequences successfully, he or she becomes more mature and healthy. When a person recovers from a stressful situation, the time is right for introducing stress-management skills to reduce the number and intensity of stressful situations in the future.

◆ Evaluation

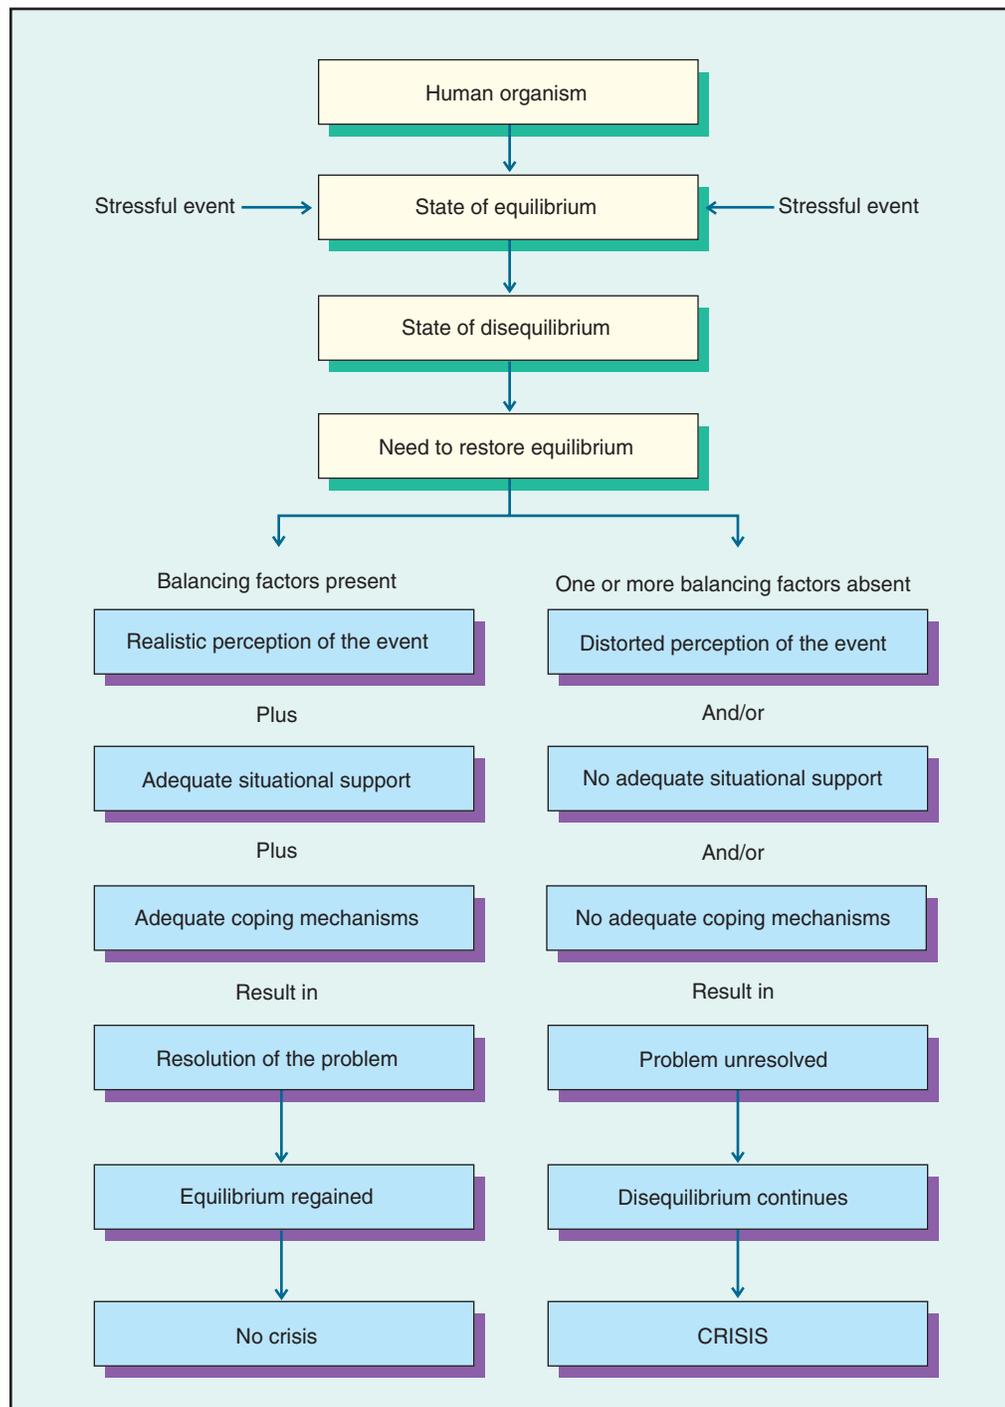
Through the Patient's Eyes. A patient recovering from acute stress often spontaneously reports feeling better when the stressor is gone. The recovery from chronic stress occurs more gradually as the patient emerges from the strain. In either situation, evaluate the patient for the presence of new or recurring stress-related symptoms (Figure 38-8). Your evaluation must include the patient's perceptions. Ask the patient about sleep patterns, appetite, and ability to concentrate. Ask how the patient feels about coping strategies that are being used and


FIGURE 38-7 Crisis intervention model. (Redrawn from Aguilera DC: *Crisis intervention: theory and methodology,* ed 8, St Louis, 1998, Mosby.)

determine their effectiveness. Ask patients to compare current feelings and behaviors with feelings and behaviors 6 months ago. If desired outcomes have been met, the patient reports feeling better now than 6 months ago.

An essential part of the evaluation process is collaborating with patients to determine if their own expectations from nursing have been met. Any revision in the plan of care includes steps to address patient expectations.

Patient Outcomes. Remember that coping with stress takes time. Maintain ongoing communication with patients regarding their

coping. Patients under severe stress or trauma often experience feelings of powerlessness, vulnerability, and loss of control. The nurse addresses these feelings by actively involving patients and families in the processes of re-examining problems, prioritizing, goal setting, and revising interventions. Involving patients in these processes gives them an opportunity to direct their energy in a positive way and moves them toward taking greater responsibility for health maintenance and promotion.

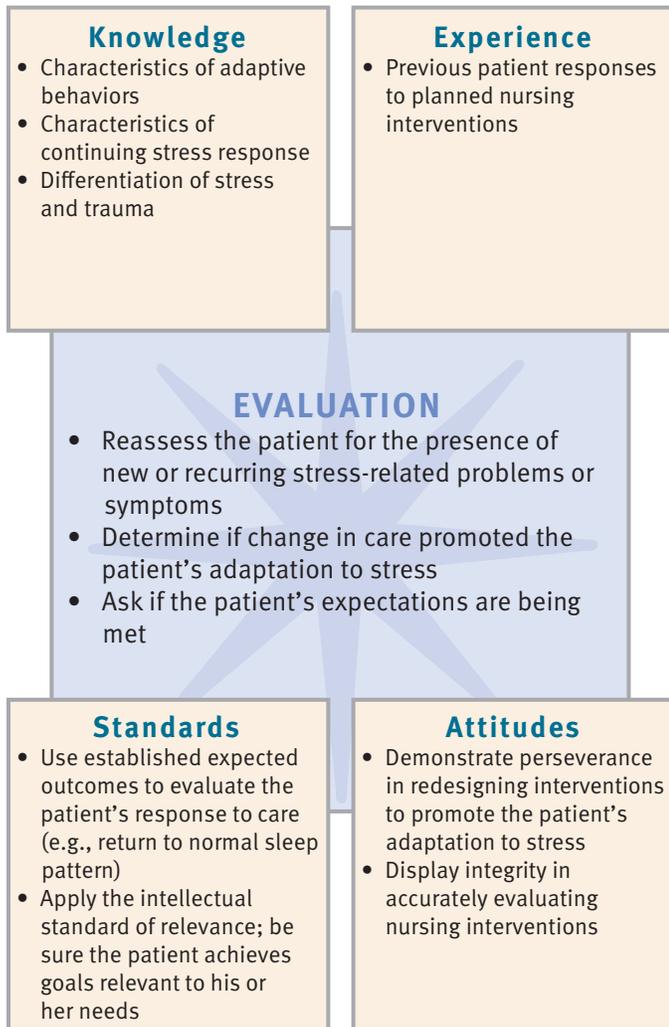
Engaging the patient as a partner in health care creates open communication. In such an environment the patient feels freer to give important feedback about interventions that are successful and helps


FIGURE 38-8 Critical thinking model for stress and coping evaluation.

the nurse better understand why some interventions fail to meet the established goals. If he or she reports continued acute stress, assess for safety by asking about whether or not there have been any recent accidents at home, in the car, or at work. Ask about coping strategies to determine if the patient is using unsafe, maladaptive strategies. If the patient reports continued chronic stress, ask about his or her perception of the stressor and coping behaviors used. Discuss the stressor with the patient to determine if it needs to be redefined. If contact with a patient ends before you have achieved the resolution of goals, it is important to refer him or her to appropriate resources so progress is not delayed or interrupted.

KEY POINTS

- The GAS is an immediate physiological response of the whole body to stress and involves several body systems, especially the autonomic nervous and endocrine systems. Physiological responses to stress also include immunological changes.
- Stress can make people ill as a result of increased levels of powerful hormones that change bodily processes.
- A person is under psychological stress only if he or she evaluates the event as a threat or a circumstance as personally significant. Such an evaluation of an event for its personal meaning is called *primary appraisal*.

- Potential stressors and coping mechanisms vary across the life span.
- Coping means making an effort to manage psychological stress.
- Coping is a process that constantly changes to manage demands on a person's resources.
- Three primary modes for stress intervention are to decrease stress-producing situations, increase resistance to stress, and learn skills that reduce physiological response to stress.
- A patient whose stress is so severe that he or she is unable to cope using any of the means that have worked before is experiencing a crisis.
- A crisis is a turning point in life and is developmental, situational, or adventitious.
- Generally a crisis is resolved in some way within approximately 6 weeks. Crisis intervention aims to return the person to a precrisis level of functioning and promote growth.

CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

1. You are meeting with Sandra and John during their second visit to the Cancer Center. You notice that Sandra is well groomed and not disheveled as she was during the last visit. John and Sandra were able to sit down and talk to one another about various treatment options. They are here today to finalize their decision. Although Sandra appears calm today, John is worried about her emotional status and the impact caring for him during treatments will have. Discuss the various stressors that need to be considered when evaluating their situation.

2. John is now in the Cancer Center for his third dose of the first round of chemotherapy. He had a strong reaction to the medications, and his white count dropped so low that he was unable to take the next dose of chemotherapy. Although John feels good physically and understands the reasons for holding the next round, Sandra is convinced that the treatment is not working. When you meet with Sandra you notice that she is talking fast, can't concentrate, and is crying. She has a friend with her, and the friend tells you that Sandra did not understand what the oncologist said. When he said that we need to skip this week's dose, Sandra interpreted it as we have to skip the chemotherapy. Which nursing diagnoses might apply to this situation?

3. John has completed his first round of chemotherapy. His blood chemistries look good, and on scan the tumor is decreased. He is now resting and will begin the second round of chemotherapy. Sandra is still fearful, but she is sleeping and eating well. She still has difficulty meeting with the doctors and understanding the treatments and impact they have on John's level of health. She says that, when she listens to the doctor, "I feel like I'm watching someone else and really don't hear or remember many details." Which approach would be the best to take in planning for Sandra?

ⓔ *Answers to Clinical Application Questions can be found on the Evolve website.*

REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. When teaching a patient about the negative feedback response to stress, the nurse includes which of the following to describe the benefits of this stress response?
   1. Results in neurophysiological response
   2. Reduces body temperature

Knowledge
- Characteristics of adaptive behaviors
- Characteristics of continuing stress response
- Differentiation of stress and trauma

Experience
- Previous patient responses to planned nursing interventions

EVALUATION
- Reassess the patient for the presence of new or recurring stress-related problems or symptoms
- Determine if change in care promoted the patient's adaptation to stress
- Ask if the patient's expectations are being met

Standards
- Use established expected outcomes to evaluate the patient's response to care (e.g., return to normal sleep pattern)
- Apply the intellectual standard of relevance; be sure the patient achieves goals relevant to his or her needs

Attitudes
- Demonstrate perseverance in redesigning interventions to promote the patient's adaptation to stress
- Display integrity in accurately evaluating nursing interventions

3. Causes a person to be hypervigilant
4. Reduces level of consciousness to conserve energy.

2. The nurse is interviewing a patient in the community clinic and gathers the following information about her: she is intermittently homeless, a single parent with two children who have developmental delays, and is suffering from chronic asthma. She does not laugh or smile, does not volunteer any information, and at times appears close to tears. She has no support system and does not work. She is experiencing an allostatic load. As a result, which of the following would be present during complete patient assessment? (Select all that apply.)
   1. Post-traumatic stress disorder
   2. Rising hormone levels
   3. Chronic illness
   4. Return of vital signs to normal
   5. Depression

3. A patient who is having difficulty managing his diabetes mellitus responds to the news that his hemoglobin A1C, a measure of blood sugar control over the past 90 days, has increased by saying, "The hemoglobin A1C is wrong. My blood sugar levels have been excellent for the last 6 months." Which defense mechanism is the patient using?
   1. Denial.
   2. Conversion.
   3. Dissociation.
   4. Displacement.

4. When doing an assessment of a young woman who was a victim of a home invasion 3 months earlier, the nurse learns that the woman has vivid images of the crash whenever she hears loud yelling or a sudden noise. The nurse recognizes this as _____.

5. A grandfather living in Japan worries about his two young grandsons who disappeared after a tsunami. This is an example of:
   1. A situational crisis.
   2. A maturational crisis.
   3. An adventitious crisis.
   4. A developmental crisis.

6. During the assessment interview of an older woman who is recently widowed, the nurse suspects that this woman is experiencing a developmental crisis. Which of the following questions provide information about the impact of this crisis? (Select all that apply.)
   1. With whom do you talk on a routine basis?
   2. What do you do when you feel lonely?
   3. How is having diabetes affecting your life?
   4. I know this must be hard for you. Let me tell you what might help.
   5. Do you have any changes in lifestyle habits: sleeping, eating, smoking, and drinking?

7. The nurse plans care for a 16-year-old male, taking into consideration that stressors experienced most commonly by adolescents include which of the following?
   1. Loss of autonomy caused by health problems
   2. Physical appearance, family, friends, and school
   3. Self-esteem issues, changing family structure
   4. Search for identity with peer groups and separation from family

8. A 10-year-old girl was playing on a slide at a playground during a summer camp. She fell and broke her arm. The camp notified the parents and took the child to the emergency department according to the camp protocol for injuries. The parents arrive at the emergency department and are stressed and frantic. The 10-year-old is happy in the treatment room, eating a Popsicle and picking out the color of her cast. List in order of priority what the nurse should say to the parents?
   1. "Can I contact someone to help you?"
   2. "Your daughter is happy in the treatment room, eating a Popsicle and picking out the color of her cast."
   3. "I'll have the doctor come out and talk to you as soon as possible."
   4. "Let me help you two calm down a bit so I can take you to your daughter."

9. When assessing an older adult who is showing symptoms of anxiety, insomnia, anorexia, and mild confusion, one of the first assessments includes which of the following?
   1. The amount of family support
   2. A 3-day diet recall
   3. A thorough physical assessment
   4. Threats to safety in her home

10. After a health care provider has informed a patient that he has colon cancer, the nurse enters the room to find the patient gazing out the window in thought. Which of the following are appropriate responses or actions of the nurse? (Select all that apply.)
    1. "I know another patient whose colon cancer was cured by surgery."
    2. Straighten the patient's bed and room
    3. "Have you thought about how you are going to tell your family?"
    4. "Would you like for me to sit down with you for a few minutes so you can talk about this?"
    5. Sit quietly with the patient

11. A 34-year-old single father who is anxious, tearful, and tired from caring for his three young children tells the nurse that he feels depressed and doesn't see how he can go on much longer. Which of the following would be the nurse's best response?
    1. "Are you thinking of suicide?"
    2. "You've been doing a good job raising your children. You can do it!"
    3. "Is there someone who can help you during the evenings and weekends?"
    4. "What do you mean when you say you can't go on any longer?"

12. The nurse is evaluating the coping success of a patient experiencing stress from being newly diagnosed with multiple sclerosis and psychomotor impairment. Which of the following statements indicate that the patient is beginning to cope with the diagnosis? (Select all that apply.)
    1. "I'm going to learn to drive a car so I can be more independent."
    2. "My sister says she feels better when she goes shopping, so I'll go shopping."
    3. "I'm going to let the occupational therapist assess my home to improve efficiency."
    4. "I've always felt better when I go for a long walk. I'll do that when I get home."
    5. "I'm going to attend a support group to learn more about multiple sclerosis."

13. A patient with type 2 diabetes is experiencing a lot of work-related stress and is fearful of losing his job. In addition, his wife is threatening divorce. His blood sugar is elevating, and his doctors want him to attend some stress-management classes. He says, "My blood sugar can't be high because of my work stress." What causes blood glucose to rise during stress? (Select all that apply.)
    1. Increases in antidiuretic hormone (ADH)
    2. Increases in cortisol

3. Increases in aldosterone
4. Increases in adrenocorticotropic hormone (ACTH)
5. Increases in epinephrine
14. A staff nurse is talking with the nursing supervisor about the stress that she feels on the job. Which of the following are true about work-related stress? (Select all that apply.)
    1. Job-related stress can affect the quality of patient care.
    2. Stress can affect nurses' efficiency and decision making.
    3. Nurses who talk about feeling stress are unprofessional and should calm down.
    4. Nurses frequently experience stress with the rapid changes in health care technology.
    5. Nurses cannot resolve job-related stress.
15. A crisis intervention nurse is working with a mother whose Down syndrome child has been hospitalized with pneumonia and who has lost her child's disability payment while the child is hospitalized. The mother worries that her daughter will fall behind in special-school classes during hospitalization. Which strategies are

effective in helping this mother cope with these stressors? (Select all that apply.)
1. Referral to social service process reestablishing the child's disability payment
2. Sending the child home in 72 hours and having the child return to school
3. Coordinating hospital-based and home-based schooling with the child's teacher
4. Teaching the mother signs and symptoms of a respiratory tract infection
5. Telling the mother that the stress will decrease in 6 weeks when everything is back to normal

Answers: 1. 1; 2, 3, 5; **3.** 1; **4.** Post-traumatic stress disorder (PTSD); **5.** 3; **6.** 1, 2, 5; **7.** 4; **8.** 2, 4, 3; **9.** 1; **10.** 4, 5; **11.** 4; **12.** 3, 5; **13.** 2, 4, 5; **14.** 1, 2, 4; **15.** 1, 3, 4.

Activity and Exercise

OBJECTIVES

- Describe the role of the musculoskeletal and nervous systems in the regulation of activity and exercise.
- Discuss the influence of immobility on body alignment, joint movement, and activity.
- Discuss implications for preventing deconditioning and deep vein thrombosis in hospitalized inpatients.
- Describe the evidence that supports regular activity and exercise in patient care.
- Describe how to maintain and use proper body mechanics.
- Describe important factors to consider when planning an exercise program for patients across the life span and for those with specific chronic illnesses.
- Describe how to assess patients for activity intolerance.

- Formulate nursing diagnoses for patients experiencing problems with activity intolerance.
- Develop an individualized nursing care plan for a patient with activity intolerance.
- Discuss the importance of no-lift policies for patients and health care providers.
- Describe equipment needed for safe patient handling and movement.
- Discuss the impact of national patient safety resources, initiatives, and regulations in relation to patient handling and movement.
- Evaluate the nursing care plan for maintaining activity and exercise for patients across the life span and with specific chronic illnesses.

Regular physical activity and exercise contribute to patients' physical and emotional well-being (Edelman et al., 2013; Esposito and Fitzpatrick, 2011). This is a principle that you, as a nurse, should apply in the care of patients in all settings. Functional decline (the loss of the ability to perform self-care or activities of daily living) may result not only from illness or adverse treatment effects but also from **deconditioning** associated with inactivity, the negative effects of which can be seen after short periods of time. Deconditioning involves physiological changes following a period of inactivity, bed rest, or sedentary lifestyle. It is a particular risk for hospitalized patients who spend most of their time in bed, even when they are able to walk. As a result, nurses play an important role in increasing the overall activity of inpatients to minimize the risk of deconditioning.

A program of regular physical activity and exercise has the potential to enhance all aspects of a patient's health. This chapter provides you

with knowledge of exercise and activity as they relate to health promotion, the acute phase of illness, and the restorative and continuing care of patients. Applying knowledge about exercise and activity will allow you to plan nursing strategies for patients' individualized exercise and activity programs. Knowing the movements and functions of muscles in maintaining posture and movement and implementing evidence-based knowledge about safe patient handling are essential to protecting the safety of both the patient and the nurse (see Chapter 28).

SCIENTIFIC KNOWLEDGE BASE

Regular physical activity and exercise contribute to both physical and emotional well-being (Edelman et al., 2013; Esposito and Fitzpatrick, 2011). Knowing the physiology and regulation of body mechanics, exercise, and activity helps provide individualized patient care.

Overview of Exercise and Activity

The coordinated efforts of the musculoskeletal and nervous systems maintain balance, posture, and body alignment during lifting, bending, moving, and performing **activities of daily living (ADLs)**. Proper balance, posture, and body alignment reduce the risk of injury to the musculoskeletal system and facilitate body movements, allowing physical mobility without muscle strain and excessive use of muscle energy (see Chapter 28).

Body Alignment. Body alignment refers to the relationship of one body part to another along a horizontal or vertical line. Correct alignment involves positioning so no excessive strain is placed on a person's joints, tendons, ligaments, or muscles, thereby maintaining adequate muscle tone and contributing to balance (see Chapter 28).

Body Balance. Body balance occurs when a relatively low **center of gravity** is balanced over a wide, stable base of support and a vertical line falls from the center of gravity through the base of support. When the vertical line from the center of gravity does not fall through the base of support, the body loses balance. Proper posture or a body position that most favors function, requires the least muscular work to maintain, and places the least strain on muscles, ligaments, and bones to enhance body balance (Patton and Thibodeau, 2012). Nurses rely on balance to maintain proper body alignment and posture through two simple techniques: (1) widening the base of support by separating the feet to a comfortable distance, and (2) increasing balance by bringing the center of gravity closer to the base of support. For example, you raise the height of a hospital bed when performing a procedure such as changing a dressing to prevent bending too far at the waist and shifting the base of support.

Coordinated Body Movement. Coordinated body movement is a result of weight, center of gravity, and balance. Weight is the force exerted on a body by gravity. When an object is lifted, the lifter must overcome the weight of the object and be aware of its center of gravity. In symmetrical objects the center of gravity is located at the exact center of the object. The force of weight is always directed downward. An unbalanced object has its center of gravity away from the midline and falls without support. Because people are not geometrically perfect, their centers of gravity are usually midline, at 55% to 57% of standing height. Like unbalanced objects, patients who are unsteady do not maintain a balance with their center of gravity, which places them at risk for falling. You need to be able to identify these patients and intervene to maintain their safety.

Friction. Friction is a force that occurs in a direction to oppose movement. It increases a patient's risk for skin and tissue damage and potential pressure ulcers (see Chapter 48). Reduce friction by following some basic principles. When you move objects, those with a greater surface area create more friction. To reduce friction, you need to decrease the surface area of the object. For example, when helping patients move up in bed, place their arms across the chest. This decreases surface area and reduces friction (see Chapter 28).

A patient who is passive or immobilized produces greater friction to movement. When possible, use some of your patients' strength and mobility when positioning and transferring them. Explain the procedure and tell your patients when to move. You decrease friction when your patients bend their knees as you help them move up in the bed.

Exercise and Activity. Exercise is physical activity that conditions the body, improves health, and maintains fitness. Sometimes it is also a therapeutic measure. A patient's individualized exercise program depends on any health-related physical limitations, his or her activity tolerance, and the type and amount of exercise or activity that he or she is able to perform. Physiological, emotional, and developmental factors influence a patient's activity tolerance.

An active lifestyle is important for maintaining and promoting health; it is also an essential treatment for chronic illnesses (Combs et al., 2013). Regular physical activity and exercise enhance functioning of all body systems, including cardiopulmonary functioning (endurance), musculoskeletal fitness (flexibility and bone integrity), weight control and maintenance (body image), and psychological well-being (Edelman et al., 2013).

The best program of physical activity includes a combination of exercises that produces different physiological and psychological benefits. Three categories of exercise are isotonic, isometric, and resistive isometric. The type of muscle contraction involved determines the classification of the exercise. Isotonic exercises cause muscle contraction and change in muscle length (isotonic contraction) (see Chapter 28). Examples are walking, swimming, dance aerobics, jogging, bicycling, and moving arms and legs with light resistance. Isotonic exercises enhance circulatory and respiratory functioning; increase muscle mass, tone, and strength; and promote osteoblastic activity (activity by bone-forming cells), thus combating osteoporosis.

Isometric exercises involve tightening or tensing muscles without moving body parts (isometric contraction) (see Chapter 28). Examples are quadriceps set exercises and contraction of the gluteal muscles. This form of exercise is ideal for patients who do not tolerate increased activity. A patient who is immobilized in bed can perform isometric exercises. The benefits are increased muscle mass, tone, and strength, thus decreasing the potential for muscle wasting; increased circulation to the involved body part; and increased osteoblastic activity.

Resistive isometric exercises are those in which an individual contracts the muscle while pushing against a stationary object or resisting the movement of an object (Resnick et al., 2012). A gradual increase in the amount of resistance and length of time that the muscle contraction is held increases muscle strength and endurance. Examples of resistive isometric exercises are push-ups and hip lifting, in which a patient in a sitting position pushes with the hands against a surface such as a chair seat and raises the hips. In some long-term care settings **footboards** are placed on the end of beds; patients push against them to move up in bed. Resistive isometric exercises help promote muscle strength and provide sufficient stress against bone to promote osteoblastic activity.

Regulation of Movement

Coordinated body movement involves the integrated functioning of the skeletal, muscular, and nervous systems. Because these three systems cooperate so closely in mechanical support of the body, they are often considered as a single functional unit.

Skeletal System. Firmness of the skeleton of the body results from inorganic salts such as calcium and phosphate that are in the bone matrix. It is related to the rigidity of the bone, which is necessary to keep bones straight and enables them to withstand weight bearing. Elasticity and skeletal flexibility change with age. For example, the newborn has a large amount of cartilage and is highly flexible but is unable to support weight. The toddler's bones are more pliable than those of an older person and are better able to withstand falls. Older adults, especially women, are more susceptible to bone loss (resorption) and osteoporosis, which increase the risk of fractures.

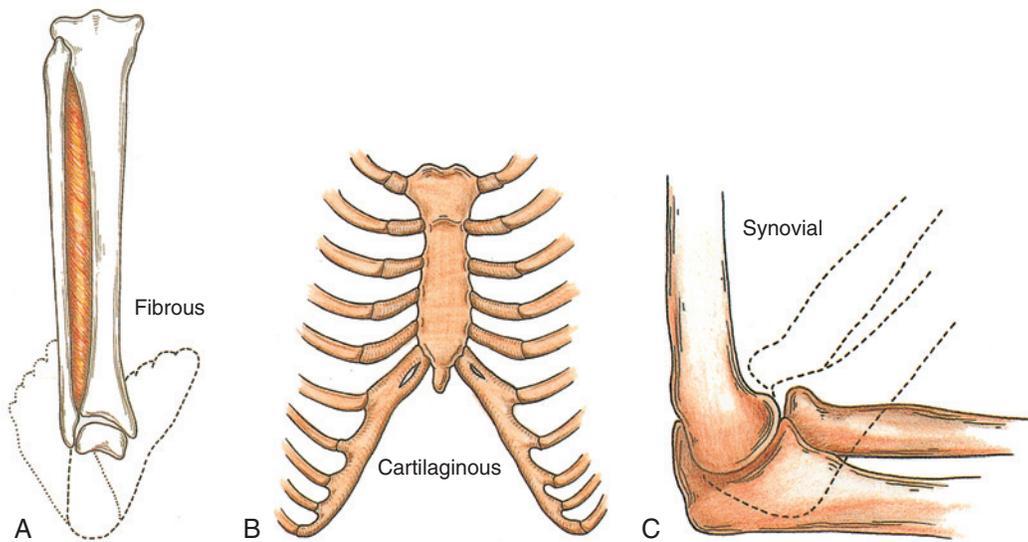
Bones perform five functions in the body: support, protection, movement, mineral storage, and hematopoiesis (blood cell formation). In the discussion of body mechanics, two of these functions (i.e.,


FIGURE 39-1 Joint types. **A,** Fibrous. **B,** Cartilaginous. **C,** Synovial.

support and movement) are most important (see Chapter 28). Bones serve as support by providing the framework and contributing to the shape, alignment, and positioning of the body parts. Bones, together with their joints, constitute levers for muscle attachment to provide movement. As muscles contract and shorten, they pull on bones, producing joint movement (Patton and Thibodeau, 2012).

Joints. An articulation, or **joint**, is the connection between bones. Each joint is classified according to its structure and degree of mobility. On the basis of connective structures, joints are classified as fibrous, cartilaginous, or synovial (Huether and McCance, 2012). **Fibrous joints** fit closely together and are fixed, permitting little, if any, movement such as the syndesmosis between the tibia and fibula (Figure 39-1, *A*). **Cartilaginous joints** have little movement but are elastic and use cartilage to unite separate bony surfaces such as the synchondrosis that attaches the ribs to the costal cartilage. When bone growth is complete, the joints ossify (see Figure 39-1, *B*). **Synovial joints**, or true joints, such as the hinge type at the elbow, are freely movable and the most mobile, numerous, and anatomically complex body joints (see Figure 39-1, *C*).

Ligaments, Tendons, and Cartilage. Ligaments, tendons, and cartilage support the skeletal system (see Chapter 28). **Ligaments** are white, shiny, flexible bands of fibrous tissue that bind joints and connect bones and cartilage. They are elastic and aid joint flexibility and support (Figure 39-2).

In addition, some ligaments serve a protective function. For example, ligaments between the vertebral bodies and the ligamentum flavum prevent damage to the spinal cord during movement of the back. **Tendons** are white, glistening, fibrous bands of tissue that occur in various lengths and thicknesses. They are strong, flexible, and inelastic as they serve to connect muscle to bone. The Achilles tendon (tendo calcaneus) is the thickest and strongest tendon in the body. It begins near the midposterior of the leg and attaches the gastrocnemius and soleus muscles in the calf to the calcaneal bone in the back of the foot (Figure 39-3).

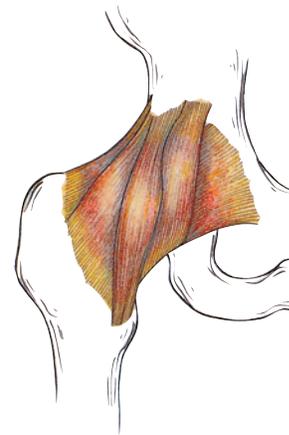
Cartilage is nonvascular, supporting connective tissue with the flexibility of a firm, plastic material. Because of its gristlelike nature, cartilage sustains weight and serves as a shock absorber between articulating bones. Permanent cartilage is **unossified** (not hardened), except in advanced age and diseases such as osteoarthritis, which impairs mobility.


FIGURE 39-2 Ligaments of hip joint.

Strength and flexibility do not result entirely from joints, ligaments, tendons, and cartilage. Adequate skeletal muscle is also necessary.

Skeletal Muscle. Muscles are made of fibers that contract when stimulated by an electrochemical impulse that travels from the nerve to the muscle across the neuromuscular junction. The electrochemical impulse causes the filaments (predominantly protein molecules of myosin and actin) within the fiber to slide past one another, with the filaments changing length.

Contraction of skeletal muscles allows people to walk, talk, run, breathe, or participate in physical activity. There are more than 600 skeletal muscles in the body. In addition to facilitating movement, these muscles determine the form and contour of our bodies. Most of our muscles span at least one joint and attach to both articulating bones. When contraction occurs, one bone is fixed while the other moves. The origin is the point of attachment that remains still; the insertion is the point that moves when the muscle contracts (Patton and Thibodeau, 2012).

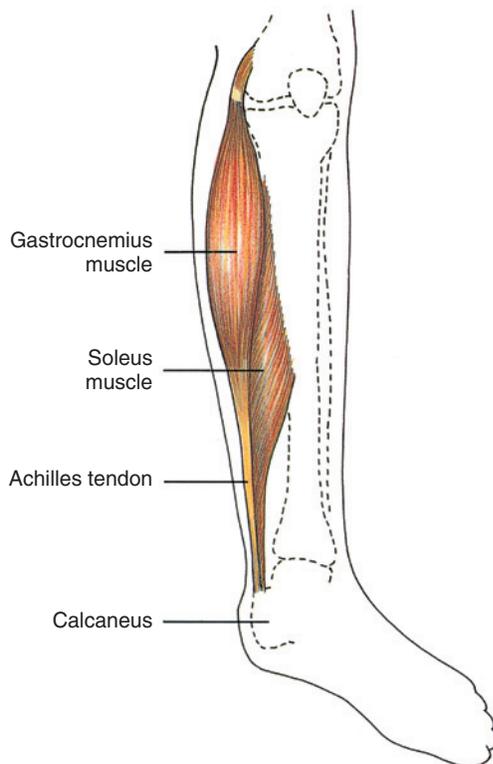
Muscle contractions are categorized by functional purpose: moving, resisting, or stabilizing body parts. In **concentric tension** increased muscle contraction causes muscle shortening, resulting in movement such as when a patient uses an overhead trapeze to pull up in bed.


FIGURE 39-3 Tendons and muscles of lower leg.

Eccentric tension helps control the speed and direction of movement. For example, when using an overhead trapeze, a patient slowly lowers himself to the bed. The lowering is controlled when the antagonistic muscles lengthen. Concentric and eccentric muscle actions are necessary for active movement and therefore are referred to as dynamic or **isotonic contraction**. **Isometric contraction** (static contraction) causes an increase in muscle tension or muscle work but no shortening or active movement of the muscle (e.g., instructing a patient to tighten and relax a muscle group, as in quadriceps set exercises or pelvic floor exercises). Voluntary movement is a combination of isotonic and isometric contractions.

Although isometric contractions do not result in muscle shortening, energy expenditure increases. This type of muscle work is comparable to having a car in neutral with the driver continually depressing the accelerator and racing the engine. The driver is not going anywhere but expends a large amount of energy. It is important to understand the energy expenditure (increased respiratory rate and increased work on the heart) associated with isometric exercises because the exercises are sometimes contraindicated in certain patients' illnesses (e.g., myocardial infarction [MI] or chronic obstructive pulmonary disease [COPD]).

Muscles Concerned with Movement. The muscles of movement are located near the skeletal region, where a lever system causes movement (Patton and Thibodeau, 2012). The lever system makes the work of moving a weight or load easier. It occurs when specific bones such as the humerus, ulna, and radius and the associated joints such as the elbow act as a lever. Thus the force applied to one end of the bone to lift a weight at another point tends to rotate the bone in the direction opposite that of the applied force. Muscles that attach to bones of leverage provide the necessary strength to move an object.

Muscles Concerned with Posture. Gravity continually pulls on parts of the body; the only way the body is held in position is for muscles to pull on bones in the opposite direction. Muscles accomplish this counterforce by maintaining a low level of sustained contraction. Poor posture places more work on muscles to counteract the force of gravity. This leads to fatigue and eventually interferes with bodily functions and causes deformities.

Posture and movement depend on the skeleton and the shape and development of skeletal muscles. They also contribute to musculoskeletal function and often reflect personality, discomfort, and mood. For example, a person with a dramatic personality gestures with the hands, a person who is tired or depressed may slouch, and a person with abdominal pain may curl into a fetal-like position.

Coordination and regulation of different muscle groups depend on muscle tone and activity of antagonistic, synergistic, and antigravity muscles. **Muscle tone**, or tonus, is the normal state of balanced muscle tension. The body achieves tension by alternating contraction and relaxation without active movement of neighboring fibers of a specific muscle group. Muscle tone helps maintain functional positions such as sitting or standing without excess muscle fatigue and is maintained through continual use of muscles. ADLs require muscle action and help maintain muscle tone. When a patient is immobile or on prolonged bed rest, activity level, activity tolerance, and muscle tone decrease.

Muscle Groups. The nervous system coordinates the antagonistic, synergistic, and antigravity muscle groups that are responsible for maintaining posture and initiating movement. **Antagonistic muscles** cause movement at a joint. During movement the active mover muscle contracts while its antagonist relaxes. For example, during flexion of the arm the active mover, the biceps brachii, contracts; and its antagonist, the triceps brachii, relaxes. During extension of the arm the active mover, now the triceps brachii, contracts; and the new antagonist, the biceps brachii, relaxes.

Synergistic muscles contract to accomplish the same movement. When the arm is flexed, the strength of the contraction of the biceps brachii is increased by contraction of the synergistic muscle, the brachialis. Thus with synergistic muscle activity there are now two active movers (i.e., the biceps brachii and the brachialis), which contract while the antagonistic muscle, the triceps brachii, relaxes.

Antigravity muscles stabilize joints. These muscles continuously oppose the effect of gravity on the body and permit a person to maintain an upright or sitting posture. In an adult the antigravity muscles are the extensors of the leg, the gluteus maximus, the quadriceps femoris, the soleus muscles, and the muscles of the back.

Skeletal muscles support posture and carry out voluntary movement. The muscles are attached to the skeleton by tendons, which provide strength and permit motion. The movement of the extremities is voluntary and requires coordination from the nervous system.

Nervous System. The nervous system regulates movement and posture. The major voluntary motor area, located in the cerebral cortex, is the precentral gyrus, or motor strip. A majority of motor fibers descend from the motor strip and cross at the level of the medulla. Thus the motor fibers from the right motor strip initiate voluntary movement for the left side of the body, and motor fibers from the left motor strip initiate voluntary movement for the right side of the body.

Transmission of the impulse from the nervous system to the musculoskeletal system is an electrochemical event and requires a neurotransmitter. Basically neurotransmitters are chemicals (e.g., acetylcholine) that transfer the electrical impulse from the nerve across the myoneural junction to stimulate the muscle, causing movement. Several disorders impair movement. For example, Parkinson's disease

alters neurotransmitter production, myasthenia gravis disrupts transfer from the neurotransmitter to the muscle, and multiple sclerosis impairs muscle activity (Huether and McCance, 2012).

Proprioception. **Proprioception** is the awareness of the position of the body and its parts (Huether and McCance, 2012). Proprioceptors, which monitor body position, are located on nerve endings in muscles, tendons, and joints. The nervous system regulates posture, which requires coordination of proprioception and balance. As a person carries out ADLs, proprioceptors monitor muscle activity and body position. For example, the proprioceptors on the soles of the feet contribute to correct posture while standing or walking. In standing, pressure is continuous on the bottom of the feet. The proprioceptors monitor the pressure, communicating this information through the nervous system to the antigravity muscles. The standing person remains upright until deciding to change position. As a person walks, the proprioceptors on the bottom of the feet monitor pressure changes. Thus, when the bottom of the moving foot comes in contact with the walking surface, the individual automatically moves the stationary foot forward.

Balance. A person needs adequate balance to stand, run, lift, or perform ADLs. The nervous system controls balance specifically through the cerebellum and the inner ear. The cerebellum coordinates all voluntary movement, particularly highly skilled movements such as those required in skiing.

Within the inner ear are the semicircular canals, three fluid-filled structures that help maintain balance. Fluid within the canals has certain inertia; when the head is suddenly rotated in one direction, the fluid remains stationary for a moment, but the canal turns with the head. This allows a person to change position suddenly without losing balance.

Principles of Transfer and Positioning Techniques

Using principles of safe patient transfer and positioning during routine activities decreases work effort and places less strain on musculoskeletal structures (Box 39-1). As a nurse you will teach colleagues and patients' families how to transfer or position patients properly. Teaching a patient's family how to transfer the patient from bed to chair increases and reinforces the family's knowledge about proper transfer and position techniques once the patient returns home.

Whether you are moving a patient who is immobile, helping a patient from the bed to the chair, or teaching a patient to carry out

---

BOX 39-1   Principles of Safe Patient Transfer and Positioning

- Mechanical lifts and lift teams are essential when a patient is unable to assist.
- When a patient is able to assist, remember the following principles:
  - The wider the base of support, the greater the stability of the nurse.
  - The lower the center of gravity, the greater the stability of the nurse.
  - The equilibrium of an object is maintained as long as the line of gravity passes through its base of support.
  - Facing the direction of movement prevents abnormal twisting of the spine.
  - Dividing balanced activity between arms and legs reduces the risk of back injury.
  - Leverage, rolling, turning, or pivoting requires less work than lifting.
  - When friction is reduced between the object to be moved and the surface on which it is moved, less force is required to move it.

ADLs efficiently, knowledge of safe patient transfer and positioning is crucial. You also incorporate knowledge of physiological and pathological influences on body alignment and mobility.

Pathological Influences on Body Alignment, Mobility, and Activity. Many pathological conditions affect body alignment and mobility. These conditions include congenital defects; disorders of bones, joints, and muscles; central nervous system damage; and musculoskeletal trauma.

Congenital Defects. Congenital abnormalities affect the efficiency of the musculoskeletal system in regard to alignment, balance, and appearance. Osteogenesis imperfecta is an inherited disorder that affects bone. Bones are porous, short, bowed, and deformed; as a result, children experience curvature of the spine and shortness of stature (Chapter 28). Scoliosis is a structural curvature of the spine associated with vertebral rotation. Muscles, ligaments, and other soft tissues become shortened. Balance and mobility are affected in proportion to the severity of abnormal spinal curvatures (Hockenberry and Wilson, 2015).

Disorders of Bones, Joints, and Muscles. Osteoporosis, a well-known and well-publicized disorder of aging, results in the reduction of bone density or mass. The bone remains biochemically normal but has difficulty maintaining integrity and support. The cause is uncertain, and theories vary from hormonal imbalances to insufficient intake of nutrients (Huether and McCance, 2012).

Osteomalacia is an uncommon metabolic disease characterized by inadequate and delayed mineralization, resulting in compact and spongy bone (Lewis et al., 2013). Mineral calcification and deposition do not occur. Replaced bone consists of soft material rather than rigid bone.

Joint mobility is altered by inflammatory and noninflammatory joint diseases and articular disruption. Inflammatory joint disease (e.g., arthritis) is characterized by inflammation or destruction of the synovial membrane and articular cartilage and systemic signs of inflammation. Noninflammatory diseases have none of these characteristics, and the synovial fluid is normal (Huether and McCance, 2012). Joint degeneration, which can occur with inflammatory and noninflammatory disease, is marked by changes in articular cartilage combined with overgrowth of bone at the articular ends. Degenerative changes commonly affect weight-bearing joints.

Articular disruption involves trauma to the articular capsules and ranges from mild, such as a tear resulting in a sprain, to severe, such as a separation leading to dislocation. Articular disruption usually results from trauma but sometimes is congenital, as with developmental dysplasia of the hip (Hockenberry and Wilson, 2015).

Central Nervous System Damage. Damage to any part of the central nervous system that regulates voluntary movement causes impaired body alignment and immobility (see Chapter 28). For example, a patient with a traumatic head injury experiences damage in the motor strip in the cerebrum. The amount of voluntary motor impairment is directly related to the amount of destruction of the motor strip. Another patient with a spinal cord injury has permanent damage below the level of the injury and has control of trunk muscles but not the lower-extremity muscles. This patient also experiences reflex and spastic movements.

It is important to understand which type of voluntary and involuntary movement is present after damage to the central nervous system. This information impacts the type of interventions selected to maximize your patient's activity level.

Musculoskeletal Trauma. Musculoskeletal trauma often results in bruises, contusions, sprains, and fractures. A fracture is a disruption of bone tissue continuity. Fractures most commonly result from

direct external trauma. They also occur because of some deformity of the bone (e.g., with pathological fractures of osteoporosis) (see Chapter 28).

NURSING KNOWLEDGE BASE

Application of nursing knowledge about activity and exercise allows you to think critically about the holistic needs of patients. Nursing knowledge as it pertains to activity and exercise helps you assess, identify, and intervene when patients have decreased activity tolerance or physical limitation that affects their mobility and/or ability to exercise (Chapter 28).

Deconditioning

Recently concerted effort has been made in hospitals to increase inpatients' activity and mobility levels as soon as possible to prevent deconditioning and other complications of immobilization. The American Association of Critical Care Nurses (2015) now recommends an early progressive mobility protocol for critical care patients (refer to agency policy for protocols used by hospital). However, when patients are transferred out to general nursing units, early mobility protocols should continue. This is often a challenge because staff nurses on general units often have difficulty routinely ambulating patients due to overall patient care demands, access to equipment, or unfamiliarity with transfer skills. Some hospitals have designated special mobility teams or mobility assistants to engage patients in early ambulation and activity.

In a study involving 78 adults who were admitted to a respiratory unit for diagnostic or preoperative evaluation and who were able to walk and were not confined to bed rest, functional capacity decreased over a 5-day period in six assessment areas: upper limb muscle strength, respiratory muscle strength, lung function, chest wall expansion, submaximal exercise tolerance, and spinal and trunk mobility. Longer periods of hospitalization inevitably led to more severe deconditioning (Suesada et al., 2007). These findings support the promotion of early mobility in hospitalized patients.

Safe Patient Handling

Nurses are exposed to the hazards related to lifting and transferring patients in many settings such as inpatient nursing units, long-term care facilities, and the operating room (Griffis, 2012). Manually lifting and transferring patients contributes to the high incidence of work-related musculoskeletal problems and back injuries in nurses and other health care staff. Current evidence shows that many nurses frequently transfer to different positions and leave the profession because of work-related injuries (Griffis, 2012). Implementing evidence-based interventions and programs (e.g., lift teams) reduces the number of work-related injuries, which improves the health of the nurse and reduces indirect costs to the health care agency (e.g., workers' compensation and replacing injured workers).

Today many states have laws that mandate safe patient handling in health care agencies. Health care agencies are implementing comprehensive safe patient–handling programs in all parts of the United States. Comprehensive safe patient–handling programs include the following elements (VISN8, 2015):

- An ergonomics assessment protocol for health care environments
- Patient assessment criteria and algorithms for patient handling and movement
- Special equipment kept in convenient locations to help transfer patients
- Back-injury resource nurses

- An "after-action review" that allows the health care team to apply knowledge about moving patients safely in different settings
- A no-lift policy

Transfer Techniques. Nurses often provide care for immobilized patients whose position must be changed, who must be moved up in bed, or who must be transferred from a bed to a chair or from a bed to a stretcher. As noted earlier, body mechanics alone do not protect nurses from injury to their musculoskeletal systems when moving, lifting, or transferring patients. Although nurses use many transfer techniques, knowledge of ergonomics and safe patient handling is crucial in maintaining caregiver and patient safety.

Assess every situation that involves patient handling and movement to minimize risk of injury. After completing the assessment, you will use an algorithm (Figures 39-4 to 39-6) to guide decisions about safe patient handling (VISN8, 2015). Skill 39-1 on pp. 811-818 describes the steps commonly used in transferring patients safely and effectively. Use a patient's strength when lifting, transferring, or moving when possible. Involving the patient has the added bonus of increasing participation in self-care, thus promoting a sense of accomplishment. In addition to handling patients safely, nurses need to assume an active role in their workplaces to ensure that a culture of safety exists and that appropriate patient-handling equipment is readily available (Hunter et al., 2010).

Factors Influencing Activity and Exercise

Factors influencing activity and exercise include developmental changes, behavioral aspects, environmental issues, family and social support, and cultural and ethnic origin. Consider these areas of knowledge and incorporate into the plan of care whether a patient is seeking health promotion, acute care, or restorative and continuing care.

Developmental Changes. Throughout the life span the appearance and functioning of the body undergo change. The greatest change and effect on the maturational process occur in childhood and old age.

Infants Through School-Age Children. A newborn infant's spine is flexed and lacks the anteroposterior curves of the adult. The first spinal curve occurs when the infant extends the neck from the prone position. As growth and stability increase, the thoracic spine straightens; and the lumbar spinal curve appears, which allows rolling over, sitting, crawling, and standing.

A toddler's posture is awkward because of the slight swayback and protruding abdomen. As the child walks, the legs and feet are usually far apart, and the feet are slightly everted (turned outward). Toward the end of toddlerhood, posture appears less awkward, curves in the cervical and lumbar vertebrae are accentuated, and foot eversion disappears.

By the third year the body is slimmer, taller, and better balanced. Abdominal protrusion decreases, the feet are not as far apart, and the arms and legs have increased in length. The child appears more coordinated. From the third year through the beginning of adolescence, the musculoskeletal system continues to grow and develop (see Chapter 12).

Adolescence. Adolescent growth is often sporadic and uneven. As a result, the adolescent appears awkward and uncoordinated. Adolescent girls usually grow and develop earlier than boys. Hips widen; and fat deposits in the upper arms, thighs, and buttocks. The adolescent boy's changes in shape are usually a result of long-bone growth and increased muscle mass (see Chapter 12).

Young to Middle Adults. An adult with correct posture and body alignment feels good, looks good, and generally appears self-confident.

- **<200 lb:** Use a friction-reducing device and two to three caregivers.
- **>200 lb:** Use a friction-reducing device and at least three caregivers.

Use full body sling lift and two or more caregivers.

- This is not a one-person task: DO NOT PULL FROM HEAD OF BED.
- When pulling a patient up in bed, the bed should be flat or in a Trendelenburg position (when tolerated) to aid in gravity, with the side rail down.
- For patients with stage III or IV pressure ulcers, care should be taken to avoid shearing force.
- The height of the bed should be appropriate for staff safety (at the elbows).
- If the patient can assist when repositioning "up in bed," ask the patient to flex the knees and push on the count of three.
- During any patient-handling task, if the caregiver is required to lift more than 35 lb of a patient's weight, then the patient should be considered to be fully dependent and assistive devices should be used.

FIGURE 39-4 Algorithm used to reposition patient in bed. (Modified from VISN8 Patient Safety Center (VISN8): *Algorithms for Safe Patient Handling and Movement*, 2015, http://www.visn8.va.gov/patientsafetycenter/safepthandling/. Accessed February 14, 2015.)

The healthy adult also has the necessary musculoskeletal development and coordination to carry out ADLs and physical exercise (see Chapter 13). Normal changes in posture and body alignment in adulthood occur mainly in pregnant women. These changes result from the adaptive response of the body to weight gain and the growing fetus. The center of gravity shifts toward the anterior. The pregnant woman leans back and is slightly swaybacked; as a result, pregnant women often complain of back pain (see Chapter 13).

Older Adults. A progressive loss of total bone mass occurs with older adults. Some of the possible causes of this loss include physical inactivity, hormonal changes, and increased osteoclastic activity (i.e., activity by cells responsible for bone tissue absorption). The effect of bone loss is weaker bones, causing vertebrae to be softer and long shaft bones to be less resistant to bending.

In addition, older adults may walk more slowly and appear less coordinated. They often take smaller steps and keep their feet closer together, which decreases the base of support and thus alters body balance. It is important to encourage or plan physical activities for older adults. These exercises are important for socialization, independence, and maintaining core body strength. Physical exercise can improve endurance, coordination, and muscle stability and reduce the risk for falls and injuries (see Chapter 14).

Behavioral Aspects. Physical activity not only benefits a patient's overall health but also is reported to reduce stress (Childs and deWit, 2014). Patients are more likely to incorporate an exercise program into their daily lives if supported by family, friends, nurses, health care providers, and other members of the health care team. As a nurse, you must consider a patient's knowledge of exercise and activity, their values and beliefs about exercise in relation to health, barriers to a program of exercise and physical activity (e.g., resources or access to a safe area to exercise), and current exercise habits. Patients are more open to developing an exercise program when they are at a stage of readiness to change their behavior. Information about the benefits of regular exercise is often helpful to a patient who is not at the stage of readiness to act. Patients' decisions to change behavior and include a daily exercise routine in their lives sometimes occur gradually with repeated information individualized to patients' needs and lifestyle (Box 39-2). Once a patient is at the stage of readiness, collaborate with him or her to develop an exercise program that fits his or her needs and provide continued follow-up support and assistance until the exercise program becomes a daily routine.

Environmental Issues

Work Site. A common barrier for many patients is the lack of time needed to engage in a daily exercise program. Some work sites help their employees overcome the obstacle of time constraints by offering opportunities, reminders, and rewards for those committed to physical fitness (McGann et al., 2013). Reminders such as signs that encourage employees to use the stairs instead of elevators are useful. Rewards such as free parking or discounted parking fees are also effective for employees who park in distant lots and walk.

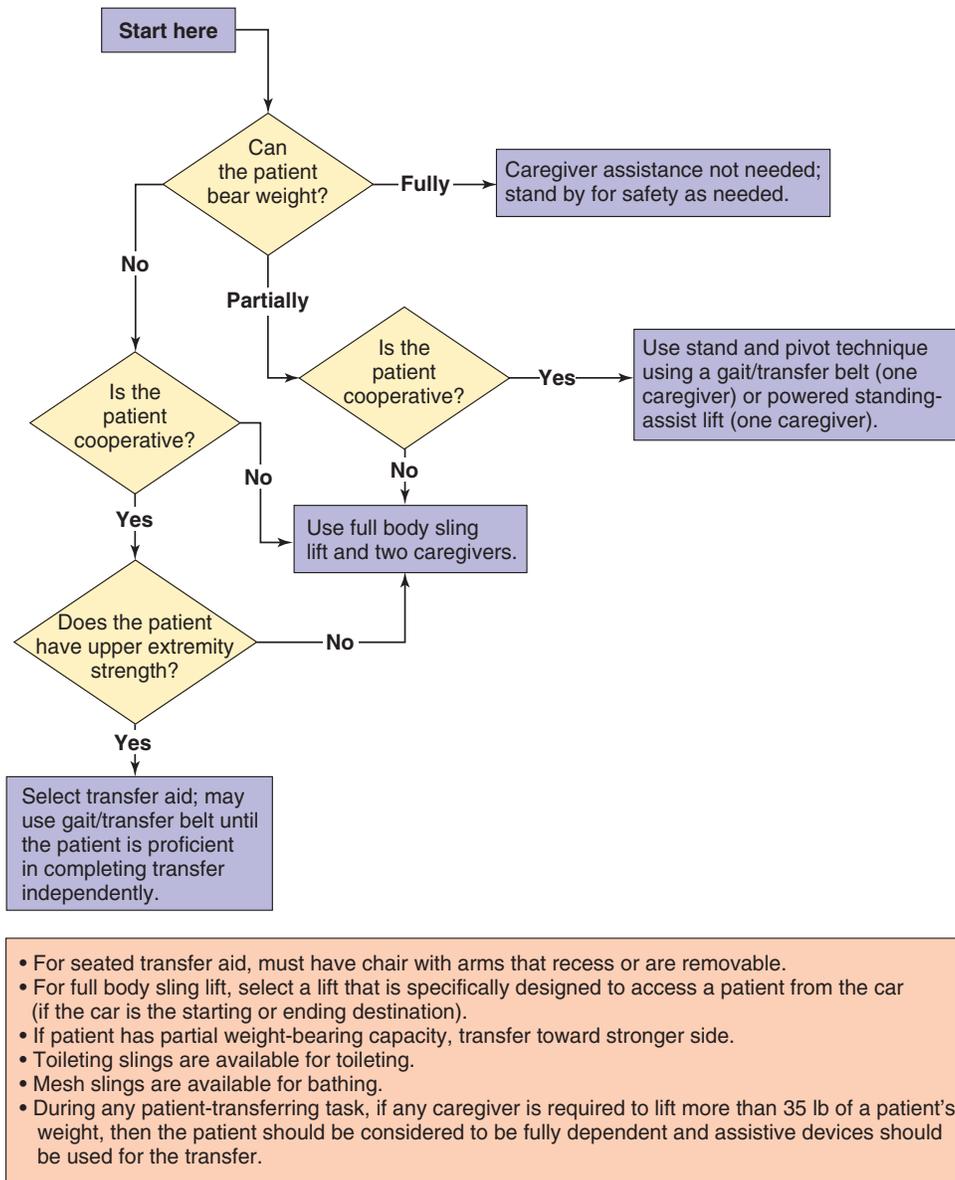
Schools. Children today are less active, resulting in an increase in childhood obesity (Bammann et al., 2014; Grossklaus and Marvicsin, 2014). Schools are excellent facilitators of physical fitness and exercise. Strategies for physical activity incorporated early into a child's daily routine often provide a foundation for lifetime commitment to exercise and physical fitness.


FIGURE 39-5 Algorithm used to transfer patient to and from bed to chair, chair to toilet, chair to chair, or car to chair. (Modified from VISN8 Patient Safety Center (VISN8): *Algorithms for safe patient handling and movement*, 2015, http://www.visn8.va.gov/patientsafetycenter/safepthandling/. Accessed February 14, 2015.)

Community. Community support of physical fitness is instrumental in promoting the health of its members (e.g., providing walking trails and track facilities in parks and physical fitness classes). Success in implementing physical fitness programs depends on a collaborative effort from public health agencies, parks and recreational associations, state and local government agencies, health care agencies, and the members of the community (Combs et al., 2013; Wallace et al., 2014).

Cultural and Ethnic Influences. Exercise and physical fitness are beneficial to all people. When developing a physical fitness program for culturally diverse populations, consider what motivates them for exercise and physical activity and what they see as appropriate, enjoyable, and beneficial. It is also important to know which specific disease entities are associated with different cultural and ethnic origins (Box 39-3).

Family and Social Support. Social support is one motivational tool to encourage and promote exercise and physical fitness. For example, a patient engages a friend or significant other to participate in a "buddy system" (i.e., they walk together each day at a specified time). This companionship provides for socialization, increases the enjoyment, and develops a lifelong commitment to physical fitness. Parents support their children in sports and physical activity by providing encouragement, praise, and transportation (Davison and Jago, 2010; Dunton, 2010). Other parents support physical activity by including their children in family outings such as bicycling or a basketball game in the neighborhood schoolyard.

CRITICAL THINKING

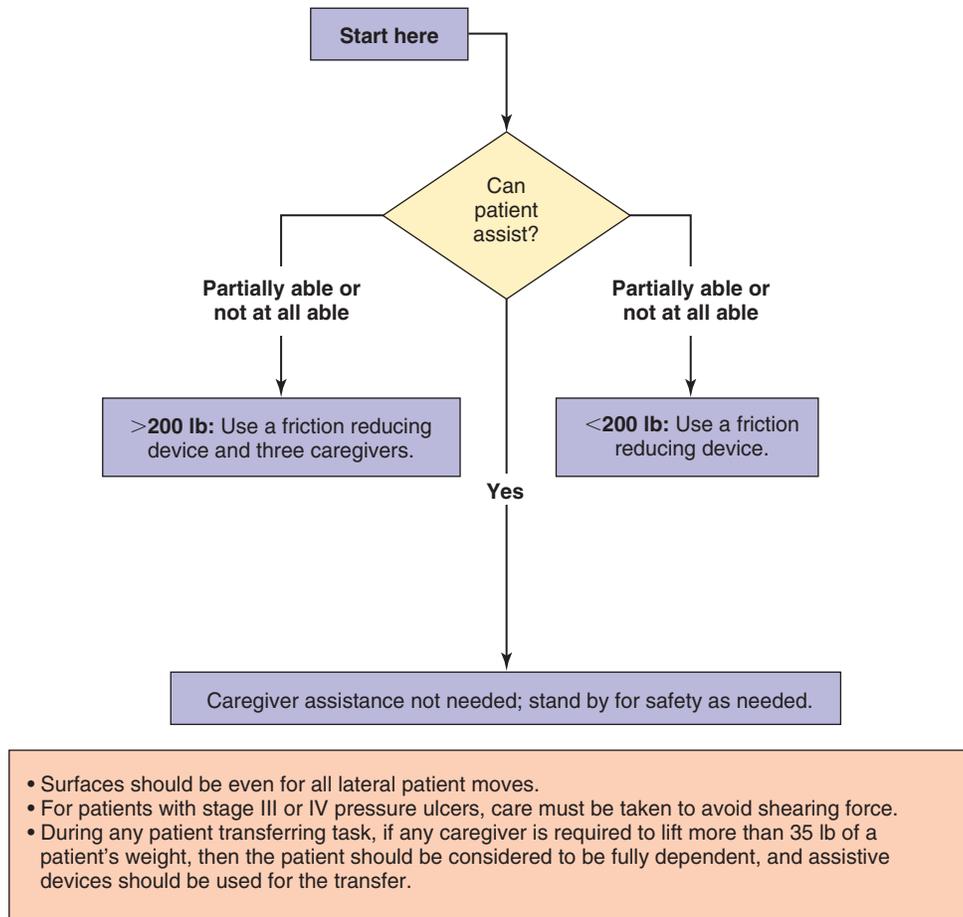
Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes,


FIGURE 39-6 Algorithm used to complete lateral transfer to and from bed to stretcher, trolley. (Modified from VISN8 Patient Safety Center (VISN8): *Algorithms for safe patient handling and movement*, 2015, http://www.visn8.va.gov/patientsafetycenter/safepthandling/. Accessed February 14, 2015.)

BOX 39-2   **General Guidelines for Initiating an Exercise Program**

Five steps to beginning an exercise program:

Step 1: Assess Fitness Level
- Seek approval from a health care provider to begin. Are there any limitations to consider before determining the exercises in the fitness program?
- Record baseline fitness scores such as pulse rate before and after walking 1 mile, how long it takes to walk 1 mile, number of pushups that can be done at a time, how far you are able to reach forward while seated on floor with legs outstretched in front, waist circumference, and body mass index.

Step 2: Design the Fitness Program
- Consider fitness goals. Make goals attainable.
- Develop a balanced routine of aerobic activity and strength training.
- Plan a logical progression of activities that goes at your own pace and put it on paper to keep track.
- Build a program that includes different activities into a daily routine.
- Allow time for recovery.

Step 3: Assemble Equipment
- Choose athletic shoes designed for the chosen exercise.
- If choosing to exercise at home, try equipment at a fitness center before purchasing; buy used fitness equipment.
- Try homemade equipment (e.g., half-gallon milk jugs filled with sand for weights).

Step 4: Get Started
- Start slowly and build up a routine gradually.
- Divide exercise time throughout day if time or fatigue is a barrier. Ten minutes of exercise 3 times a day instead of a single 30-minute workout may be better for some patients' schedules and medical conditions.
- Take rest periods as condition warrants.

Step 5: Monitor Progress
- Retake fitness assessment at 6 weeks and then every 3 to 6 months.
- If losing motivation: set new goals, exercise with a friend, or incorporate new activities.

Modified from Mayo Clinic Healthy Living Fitness Program: *5 steps to getting started,* 2014, http://www.mayoclinic.com/healthy-living/fitness/in-depth/fitness/art-20048269?pg=1. Accessed August 12, 2014.

Incidence and Challenges of Type 2 Diabetes Among Ethnic Groups in the United States

Recent data in the United States shows the prevalence of diabetes among adults ages 65 years and older to average around 28%. Obesity and a sedentary lifestyle are consistent contributing factors across all cultural groups diagnosed with type 2 diabetes. Physical activity plays an important role in preventing and treating it. However, populations identified as prone to develop type 2 diabetes are also those who are disadvantaged and lack access to or have difficulty navigating the health care system (Clarke et al., 2014; Jain and Paranjape, 2013).

Implications for Patient-Centered Care
- Physical inactivity is a modifiable risk factor for the development of type 2 diabetes. Prevention and treatment programs need to focus on exercise and be tailored to the activity tolerance and interests of each patient.
- Work with patient's community to support promotion of physical activity through formal programs in schools, churches, and government agencies within disadvantaged communities.
- Incorporate motivational factors into the exercise program such as providing a healthy snack or meal for the participants and furnishing each patient with a log to monitor weight loss and blood glucose levels (Clarke et al., 2014).
- Exercise and diabetes-prevention programs need to remove potential barriers such as transportation and cost to facilitate commitment to the program.

and intellectual and professional standards. Clinical judgments require you to anticipate information, analyze the data, and make decisions regarding patient care.

To understand activity tolerance, physical fitness, and the effects on patients, you integrate knowledge from nursing and other disciplines, previous experiences, and information gathered from patients. As you plan patient care, consider the relationship among a variety of concepts to provide the best outcome for your patients. For example, you lay the foundation for planning and decision making by understanding the relationship between the musculoskeletal system and health alterations that may create problems with activity and exercise, positioning, and transferring. Professional standards such as those developed by the American College of Sports Medicine (ACSM) (2011), the ACSM and American Diabetes Association (ADA) (2010), and the Association for Critical Care Nurses (AACN) (2015) provide valuable guidelines for exercise and physical fitness. In addition, the American Nurses Association (ANA) (2010) issued a statement to the committee on Health, Education, Labor and Pensions Subcommittee on Employment and Workplace Safety of the United States Senate. The statement applauded and supports the enactment of the Nurse and Health Care Worker Act of 2009 (H.R. 2381/S.1788).

Your experiences and critical thinking attitude affect the problem-solving approach with patients and are evaluated with each new patient. Remember that some patients have the capacity for recovery in spite of the loss of some physical function. Restoration of function begins early in the care of patients whose ability to perform self-care is disrupted. Encouragement, support, commitment, and perseverance are important attitudes in critical thinking for these patients.

Perseverance is necessary when caring for patients who depend on you for assistance with ambulation or exercise. In addition, responsibility for positioning often becomes repetitive, and some nurses lose sight of its importance (see Chapter 28). Perseverance is especially

important in delegating these activities to other personnel and being sure they are completed. Making certain that the task is performed correctly is also an essential nursing function. Problems with activity and mobility are often prolonged; creativity is necessary when designing interventions for improving activity tolerance and mobility skills.

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care.

◆ Assessment

During the assessment process thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care. Complete the assessment of body alignment and posture with the patient standing, sitting, or lying down. Use assessment to determine normal physiological changes in growth and development; deviations related to poor posture, trauma, muscle damage, or nerve dysfunction; and any learning needs of patients. In addition, provide opportunities for patients to observe their posture and obtain important information about other factors that contribute to poor alignment such as inactivity, fatigue, malnutrition, and psychological problems. Ask questions related to the patient's exercise and activity tolerance to gather important information (Box 39-4). During assessment (Figure 39-7) consider all of the elements that help you make appropriate nursing diagnoses. The first step in assessing body alignment is to put the patient at ease so he or she does not assume unnatural or rigid positions. When assessing body alignment of a patient who is immobilized or unconscious, remove pillows from the bed if not contraindicated and place the patient in the supine position.

Through the Patient's Eyes. In patient-centered care, assessing a patient's expectations, values, and beliefs concerning activity and exercise and determining individual perceptions of what is normal or acceptable are of utmost importance in developing a plan of care. Perceived self-efficacy is a judgment of capability and applies to a person's willingness to engage in exercise. The outcomes people anticipate, such as from an exercise program, depend on their judgments of how well they will be able to perform in given situations (Bandura, 2006). Ask the patient to what extent he or she enjoys exercising and his or her belief in the ability to exercise. This is a factor positively associated with adult physical activity (*Healthy People 2020,* 2015). Another example of assessing a patient's perceptions of what is acceptable activity is focusing on a patient's pain. One of the factors affecting physical activity is freedom from pain. When patients experience pain or fatigue following exercise, they often lack commitment to desired interventions. When patients are content with their present physical activity and fitness, they do not perceive a need for improvement.

Standing. Assessment of the standing patient includes the following: the head is erect, and midline body parts are symmetrical; the spine is straight with normal curvatures (cervical concave, thoracic convex, lumbar concave); the abdomen is comfortably tucked; the knees are in a straight line between the hips and ankles and slightly flexed; the feet are flat on the floor and pointed directly forward and slightly apart to maintain a wide base of support; and the arms hang comfortably at the sides (Figure 39-8). The patient's center of gravity is in the midline, and the line of gravity is from the middle of the forehead to a midpoint between the feet. Laterally the line of gravity

BOX 39-4 Nursing Assessment Questions

Nature of the Problem
- Tell me about the types of problems you are having with activities and exercise?
- How much do you exercise each day?
- Which type of exercise do you prefer?
- Describe for me your typical day. What type of activities do you do?
- How long do you exercise at any given time?

Signs and Symptoms
- Do you have muscle or joint pain during or after exercise?
- Do you have shortness of breath during any activity?
- Do you ever feel chest discomfort or pain during exercise or activity?

Onset and Duration
- Which activities cause you to become short of breath?
- How long does it take to resume normal breathing after exercise or an activity?

Severity
- How far do you walk before the pain in your legs begins?
- On a scale of 0 to 10 (10 being the worst discomfort), rate your leg pain.
- Do you describe your shortness of breath as minimal, moderate, or severe after activities and/or exercise?

Barriers to Exercise and Activity
- Do you have any chronic illnesses that affect your ability to carry out daily activities such as grocery shopping, washing clothes, or daily walking? Do you have any physical limitations that prevent you from exercising on a daily basis?
- Do you have access to a community walking path and exercise equipment?
- What prevents you from exercising 30 minutes each day?

Patient Values
- Tell me what you believe about the importance of regular exercise.
- How confident are you in being able to perform the exercises your doctor has recommended?

Effect on Patient
- How has the lack of an exercise routine affected your weight?
- Do you feel more tired since you have not been able to exercise routinely?
- Have you noticed any increase in shortness of breath when performing activities that require little exertion?

Knowledge
- Normal activity needs for the patient's developmental stage
- Normal activity patterns
- Effects of therapies on the patient's activity and exercise patterns
- Physiological and emotional effects of exercise
- The influence of patient's culture on preferences for activity

Experience
- Caring for patients who require activity and exercise reconditioning
- Personal experience in beginning an exercise program

ASSESSMENT
- Assess the patient's body alignment, posture, and mobility
- Identify the effect of activity and exercise on the patient's overall level of health
- Assess the patient's routine exercise pattern
- Observe the patient's body systems' response to activity and exercise

Standards
- Apply intellectual standards such as accuracy, relevancy, and specificity when obtaining data related to the patient's activity and exercise status
- Apply professional standards such as those from the ACSM, ADA, and ANA

Attitudes
- Use creativity in observing the patient's activity and exercise patterns
- Carry out your responsibility for collecting appropriate assessment data to assess the patient's activity and exercise pattern

FIGURE 39-7 Critical thinking model for activity and exercise assessment. *ACSM,* American College of Sports Medicine; *ADA,* American Diabetes Association; *ANA,* American Nurses Association.

circulation. Proper sitting alignment reduces the risk of musculoskeletal system damage.

Recumbent Position. When assessing a patient in the recumbent position, you place him or her in the lateral position, removing all positioning supports and all but one pillow. The vertebrae are in straight alignment without observable curves. This assessment provides baseline data concerning the patient's body alignment.

Conditions that create a risk of damage to the musculoskeletal system when lying down include impaired mobility (e.g., traction), decreased sensation (e.g., hemiparesis from a stroke), impaired circulation (e.g., diabetes), and lack of voluntary muscle control (e.g., spinal cord injuries) (see Chapter 28).

When a patient is unable to change position voluntarily, assess the position of body parts while he or she is lying down. Make sure that the vertebrae are in straight alignment without any observable curves. Also check that the extremities are in alignment and not crossed over one another. The head and neck need to be aligned without excessive flexion or extension.

runs vertically from the middle of the skull to the posterior third of the foot (Wilson and Giddens, 2013).

Sitting. Assessment of a patient in the sitting position includes the following: the head is erect, and the neck and vertebral column are in straight alignment; the body weight is distributed on the buttocks and thighs; the thighs are parallel and in a horizontal plane (be careful to avoid pressure on the popliteal nerve and blood supply); the feet are supported on the floor; and the forearms are supported on the armrest, in the lap, or on a table in front of the chair.

Assessment of alignment in the sitting position is particularly important for the patient with muscle weakness, muscle paralysis, or nerve damage. A patient with these alterations has diminished sensation in affected areas and is unable to perceive pressure or decreased

FIGURE 39-8 Correct body alignment when standing.

Mobility. Assessment of mobility helps to determine a patient's coordination and balance while walking, the ability to carry out ADLs, and the ability to participate in an exercise program. The assessment of mobility has three components: range of motion (ROM), gait, and exercise (see Chapter 28).

Gait. Gait is the manner or style of walking, including rhythm, cadence, and speed. Assessing gait allows you to draw conclusions about balance, posture, and the ability to walk without assistance. Assessment findings in patients with normal gait include a regular, smooth rhythm; symmetry in the length of leg swing; smooth swaying related to the gait phase; and a smooth, symmetrical arm swing (Wilson and Giddens, 2013).

Exercise and Activity. Regular exercise conditions the body, improves health, maintains fitness, and provides therapy for correcting a deformity or restoring the overall body to a maximal state of health. Daily activity is a barometer for a patient's functional status. When a person engages in physical activity, physiological changes occur in body systems (Box 39-5). Determine the types of activities a patient engages in normally at home and how much the patient exercises regularly.

Activity Tolerance. Activity tolerance is the response a person has to the type and amount of exercise or activity that he or she performs. Before ambulation, sitting in a chair, or other planned activities, obtain a patient's vital signs, observe skin color, and ask about his or her level of comfort and current energy level or sense of fatigue. Assessment of activity tolerance is necessary when planning physical activity for health promotion and for health maintenance for patients with acute or chronic illness. This assessment provides baseline data about the patient's activity patterns and helps determine which factors (physical, psychological, or motivational) affect activity tolerance (Box 39-6).

◆ Nursing Diagnosis

Assessment of the patient's activity tolerance, physical fitness, body alignment, and joint mobility provides clusters of data or defining characteristics to support a nursing diagnosis. You need to be accurate when identifying diagnoses. For example, you consider nursing

---

BOX 39-5 Effects of Exercise

Cardiovascular System
- Increased cardiac output
- Improved myocardial contraction, thereby strengthening cardiac muscle
- Decreased resting heart rate
- Improved venous return

Pulmonary System
- Increased respiratory rate and depth followed by a quicker return to resting state
- Improved alveolar ventilation
- Decreased work of breathing
- Improved diaphragmatic excursion

Metabolic System
- Increased basal metabolic rate
- Increased use of glucose and fatty acids
- Increased triglyceride breakdown
- Increased gastric motility
- Increased production of body heat

Musculoskeletal System
- Improved muscle tone
- Increased joint mobility
- Improved muscle tolerance to physical exercise
- Possible increase in muscle mass
- Reduced bone loss

Activity Tolerance
- Improved tolerance
- Decreased fatigue

Psychosocial Factors
- Improved tolerance to stress
- Reports of "feeling better"
- Reports of decrease in illness (e.g., colds, influenza)

Data from Huether SE, McCance KL: *Understanding pathophysiology,* ed 5, St Louis, 2012, Mosby.

BOX 39-6 Factors Influencing Activity Tolerance

Physiological Factors
- Skeletal abnormalities
- Muscular impairments
- Endocrine or metabolic illnesses (e.g., diabetes mellitus, thyroid disease)
- Hypoxemia
- Decreased cardiac function
- Decreased endurance
- Impaired physical stability
- Pain
- Sleep pattern disturbance
- Prior exercise patterns
- Infectious processes and fever

Emotional Factors
- Anxiety
- Depression
- Chemical addictions
- Motivation

Developmental Factors
- Age
- Sex

Pregnancy
- Physical growth and development of muscle and skeletal support

Modified from Lewis SL et al: *Medical-surgical nursing assessment and management of clinical problems,* ed 9, St Louis, 2014, Mosby.

---

diagnoses of *Activity Intolerance* or *Fatigue* in a patient who reports being tired and weak. Further review of assessed defining characteristics (e.g., abnormal heart rate and verbal report of weakness) leads to the definitive diagnosis (*Activity Intolerance*).

When patients have problems with activity and exercise, nursing diagnoses often focus on the ability to move. The diagnostic label and related factors direct nursing interventions. This requires the correct selection of the related factors. For example, *Activity Intolerance related to excess weight gain* requires very different interventions than if the related factor is prolonged bed rest. Box 39-7 provides an example of how the diagnostic process leads to accurate diagnosis selection. The

BOX 39-7   Nursing Diagnostic Process

Impaired Physical Mobility

Assessment Activities	Defining Characteristics
Observe patient's gait.	Shuffled gait Uncoordinated gait Patient report of slower walking speed
Observe patient performing tasks such as feeding, dressing, or recreational activities.	Uncoordinated movements Limited fine-motor coordination
Measure range of joint motion.	Reduced joint motion in lower and/or upper extremities Stiffness in joints
Measure patient's strength.	Has difficulty rising to sitting position or exiting bed

following are examples of nursing diagnoses related to activity and exercise:

- *Activity Intolerance*
- *Ineffective Coping*
- *Impaired Gas Exchange*
- *Risk for Injury*
- *Impaired Bed Mobility*
- *Impaired Physical Mobility*
- *Acute or Chronic Pain*

◆ Planning

During planning synthesize information from multiple resources (Figure 39-9). Critical thinking ensures that the patient's plan of care integrates all patient information. Professional standards are especially important to consider when developing a plan of care. These standards often establish scientifically proven guidelines for selecting effective nursing interventions.

A concept map is a tool to assist in the planning of care. It shows the relationship between multiple nursing diagnoses and planned interventions. Figure 39-10 shows the relationship between a patient's medical diagnosis of heart failure and the identified nursing diagnoses and related nursing interventions.

Goals and Outcomes. Once you identify the nursing diagnoses, you and the patient set goals and expected outcomes to direct interventions. The plan includes consideration of any risks for injury to the patient and preexisting health concerns. It is especially important to have knowledge of the patient's home environment when planning therapies to maintain or improve activity, body alignment, and mobility. Include the patient's family caregiver in the care plan unless the patient prefers no family involvement. Family caregivers play critical roles in the home environment, motivating and coaching patients to stay active. The general goal related to exercise and activity is to improve or maintain the patient's motor function and independence. The following are examples of outcomes for patients with deficits in activity and exercise (Ackley and Ladwig, 2014):

- Participates in prescribed physical activity while maintaining appropriate heart rate, blood pressure, and breathing rate
- Verbalizes an understanding of the need to gradually increase activity on the basis of tolerance and symptoms
- Expresses understanding of balancing rest and activity

Knowledge

- Role of physical therapists and exercise trainers in improving the patient's activity and exercise pattern
- Effect of medication on the patient's activity tolerance
- Extent of any physical limitations experienced by the patient

Experience

- Previous patient care experiences with therapies designed to improve exercise and activity tolerance
- Personal experience with exercise regimens

PLANNING

- Consult/collaborate with members of the health care team to increase activity
- Involve the patient and family in designing an activity and exercise plan
- Consider the patient's ability to increase activity level

Standards

- Individualize therapies to the patient's activity tolerance
- Apply safe patient handling standards (ANA, 2010)
- Apply activity and exercise goals published by the American College of Sports Medicine

Attitudes

- Be creative when designing interventions to improve the patient's activity tolerance
- Carry out your responsibility to adapt interventions to increase the patient's activity tolerance in multiple health care settings

FIGURE 39-9 Critical thinking model for activity and exercise planning. *ANA,* American Nurses Association.

Setting Priorities. Care planning is patient centered, taking into consideration the patient's most immediate needs. For example, is a patient comfortable enough to participate in exercise, or does the acute occurrence of symptoms require you to delay an exercise session? You determine the immediacy of any problem by its effect on the patient's mental and physical health. Because of the many skills associated with the care of patients who have the diagnoses of activity intolerance and/or impaired mobility, such as turning, transferring, and positioning, it is easy to overlook the complications associated with these health alterations. Therefore be vigilant in monitoring the patient and supervising assistive personnel in carrying out activities to prevent complications and potential injury.

Teamwork and Collaboration. Planning involves understanding a patient's need to maintain function and independence. For example, it is important to collaborate with physicians and physical and occupational therapists. Sometimes long-term rehabilitation is necessary. Discharge planning begins when a patient enters the health care system and involves identifying his or expectations regarding physical activity and what is planned by the health care team. In addition, always individualize a plan of care directed at meeting the actual or potential needs of the patient (see the Nursing Care Plan).

◆ Implementation

Health Promotion. A sedentary lifestyle contributes to the development of health-related problems. You promote health by

CONCEPT MAP

Nursing diagnosis: Fatigue related to poor physical condition
- Decreased energy level
- Unable to complete ADLs
- Limited ability to participate in family activities

Interventions
- Schedule rest periods between nursing activities
- Reduce the number of nighttime interruptions

Nursing diagnosis: Impaired gas exchange related to decreased cardiac output
- Dyspnea on exertion
- Respiratory rate >28 beats/min
- SpO_2: 82% to 85%
- Diaphoresis

Interventions
- Instruct patient about home O_2
- Administer O_2 at 2 L/min via nasal cannula

Primary health problem: Heart failure and exercise intolerance
Priority assessments: Exercise tolerance, functional health status, mental status

Nursing diagnosis: Decreased cardiac output related to decreased myocardial contractility
- Fatigue on exertion
- Dyspnea on exertion
- Increased heart rate >10 beats/min with any exercise
- Decreased BP <100 mm Hg systolic with any exercise

Interventions
- Provide low-calorie, low-sodium, and high-protein diet
- Instruct patient to take medications as ordered
- Teach patient how to restrict fluids

Nursing diagnosis: Activity intolerance related to physical deconditioning
- Gained 50 lbs over past year
- Easily fatigued with ADLs
- Stress with demands of family

Interventions
- Perform 2-3 mile brisk walk and isometric exercises 3-4 times/week
- Record activity in exercise log daily including response

——— Link between medical diagnosis and nursing diagnosis   - - - - - Link between nursing diagnoses

FIGURE 39-10 Concept map for Mrs. Smith. *ADLs,* Activities of daily living; *BP,* blood pressure.

◎ NURSING CARE PLAN

Activity Intolerance

ASSESSMENT

Mrs. Smith is a 45-year-old housewife. She is in a cardiovascular rehabilitation program prescribed by her health care provider and conducted by Erich, a registered nurse. Mrs. Smith has a history of cardiovascular disease with mild heart failure. She expresses feelings of stress caused by excessive demands on her time. Erich's assessment includes a discussion of Mrs. Smith's current health problem and a pertinent physical examination.

Assessment Activities

Ask Mrs. Smith what prompted her health care provider to recommend a cardiovascular rehabilitation program.

Ask Mrs. Smith about her exercise and eating habits.

Findings/Defining Characteristics*

She responds, "I **gained 50 lbs** over the past year. I become easily **fatigued** and lack the energy to keep up with even simple household chores. I don't want to leave the house anymore. I don't have extra money to join one of those fancy gyms."

She responds, "I want to exercise, but with the demands of child care and taking care of my aging parents, I just don't feel like it. I feel pulled in every direction; that increases my **stress**, and then I want to eat, eat, and eat!"

◎ **NURSING CARE PLAN**

Activity Intolerance—cont'd

Assessment Activities	*Findings/Defining Characteristics**
Perform baseline assessment.	Height: 5 feet 3 inches
	Weight: **225 lbs** (102 kg)
	Blood pressure: **152/90 mm Hg** (at rest)
	Pulse: 96 beats/min (at rest)
	Breathing rate: 20 breaths/min (at rest)
	Blood pressure: **164/96 mm Hg** (after climbing 10 steps)
	Pulse: **120 beats/min** (after climbing 10 steps)
	Breathing rate: 36 breaths/min (after climbing 10 steps)

*****Defining characteristics** are shown in bold type.

NURSING DIAGNOSIS: Activity intolerance related to inactivity and lack of cardiovascular fitness

PLANNING

Goals	*Expected Outcomes (NOC)*[†]
	Activity Tolerance
Mrs. Smith's activity tolerance will improve above baseline.	Mrs. Smith performs 20-minute exercise two times a week over the next 2 weeks.
	Mrs. Smith's level of fatigue associated with exercise remains the same or decreases.
	Cardiac Pump Effectiveness
Mrs. Smith's cardiopulmonary response to exercise will improve.	Mrs. Smith's resting diastolic blood pressure remains below 80 mm Hg. Her systolic blood pressure is below 120 mm Hg. Her resting heart rate ranges between 75 and 85 beats/min. Her breathing rate is 16 breaths/min (at rest).

[†]Outcome classification labels from Moorhead S et al, editors: *Nursing outcomes classification (NOC),* ed 5, St Louis, 2013, Mosby.

INTERVENTIONS (NIC)[‡]	**RATIONALE**
Exercise Promotion	
Instruct Mrs. Smith about the physiological benefits of a regular exercise program. Match instruction with her beliefs about the value of exercise.	Physical activity and exercise protect against the further development of cardiovascular disease (CVD) and decrease other risk factors associated with CVD such as obesity, hypertension, and hyperlipidemia (Campos-Outcalt, 2014; Donges et al., 2010).
Develop a progressive plan of exercise with Mrs. Smith such as 2 to 3 miles or 20 minutes of brisk walking and quadriceps, bicep, and gluteal muscle isometric exercises 3 to 4 times per week.	Cross-training (combination of exercise activities) provides variety to combat boredom and increases potential for total-body conditioning (Edelman et al., 2013).
Instruct Mrs. Smith to use an exercise log and record the day, time, duration, and responses (pulse, feelings, shortness of breath, daily weight).	Keeping a log may increase adherence to exercise prescription. Monitoring cardiopulmonary response can indicate potential symptoms of intolerance to activity that may cause harm (Urden L et al., 2014).
Schedule routine visits with Mrs. Smith for follow-up and review of exercise log, progress, and barriers.	Patients are more likely to increase physical activity and remain compliant with an exercise program if they are counseled by a health care professional (Edelman et al., 2013).

[‡]Intervention classification labels from Bulechek GM et al, editors: *Nursing interventions classification (NIC),* ed 6, St Louis, 2013, Mosby.

EVALUATION

Nursing Actions	*Patient Response/Finding*	*Achievement of Outcome*
Review patient's exercise log.	Patient walked 20 minutes twice the first week, 20 minutes three times the next week.	Participation in exercise is increasing.
Record weight, blood pressure, and pulse.	Weight, 210 lbs; resting heart rate remains between 80 and 85 beats/min; blood pressure, 146/86 mm Hg.	15-lb weight loss
		Improved cardiovascular effects of exercise:
		• Heart rate is within normal range.
		• Blood pressure is lower but not at expected range. Monitor blood pressure as patient continues to lose weight.
Ask Mrs. Smith if exercise is helping to lower fatigue level.	"At first, finding time to exercise was hard; but once I started feeling less tired and even less stressed, it was easy to integrate exercise into my daily activities."	Activity tolerance improved with exercise.

BOX 39-8   PROCEDURAL GUIDELINES

Helping Patients to Exercise

Delegation Considerations

The skill of helping patients exercise is a self-care activity. However, in the acute care setting it can be delegated to nursing assistive personnel (NAP). A nurse first must assess the patient's ability and tolerance to exercise. The nurse also teaches patients and their families how to implement exercise programs at home. NAP can prepare patients for exercise (e.g., putting on shoes and clothing, providing hygiene needs and obtaining preexercise and post-exercise vital signs). Instruct NAP to do the following:

- Notify nurse if patient reports pain before, during, or after exercise.
- Notify nurse if patient complains of increased fatigue, dizziness, or light-headedness when obtaining preexercise and/or post-exercise vital signs.
- Notify nurse of vital sign values.

Steps

1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number according to agency policy).
2. Assess for any medical limitations (e.g., weight-bearing status, untreated fracture, partial paralysis, peripheral neuropathy of feet, current pregnancy, cardiovascular disease).
3. Know patient's mobility level before trauma, illness, or hospitalization.
4. Gather baseline assessment of vital signs and O_2 saturation (if available).
5. Assess patient's pain level. Ask patient to rate pain on a scale of 0 to 10, with 0 being no pain and 10 being the worst pain ever. An analgesic may be needed 30 minutes before exercise but should not have sedative properties.
6. Assess patient's beliefs, values, and perceptions regarding current health status and confidence in being capable of performing exercise.
7. Assess patient's cognitive status and ability to follow instructions while implementing exercise.
8. Assess for joint limitations and do not force a muscle or a joint during exercise.
9. Have patient wear comfortable nonskid shoes. In the home setting, encourage wearing comfortable clothes.
10. Instruct patient to take slow, deep breaths and to focus on relaxation to reduce anxiety and fully oxygenate tissues and expand lungs.
11. When exercising (e.g., ambulating or moving to a chair, walking at home), have the patient move at his or her own pace.
12. Monitor for dizziness, which is an indicator of postural hypotension.
13. Observe for proper posture, body alignment, and body mechanics during exercise.
14. Monitor vital signs before, during, and after exercise.
15. Terminate physical activity if patient's heart rate is greater than 30 beats per minute over baseline; if there is a change in patient's heart rhythm; if the patient is hypotensive (change in systolic BP of 30 mm Hg or change in diastolic BP of 10 mm Hg); if the patient develops dizziness that lasts 60 seconds, fainting, or diaphoresis; if there is a change in patient's breathing pattern with an increase in accessory muscle use; or if patient develops extreme fatigue or severe dyspnea with respiratory rate greater than baseline by more than 20 breaths/min (Perme and Chandrashekar, 2009; Myszenski, 2014).
16. Use **Teach Back** to determine patient and family understanding about safe exercise activities. State, "I want to be sure I explained how to safely exercise at home or in your community to prevent the risk for exercise-related injury. Can you explain to me the proper shoes for exercise and how to gradually increase your activity?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.
17. Document patient's progress and provide feedback as patient exercises.

Data from Edelman CL et al: *Health promotion throughout the life span,* ed 8, St Louis, 2013, Mosby; and Lewis SL et al: *Medical-surgical nursing assessment and management of clinical problems,* ed 9, St Louis, 2014, Mosby.

---

encouraging patients to engage in a regular exercise program in any setting (Box 39-8). Take a holistic approach to develop and implement a plan that enhances the patient's overall physical fitness. Discuss recommendations for physical activity and fitness and collaborate with the patient to design an exercise program.

Before starting an exercise program, teach patients to calculate their maximum heart rate by subtracting their current age in years from 220 and then obtaining their target heart rate by taking 60% to 90% of the maximum, depending on their health care provider's recommendation. No matter which exercise prescription is implemented for the patient, warm-up and cool-down periods need to be included in the program (Edelman et al., 2013). The warm-up period usually lasts about 5 to 10 minutes and frequently includes stretching, calisthenics, and/or the aerobic activity performed at a lower intensity. It prepares the body and decreases the potential for injury. The cool-down period follows the exercise routine and usually lasts about 5 to 10 minutes. It allows the body to readjust gradually to baseline functioning and provides an opportunity to combine movement such as stretching with relaxation-enhancing mind-body awareness. The American Heart Association (2015) has recommendations for physical activity in adults (http://www.heart.org/HEARTORG/Getting Healthy/PhysicalActivity/FitnessBasics/American-Heart-Association -Recommendations-for-Physical-Activity-in-Adults_UCM_307976 _Article.jsp#.VlCR96SFOpo).

> **QSEN   QSEN: BUILDING COMPETENCY IN QUALITY IMPROVEMENT**   To assess individualized improvement in the patient's tolerance to activity, you need to establish consistent and measurable outcomes for collaborative care. Determine the optimal cardiopulmonary response(s) to exercise for the patient in the nursing care plan, 45-year-old Mary Smith.
>
> ⊜ *Answers to QSEN Activities can be found on the Evolve website.*

Many patients find it difficult to incorporate an exercise program into their daily lives because of time constraints or lack of resources (e.g., no open parks or walking paths). For these patients it is beneficial to reinforce that they can use ADLs (e.g., gardening, climbing stairs when doing laundry) to accumulate the recommended 30 minutes or more per day of moderate-intensity physical activity.

Other patients benefit from a prescribed exercise and physical fitness program carefully designed to meet their needs and expectations. An exercise prescription usually includes a combination of aerobic exercises, stretching and flexibility exercises, and resistance training. Aerobic exercise includes walking, running, bicycling, aerobic dance, jumping rope, and cross-country skiing. Recommended frequency of aerobic exercise is 3 to 5 times per week or every other day for approximately 30 minutes. Cross-training is recommended for the

patient who prefers to exercise every day. For example, the patient runs one day and does yoga the next day.

Stretching and flexibility exercises include active ROM and stretching of all muscle groups and joints. This form of exercise is ideal for warm-up and cool-down periods. Benefits include increased flexibility, improved circulation and posture, and an opportunity for relaxation.

Resistance training increases muscle strength and endurance and is associated with improved performance of ADLs and avoidance of injuries and disability. Formal resistance training includes weight training; but patients can obtain the same benefits by performing ADLs such as pushing a vacuum cleaner, raking leaves, shoveling snow, and kneading bread. Some patients use weight training to bulk up their muscles. However, its purpose from a health perspective is to develop tone and strength and stimulate and maintain healthy bone (O'Donovan et al., 2010).

Body Mechanics. The U.S. Occupational Safety and Health Administration released federal ergonomic guidelines to prevent musculoskeletal injuries in the workplace (OSHA, 2009). Half of all back pain is associated with manual lifting tasks (Box 39-9). Coordinated musculoskeletal activity is necessary when positioning and transferring patients. The most common back injury is strain on the lumbar muscle group, which includes the muscles around the lumbar vertebrae. Injury to these areas affects the ability to bend forward, backward, and from side to side. The ability to rotate the hips and lower back is also decreased (Lin et al., 2012). Body mechanics alone are not sufficient to prevent musculoskeletal injuries when positioning or transferring patients (Table 39-1).

Before lifting, assess the weight to be lifted, determine the assistance needed, and evaluate available resources. Use safe patient–handling equipment when a patient is unable to assist in transfer. Lift teams, consisting of two physically fit people competent in lifting techniques, reduce the risk of injury to the patient and members of the health care team (Burnfield et al., 2013; Cowley and Leggett, 2010). Use manual lifting only as a last resort when you need to lift a small part of a patient's weight (Tullar et al., 2010). Teaching health care workers about patient-handling equipment, proper body mechanics, and the use of lift teams is most effective in preventing injury (Hunter et al., 2010).

Acute Care. Encourage patients who are hospitalized to do stretching exercises, active ROM exercises, and low-intensity walking, depending on their condition. Physical therapists can also assist patients with isometric exercises. When patients cannot participate in active ROM, maintain joint mobility and prevent contractures by implementing passive ROM into the plan of care. If needed, medicate patients for pain 30 minutes before exercise. Do not administer an analgesic that makes the patient feel dizzy.

Musculoskeletal System. Help maintain the musculoskeletal system during acute care by encouraging the use of stretching and isometric exercises. Review the patient's chart and collaborate with physical therapy and the health care provider to identify possible contraindications before initiating isometric exercises. A physical therapist will design an isometric exercise program for the specific needs of a patient. Your role will be to follow that program and assist patients accordingly. For example, an exercise program includes isometric exercises of the biceps and triceps to prepare a patient for crutch walking. Instruct the patient to stop the activity if pain, fatigue, or discomfort is experienced.

During isometrics, a patient tightens or contracts a muscle group for 10 seconds and then completely relaxes for several seconds (Resnick et al., 2012). Repetitions are increased gradually for each muscle group

BOX 39-9   EVIDENCE-BASED PRACTICE

Promoting Safe Handling of Patients and Prevention of Injury to Nurses and Their Patients

PICO Question: What is the effect on nurse safety in health care agencies that have safe patient handling policies when compared with agencies that do not have these policies?

Evidence Summary

Musculoskeletal disorders are the most prevalent and debilitating occupational health hazards for nurses. Preventive interventions are needed to avoid the hazards and economic burdens associated with patient-handling tasks. The American Nurses Association (ANA, 2010) position statement calls for the use of assistive equipment and devices to promote a safe health care environment for nurses and their patients. The use of assistive equipment and continued use of proper body mechanics significantly reduce the risk of musculoskeletal injuries. The Occupational Safety and Health Administration (OSHA, 2009) recommends minimizing or eliminating manual lifting of patients. Current evidence supports the benefits of instituting safe patient handling (SPH) programs in health care organizations. However, The U.S. Bureau of Labor Statistics (2010) reported that workers in the health care industry suffered the most loss of time because of general musculoskeletal pain and back pain. As a result, many facilities are implementing limited lift policies to minimize patient handling by nurses and using lift devices. Research shows that these policies effectively reduce on-the-job injuries (Cowley and Leggett, 2010; Tullar et al., 2010).

Application to Nursing Practice

- Be familiar with health care agency safety information and training concerning the transfer, positioning, and lifting of patients.
- Use sufficient personnel along with patient-handling equipment when moving patients who are overweight, confused, or unable to assist (Cowley and Leggett, 2010; VISN8, 2015).
- Use recommended back safety guidelines and appropriate safe patient–handling equipment to reduce the risk for musculoskeletal injuries (Lin et al., 2012).
- Use current research, standards, algorithms, and guidelines regarding safe positioning and transferring of patients (VISN8, 2015).
- Use "lift teams" and patient-handling equipment such as mechanical lifts to prevent injury to yourself and the patient (VISN8, 2015).

until the isometric exercise is repeated 8 to 10 times. Instruct patients to perform the exercises slowly and increase repetitions as their physical condition improves. A patient needs to do isometric exercise for quadriceps and gluteal muscle groups, which are used for walking, 4 times per day until a patient is ambulatory.

Joint Mobility. The easiest intervention to maintain or improve joint mobility for patients and one that can be coordinated with other activities is the use of ROM exercises (see Chapter 28). In active ROM exercises patients are able to move their joints independently. With passive ROM exercises you move each joint in patients who are unable to perform these exercises themselves. The use of ROM exercises provides data to systematically assess and improve the patient's joint mobility.

Joints that are not moved periodically are at risk for contractures, a permanent shortening of a muscle followed by the eventual shortening of associated ligaments and tendons. Over time the joint becomes fixed in one position, and the patient loses normal use of it. Passive ROM exercises are the exercises of choice for patients who do not have voluntary motor control.

TABLE 39-1 Preventing Lift Injuries in Health Care Workers

Action	Rationale
When planning to move a patient, arrange for adequate help. If your institution has a lift team, use it as a resource (Lin et al., 2012; VISN8, 2015).	A lift team is properly educated in techniques to prevent musculoskeletal injuries.
Use patient-handling equipment and devices such as height-adjustable beds, ceiling-mounted lifts, friction-reducing slide sheets, and air-assisted devices (Hunter et al., 2010; Tullar et al., 2010).	These devices reduce the caregiver's muscular strain during patient handling.
Encourage patient to help as much as possible.	This promotes patient's independence and strength while minimizing workload.
Take position close to patient (or object being lifted).	Keeps object in same plane as lifter and close to caregiver's center of gravity. Reduces horizontal reach and stress on caregiver's back.
Tighten abdominal muscles and keep back, neck, pelvis, and feet aligned. Avoid twisting.	Reduces risk of injury to lumbar vertebrae and muscle groups. Twisting increases risk of injury (Lin et al., 2012).
Bend at knees; keep feet wide apart.	A broad base of support increases stability. Maintains center of gravity.
Use arms and legs (not back).	Leg muscles are stronger, larger muscles capable of greater work without injury.
Slide patient toward your body using pull sheet or slide board. When transferring patient onto a stretcher or bed, a slide board is more appropriate.	Sliding requires less effort than lifting. Pull sheet minimizes shearing forces, which can damage patient's skin.
Person with heaviest load coordinates efforts of team involved by counting to three.	Simultaneous lifting minimizes load for any one lifter.
Perform manual lifting as last resort and only if it does not involve lifting most or all of patient's weight.	Lifting is a high-risk activity that causes significant biochemical and postural stressors (Tullar et al., 2010).

BOX 39-10 FOCUS ON OLDER ADULTS

Helping the Older Adult Initiate and Maintain an Exercise Program

- Encourage older adults to avoid prolonged sitting and get up and stretch. Frequent stretching decreases the risk of developing joint contractures.
- Be sure that the older patient maintains proper body alignment when sitting to minimize joint and muscle stress.
- Teach patients how to use stronger joints or larger muscle groups. Efficient distribution of the workload decreases joint stress and pain.
- Provide resources for planned exercise programs. Weight-bearing and resistance exercise slows bone loss and prevents fractures in older adults with osteoporosis (Roush, 2011).
- Recommend resistance- and agility-training programs. These forms of exercise reduce fear of falling and increase sense of well-being in older adults (Kwun et al., 2012).
- Teach older adults that it is never too late to begin an exercise program (Edelman et al., 2013; Elliott, 2011). Consult a health care provider before beginning an exercise program, particularly in the presence of heart or lung disease and other chronic illnesses.
- Use assessment data and consult with physical therapy to determine when you need to adjust exercise programs for those in advanced age.
- Encourage older adults who are unable to participate in a formal exercise program to improve joint mobility and enhance circulation by simply stretching and exaggerating movements during the performance of routine activities of daily living.

Older adults experiencing a decline in physical activity and changes in joints often have limited mobility and joint flexibility. Use a variety of recommended approaches to help older adults use proper body mechanics and prevent injury (Box 39-10).

The continuous passive motion (CPM) machine is designed to exercise various joints such as the hip, ankle, knee, shoulder, and wrist through repetitive ROM. The CPM machine is most commonly used after knee surgery. However, questions have been raised about CPM benefits (Maniar et al., 2012). A recent review of studies involving knee arthroplastic surgery show that CPM probably improves the ability of a patient to bend the knee slightly but may not improve pain or function (Harvey et al., 2014). It is usually prescribed from the first to fourth day after surgery and is applied for 1.5 to 24 hours a day depending on the surgeon's preference and the patient's condition (Lewis et al., 2013; Harvey et al., 2014). You set the machine to certain degrees of joint mobility based on the health care provider's order, with increasing joint mobility or flexion as the goal.

Unless contraindicated, the nursing care plan includes exercising each joint through as nearly a full ROM as possible. Initiate passive ROM exercises as soon as the patient loses the ability to move the extremity or joint. Chapter 28 details ROM exercises for each area and illustrates the motion of each joint.

Walking. Walking increases joint mobility and can be measured by length of time or distance walked. Measure distances walked in feet or yards instead of charting "ambulated to nurses' station and back." Illness or trauma usually reduces activity tolerance, resulting in the need for help with walking or the use of assistive devices such as crutches, canes, or walkers. Patients who increase their walking distance before discharge improve their ability to independently perform basic ADLs, increase activity tolerance, and have a faster recovery after surgery (AAN, 2015; Pashikanti and Von Ah, 2012)

Helping a Patient Walk. Helping a patient walk requires preparation. Assess the patient's strength, coordination, baseline vital signs, and balance to determine the type of assistance needed. Also assess his or her orientation and determine if there are any signs of distress. Postpone walking if you determine that the patient cannot walk safely. Evaluate the environment for safety before ambulation (e.g., removal of obstacles, a clean and dry floor, and the identification of rest points in case the patient's activity tolerance becomes less than expected or if the patient becomes dizzy). Also have the patient wear supportive, nonskid shoes.

FIGURE 39-11 **A,** Stand with feet apart to provide a broad base of support. **B,** Extend one leg and let patient slide against it to the floor. **C,** Bend knees to lower body as patient slides to the floor.

Help the patient to a position of sitting at the side of the bed and dangling the legs over the side of the bed for 1 to 2 minutes before standing. Some patients experience orthostatic hypotension (i.e., a drop in blood pressure that occurs when they change from a horizontal to a vertical position) (Fedorowski and Melander, 2013; Lewis et al., 2013). Those at higher risk are patients who are immobilized, patients who are on prolonged bed rest, older adults, and patients with chronic illnesses such as diabetes mellitus and cardiovascular disease. Signs and symptoms of orthostatic hypotension include dizziness, light-headedness, nausea, tachycardia, pallor, and even fainting. Orthostatic hypotension usually stabilizes quickly, but if the patient develops dizziness lasting 60 seconds, return the patient to bed (Perme and Chandrashekar, 2009; Myszenski, 2014). Dangling a patient's legs before standing is an intermediate step that allows assessment of the patient before changing positions to maintain safety and prevent injury to the patient. In some instances you need to take the patient's blood pressure while he or she is sitting on the side of the bed.

Several methods are used to help a patient ambulate. Always provide support at the waist with a gait belt so the patient's center of gravity remains midline. A gait belt encircles the patient's waist snugly. You hold the back of the belt behind the patient. Some belts have handles attached for you to hold while the patient ambulates.

If the patient has a fainting (syncope) episode or begins to fall, assume a wide base of support with one foot in front of the other, thus supporting the patient's body weight (Figure 39-11, *A*). Extend one leg, let the patient slide against the leg, and gently lower him or her to the floor, protecting the head (Figure 39-11, *B* and *C*). Practice this technique with a friend or classmate before attempting it in a clinical setting. Use caution to prevent your own injury, especially if the patient is overweight. When the patient attempts to ambulate again, proceed more slowly, monitoring for reports of dizziness; and take the patient's blood pressure before, during, and after ambulation.

Restorative and Continuing Care. Restorative and continuing care involves implementing activity and exercise strategies to help the patient with ADLs after acute care is no longer needed. Restorative and continuing care also includes activities and exercises that restore and

FIGURE 39-12 Patient using a walker.

promote optimal functioning in patients with specific chronic illnesses such as coronary heart disease (CHD), hypertension, COPD, and diabetes mellitus.

Assistive Devices for Walking. In collaboration with other health care professionals such as physical therapists, promote activity and exercise by teaching the proper use of canes, walkers, or crutches, depending on the assistive device most appropriate for the patient's condition.

Walkers. A walker is a lightweight, movable device that stands about waist high and consists of a metal frame with handgrips, four widely placed sturdy legs, and one open side (Figure 39-12). Because it has a wide base of support, the walker provides great stability and

security during walking. A walker can be used by a patient who is weak or has problems with balance. Walkers with wheels are useful for patients who have difficulty lifting and advancing the walker as they walk because of limited balance or endurance. However, the disadvantage is that the walker can roll forward when weight is applied. You measure walkers by having patients relax their arms at the side of their body and stand up straight. The top of the walker should line up with the crease on the inside of the wrist (American Academy of Orthopaedist Surgeons, 2015). Elbows should be flexed about 15 to 30 degrees when standing inside the walker, with hands on the handgrips. A patient holds the handgrips on the upper bars, takes a step, moves the walker forward, and takes another step. A walker requires a patient to lift the device up and forward. Teach patients how to use walkers safely and avoid risk of falling.

Canes. Canes are lightweight, easily movable devices made of wood or metal. They provide less support than a walker and are less stable. A person's cane length is equal to the distance between the greater trochanter and the floor (Pierson and Fairchild, 2013). Two common types of canes are the single straight-legged cane and the quad cane. The single straight-legged cane is more common and is used to support and balance a patient with decreased leg strength. Have the patient keep the cane on the stronger side of the body. For maximum support when walking, the patient places the cane forward 15 to 25 cm (6 to 10 inches), keeping body weight on both legs. He or she moves the weaker leg forward to the cane so body weight is divided between the cane and the stronger leg. The patient then advances the stronger leg past the cane so the weaker leg and the body weight are supported by the cane and weaker leg. During walking the patient continually repeats these three steps. The patient needs to learn that two points of support such as both feet or one foot and the cane are on the floor at all times.

The quad cane provides the most support and is used when there is partial or complete leg paralysis or some hemiplegia (Figure 39-13). You teach the patient the same three steps that are used with the straight-legged cane.

Crutches. Crutches are often needed to increase mobility. Begin crutch instruction with guidelines for safe use (Box 39-11). The use of crutches is often temporary (e.g., after ligament damage to the knee). However, some patients with paralysis of the lower extremities need them permanently. A crutch is a wooden or metal staff. The two types of crutches are the double adjustable or forearm crutch and the axillary wooden or metal crutch, which is the most common. The forearm crutch has a handgrip and a metal band that fits around the patient's forearm. The metal band and the handgrip are adjusted to fit the patient's height. The axillary crutch has a padded curved surface at the top, which fits under the axilla. A handgrip in the form of a crossbar is held at the level of the palms to support the body. It is important to measure crutches for the appropriate length and to teach patients how to use their crutches safely to achieve a stable gait, ascend and descend stairs, and rise from a sitting position.

Measuring for Crutches. Measurement for an axillary crutch includes the patient's height, the angle of elbow flexion, and the distance between the crutch pad and the axilla. When crutches are fitted, ensure that the length of the crutch is two to three finger widths from the axilla and position the tips approximately 2 inches lateral and 4 to 6 inches anterior to the front of the patient's shoes (Figure 39-14).

Position the handgrips so the axillae are not supporting the patient's body weight. Pressure on the axillae increases risk to underlying nerves, which sometimes results in partial paralysis of the arm. Determine correct position of the handgrips with the patient upright, supporting weight by the handgrips with the elbows slightly flexed at 20 to 25 degrees. Elbow flexion may be verified with a goniometer (Figure 39-15). When you determine the height and placement of the handgrips, verify that the distance between the crutch pad and the patient's axilla is approximately 2 inches (two to three finger widths) (Figure 39-16).

BOX 39-11 PATIENT TEACHING

Crutch Safety

Objective
- Patient will describe and demonstrate safe crutch walking.

Teaching Strategies
- Teach patient not to lean on crutches to support body weight.
- Teach patient with axillary crutches about the dangers of pressure on the axillae, which occurs when patient leans on the crutches to support body weight.
- Explain why patient needs to use only crutches that were measured for him or her.
- Show patient how to routinely inspect crutch tips. Securely attach rubber tips to crutches. Replace worn tips. Rubber crutch tips increase surface friction and help prevent slipping.
- Explain that crutch tips need to remain dry. Water decreases surface friction and increases risk of slipping. Show patient how to dry crutch tips if they become wet; patient may use paper or cloth towels.
- Show patient how to inspect structure of crutches. Cracks in a wooden crutch decrease its ability to support weight. Bends in aluminum crutches alter body alignment.
- Provide patient with list of medical supply companies in the community for obtaining repairs, new rubber tips, handgrips, and crutch pads.
- Instruct patient to have spare crutches and tips readily available.

Evaluation
- Patient states principles of crutch safety.
- Patient correctly demonstrates proper use of crutches.
- Axilla is free of pressure.

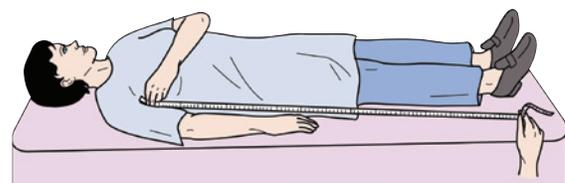
FIGURE 39-13 Bottom of quad cane.


FIGURE 39-14 Measuring crutch length.
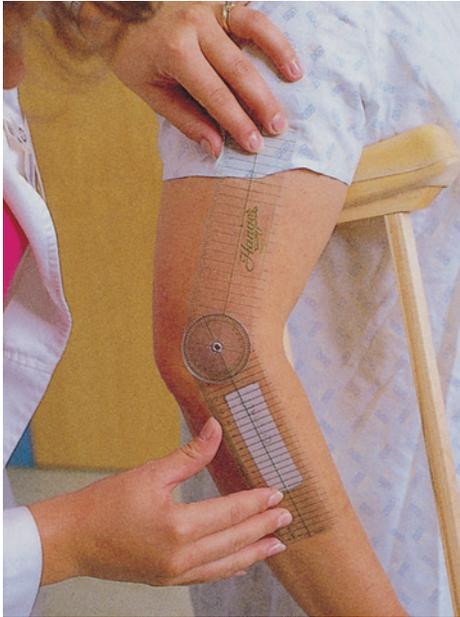

FIGURE 39-15 Using the goniometer to verify correct degree of elbow flexion for crutch use.

FIGURE 39-16 Verifying correct distance between crutch pads and axilla.

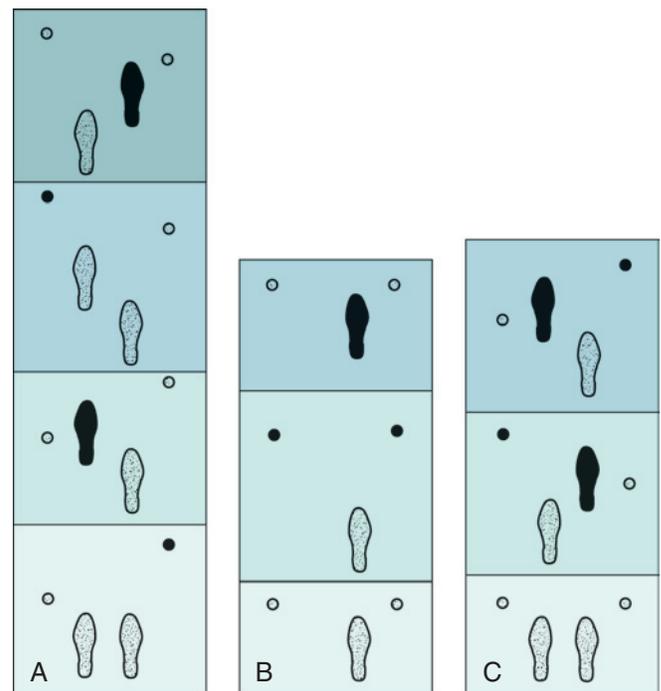
FIGURE 39-17 Tripod position, basic crutch stance.


FIGURE 39-18 A, Four-point alternating gait. Solid feet and crutch tips show the order of foot and crutch tip movement in each of the four phases. (Read from bottom to top.) **B,** Three-point gait with weight borne on unaffected leg. Solid foot and crutch tips show weight bearing in each phase. (Read from bottom to top.) **C,** Two-point gait with weight borne partially on each foot and each crutch advancing with opposing leg. Solid areas indicate leg and crutch tips bearing weight. (Read from bottom to top.)

Crutch Gait. Patients assume a **crutch gait** by alternately bearing weight on one or both legs and on the crutches. Determine the gait by assessing the patient's physical and functional abilities and the disease or injury that resulted in the need for crutches. This section summarizes the basic crutch stance and the four standard gaits: four-point alternating gait, three-point alternating gait, two-point gait, and swing-through gait.

The basic crutch stance is the tripod position, formed when the crutches are placed 15 cm (6 inches) in front of and 15 cm (6 inches) to the side of each foot (Figure 39-17). This position improves the patient's balance by providing a wider base of support. The body alignment of the patient in the tripod position includes an erect head and neck, straight vertebrae, and extended hips and knees. The axillae should not bear any weight. The patient assumes the tripod position before crutch walking.

Four-point alternating, or four-point, gait gives stability to the patient but requires weight bearing on both legs. Each leg is moved alternately with each opposing crutch so three points of support are on the floor at all times (Figure 39-18, A).

Three-point alternating, or three-point, gait requires the patient to bear all of the weight on one foot. In a three-point gait the patient bears weight on both crutches and then on the uninvolved leg, repeating the sequence (see Figure 39-18, B). The affected leg does not touch the ground during the early phase of the three-point gait. Gradually the patient progresses to touchdown and full weight bearing on the affected leg.

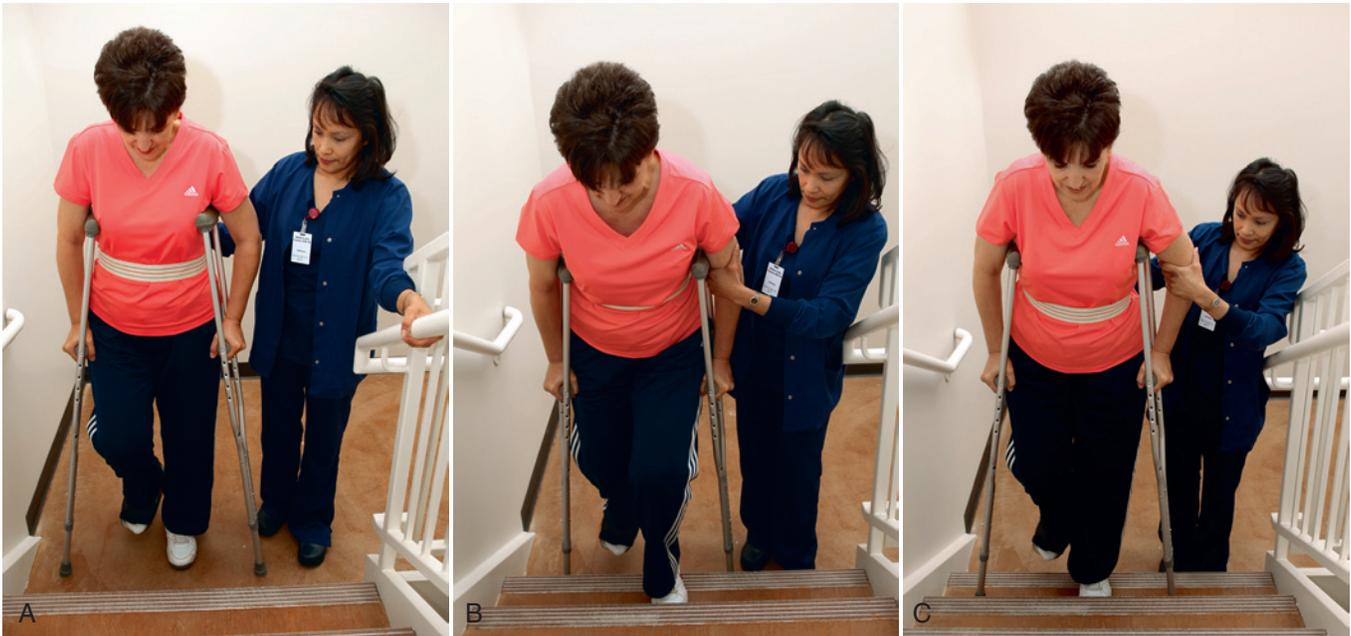
The two-point gait requires at least partial weight bearing on each foot (see Figure 39-18, C). The patient moves a crutch at the same time as the opposing leg so the crutch movements are similar to arm motion during normal walking.


FIGURE 39-19 Ascending stairs. **A,** Weight is placed on crutch. **B,** Weight is transferred from crutches to unaffected leg on stairs. **C,** Crutches are aligned with unaffected leg on stairs.

FIGURE 39-20 Descending stairs. **A,** Body weight is on unaffected leg. **B,** Body weight is transferred to crutches. **C,** Unaffected leg is aligned on stairs with crutches.

Individuals with paraplegia who wear weight-supporting braces on their legs frequently use the swing-through gait. With weight placed on the supported legs, the patient places the crutches one stride in front and then swings to or through them while they support his or her weight.

Crutch Walking on Stairs.   When ascending stairs on crutches, the patient usually uses a modified three-point gait (Figure 39-19). He or she stands at the bottom of the stairs and transfers body weight to the crutches. He or she advances the unaffected leg between the crutches to the stairs. The patient then shifts weight from the crutches to the unaffected leg. Finally he or she aligns both crutches on the

stairs. The patient repeats this sequence until he or she reaches the top of the stairs.

A three-phase sequence is also used to descend the stairs (Figure 39-20). The patient transfers body weight to the unaffected leg. He or she places the crutches on the stairs and begins to transfer body weight to them, moving the affected leg forward. Finally the patient moves the unaffected leg to the stairs with the crutches. The patient repeats the sequence until reaching the bottom of the stairs.

Because in most cases patients need to use crutches for some time, they need to be taught to use them on stairs before discharge. This instruction applies to all patients who are dependent on crutches, not

FIGURE 39-21 Sitting in a chair. **A,** Both crutches are held in one hand. Patient transfers weight to crutches and unaffected leg. **B,** Patient grasps arm of chair with free hand and begins to lower herself into chair. **C,** Patient completely lowers herself into chair.

only those who have stairs in their homes. You will frequently collaborate with physical therapists to provide instruction about crutch walking.

Sitting in a Chair with Crutches. As with crutch walking and crutch walking up and down stairs, the procedure for sitting in a chair involves phases and requires the patient to transfer weight (Figure 39-21). First the patient positions himself or herself at the center front of the chair with the posterior aspect of the legs touching the chair. Then the patient holds both crutches in the hand opposite the affected leg. If both legs are affected, as with a person with paraplegia who wears weight-supporting braces, the patient holds the crutches in the hand on his or her stronger side. With both crutches in one hand, the patient supports body weight on the unaffected leg and the crutches. While still holding the crutches, the patient grasps the arm of the chair with the remaining hand and lowers his or her body into it. To stand the procedure is reversed; and the patient, when fully erect, assumes the tripod position before beginning to walk.

Restoration of Activity and Chronic Illness. Nurses design care plans to increase activity and exercise in patients with specific disease conditions and chronic illnesses such as CHD, hypertension, COPD, and diabetes mellitus.

Coronary Heart Disease. Research shows that activity and exercise play a role in secondary prevention or recurrence of CHD. Cardiac rehabilitation is an integral part of comprehensive care of patients diagnosed with CHD. Nurses are involved in many aspects of cardiac rehabilitation and help patients develop a program of exercise that fits their needs and level of functioning. Increased physical activity benefits individuals with MI, angina pectoris, or heart failure and patients who have had a coronary artery bypass graft (CABG) or percutaneous transluminal coronary angioplasty (PTCA). Patients with CHD benefit from exercise and activity in terms of reduced mortality and morbidity, improved quality of life, improved left ventricular function, increased functional capacity, decreased blood lipids and apolipoproteins (protein components of lipoprotein complexes), and psychological well-being (Campos-Outcalt, 2014; Donges et al., 2010).

Hypertension. Exercise reduces systolic and diastolic blood pressure readings. Research shows that low- to moderate-intensity aerobic exercise (brisk walking or bicycling) is the most effective in lowering blood pressure. In addition, a tai chi exercise program has demonstrated a significant reduction in systolic and diastolic blood pressures (Balady et al., 2010; Edelman et al., 2013; Lo et al., 2012).

Chronic Obstructive Pulmonary Disease. Pulmonary rehabilitation helps patients reach an optimal level of functioning. Some patients are fearful of participating in exercise because of the potential of worsening dyspnea (difficulty breathing). This aversion to physical activity sets up a progressive deconditioning in which minimal physical exertion results in dyspnea. Pulmonary rehabilitation provides a safe environment for monitoring patients' progress. In addition, they receive encouragement and support to increase activity and exercise (Berry et al., 2010; Salhi et al., 2010).

Diabetes Mellitus. Along with diet, glucose monitoring, and medication, exercise is an important component in the care of patients with diabetes mellitus. Individuals with type 1 diabetes need to exercise because it leads to improved glucose control, cardiovascular fitness, and psychological well-being. Exercise lowers blood sugar levels, and the effects of exercise on blood sugar levels often last for at least 24 hours. Instruct the patient with type 1 diabetes about the risks and precautions regarding exercise. Instruction includes the need for a physical examination before beginning an exercise program and precautions to monitor blood glucose level immediately before and after exercise. Also instruct patients to perform low- to moderate-intensity exercises, carry a concentrated form of carbohydrates (sugar packets or hard candy), and wear a medical-alert bracelet. Endurance and resistance exercise appear equally effective in improving the control of metabolism in patients with type 2 diabetes. However, exercise must

occur on a regular basis to have the desired continued benefits in the management of blood glucose levels, lipids, and overall quality of life (ACSM and ADA, 2010; Hameed et al., 2011).

◆ **Evaluation**

Through the Patient's Eyes. For activity and exercise you measure the effectiveness of nursing interventions by the success of meeting the patient's expected outcomes and goals of care. The patient is the only one who knows the effectiveness and benefits of activity and exercise (Figure 39-22). Ask the patient questions such as, "How well did you tolerate walking, and is that what you expected?" and "You have been walking regularly for a month now, how has it made you feel?" Continuous evaluation helps to determine whether new or revised therapies are needed and if new nursing diagnoses have developed.

Patient Outcomes. To evaluate the effectiveness of nursing interventions to enhance activity and exercise, make comparisons with baseline measures that include pulse, blood pressure, oxygen saturation (when available), strength, fatigue, and psychological well-being. Compare actual outcomes with expected outcomes to determine the patient's health status and progression. The following is an example of questions you ask when your patients do not meet their expected outcomes:

- The last time we met you planned to walk outside for 20 minutes 3 days a week. However, you report that you are only able to walk twice a week right now. What do you think is preventing you from meeting your goal?
- Your weight is the same this month as it was last month. We were hoping that increasing your activity would lead to a decrease in your weight. Help me understand the factors you believe are preventing you from losing weight right now.
- You state that you experience leg pain after walking short distances. Describe your pain. Which pain-relieving measures have you tried?

Knowledge
- Characteristics of improved activity and exercise tolerance
- Role of community resources in maintaining activity and exercise

Experience
- Consider previous patient responses to activity and exercise therapies

EVALUATION
- Reassess the patient for signs of improved activity and exercise tolerance
- Ask for the patient's perception of activity and exercise status after interventions
- Ask if the patient's expectations are being met

Standards
- Use established expected outcomes to evaluate the patient's response to care (e.g., return to resting heart rate within 5 minutes) as standards for evaluation
- Apply goals published by the American College of Sports Medicine to evaluate response to exercise

Attitudes
- Use creativity in redesigning new interventions to improve the patient's activity and exercise tolerance
- Demonstrate perseverance to design interventions to keep the patient motivated to adhere to the activity and exercise plan

FIGURE 39-22 Critical thinking model for activity and exercise evaluation.

SAFETY GUIDELINES FOR NURSING SKILLS

Ensuring patient safety is an essential role of the professional nurse. To ensure patient safety, communicate clearly with the members of the health care team, assess and incorporate the patient's priorities of care and preferences, and use the best evidence when making decisions about your patient's care. When performing the skills in this chapter, remember the following points to ensure safe patient handling and individualized patient-centered care.

- Mentally review the transfer steps before beginning the procedure; this ensures both your safety and that of the patient.
- Assess the patient's mobility and strength to determine the assistance that he or she is able to offer during transfer. Stand on patient's weak side when assisting (Pierson and Fairchild, 2013).
- Determine the amount and type of assistance required for transfer, including the type of transfer equipment and the number of personnel to safely transfer and prevent harm to the patient and health care providers.

- Raise the side rail on the side of the bed opposite of where you are standing to prevent the patient from falling out of bed on that side.
- Arrange equipment (e.g., intravenous lines, feeding tube, indwelling catheter) so it does not interfere with the positioning or transfer process.
- Evaluate the patient for correct body alignment and pressure risks after the transfer.
- Make sure that all personnel understand how the equipment functions before it is used.
- Educate patients about how equipment functions to reduce their anxiety and enlist their cooperation.

SKILL 39-1   USING SAFE AND EFFECTIVE TRANSFER TECHNIQUES

DELEGATION CONSIDERATIONS

The skill of effective transfer techniques can be delegated to nursing assistive personnel (NAP). Patients who are transferred for the first time after prolonged bed rest, extensive surgery, critical illness, or spinal cord trauma usually require supervision by the nurse. Instruct NAP about:

- Seeking assistance when moving or lifting a patient (e.g., when the patient is overweight, medicated, or confused).
- Patient limitations (e.g., changes in blood pressure, mobility restrictions) that affect safe transfer techniques.

EQUIPMENT

- Transfer belt, sling, or lapboard (as needed)
- Nonskid shoes, bath blankets, and pillows
- Wheelchair (Position chair at 45- to 60-degree angle to bed, lock brakes, remove footrests, and lock bed brakes.)
- Stretcher (Position next to bed, lock brakes on stretcher, lock brakes on bed.)
- Mechanical/hydraulic lift (Use frame, canvas strips or chains, and hammock or canvas strips.)
- Stand-assist lift device

STEP	RATIONALE
ASSESSMENT	
1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy. Explain procedure.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
2. Assess physiological capacity to transfer:	Provides information relative to patient's abilities, physical status, ability to comprehend, and number of individuals needed to provide safe transferring.
a. Muscle strength (legs and upper arms)	Immobile patients have decreased muscle strength, tone, and mass. Affects ability to bear weight or raise body.
b. Joint mobility (range of motion [ROM]) and contracture formation	Immobility or inflammatory processes (e.g., arthritis) sometimes lead to contracture formation and impaired joint mobility.
c. Paralysis or paresis (spastic or flaccid)	Patient with central nervous system damage often has bilateral paralysis (requiring transfer by swivel bar, sliding bar, or mechanical lift) or unilateral paralysis, which requires belt transfer to "best" side. Weakness (paresis) requires stabilization of knee while transferring. Flaccid arm needs to be supported with sling during transfer.
d. Bone continuity.	Patients with trauma to one leg or hip may be non–weight bearing during transfer. Amputees may use slide board to transfer.
3. Assess for weakness, dizziness, or orthostatic (postural) hypotension or risk for orthostatic hypotension (e.g., previously on bed rest, first time arising from supine position following surgical procedure, history of dizziness when arising)	Determines risk of fainting or falling during transfer. Immobilized patients have decreased ability for autonomic nervous system to equalize blood supply, resulting in drop of 20 mm Hg systolic or more in blood pressure when rising from sitting position (Fedorowski and Melander, 2013; Lewis et al., 2013).
4. Activity tolerance, noting for fatigue during activity	Determines ability of patient to help with transfer.
5. Assess proprioceptive function (awareness of posture and equilibrium), including ability to maintain balance while sitting in bed or on side of bed and tendency to sway toward one side.	Determines stability of patient's balance for transfer and risk for falls.
6. Assess sensory status, including central and peripheral vision, adequacy of hearing, and presence of peripheral sensation loss.	Determines influence of sensory loss on ability to make transfer. Visual field loss decreases patient's ability to see in direction of transfer. Peripheral sensation loss decreases proprioception. Patients with visual and hearing losses need transfer techniques adapted to deficits. Patients with a cerebrovascular accident (CVA) sometimes lose area of visual field, which profoundly affects vision and perception.

CLINICAL DECISION: *Patients with hemiplegia also often "neglect" one side of the body (inattention to or unawareness of one side of body or environment), which distorts perception of the visual field. If patient experiences neglect of one side, instruct him or her to scan all visual fields when transferring.*

7. Assess level of comfort (e.g., joint discomfort, muscle spasm) and measure level of pain on a 0-10 scale. Offer prescribed analgesic 30 minutes before transfer.	Pain reduces patient's motivation and ability to be mobile. Pain relief before transfer enhances patient participation (Christo et al., 2011).
8. Assess vital signs.	Vital sign changes such as increased pulse and respiration and drop in BP indicate activity intolerance (see Chapter 30).
9. Assess patient's cognitive status, including ability to follow verbal instructions, short-term memory, and recognition of physical deficits and limitations to movement.	Determines patient's ability to follow directions and learn transfer techniques.

CLINICAL DECISION: *Patients with head trauma or CVA may have perceptual cognitive deficits that create safety risks. If the patient has difficulty comprehending, simplify instructions by providing one step at a time and maintain consistency.*

10. Assess patient's level of motivation such as eagerness versus unwillingness to be mobile and perception of value of exercise.	Altered physiological and psychological conditions reduce a patient's desire to engage in activity.

SKILL 39-1	USING SAFE AND EFFECTIVE TRANSFER TECHNIQUES—cont'd

STEP	RATIONALE
11. Assess patient's specific risk for falling or being injured during transfer (e.g., neuromuscular deficits, visual loss, motor weakness, fear of falling, or bone loss).	Causes risk for tripping, losing balance.
12. Assess previous mode of transfer (if applicable).	Determines mode of transfer and assistance required to provide continuity.
13. Assess patient's specific risk of falling or being injured when transferred (e.g., neuromuscular deficits, motor weakness, calcium loss from bones, cognitive and visual dysfunction, altered balance).	Certain conditions increase risk of falling or potential injury.
14. Assess special transfer equipment needed for home setting and previous mode of transfer (if applicable).	Prior teaching of family and support people, assessing home for safety risks and functionality, and providing applicable aids greatly enhance transfer ability at home.

PLANNING

1. Gather appropriate equipment.	
2. Determine number of people needed to assist with transfer by referring to proper algorithm. Do not start procedure until all caregivers are available.	Ensures safe patient transfer. Algorithms for safe patient handling and movement are provided at http://www.visn8.va.gov/patientsafetycenter/safepthandling
3. Perform hand hygiene. Verify that bed brakes are locked.	Reduces transmission of microorganisms. Promotes patient and caregiver safety.
4. Explain procedure to patient.	Increases patient participation.

IMPLEMENTATION

1. Transfer patient.

    a. Assisting cooperative patient to sitting position in bed:

> **CLINICAL DECISION:** *Careful assessment of your patient's ability to assist in the following position technique is extremely important. Consider the use of a mechanical lift. Your role in helping your patient to a sitting position is to be a guide and instruct. If patient can bear weight and move to a sitting position independently, allow him or her to do so and offer assistance (VISN8, 2015).*

(1) Raise bed to waist level. Place patient in supine position.	Enables you to assess patient's body alignment continually.
(2) Face head of bed at 45-degree angle and remove pillows.	Proper positioning reduces twisting of your body when moving patient. Pillows cause interference when patient is sitting up in bed.
(3) Place feet in wide base of support, with foot closer to bed in front of other foot.	Improves balance and allows transfer of body weight as you move patient to sitting position.
(4) Place arm nearer head of bed under patient's shoulders, supporting his or her head and cervical vertebrae.	Maintains alignment of head and cervical vertebrae and allows for even lifting of patient's upper trunk.
(5) Place other hand on bed surface.	Provides support and balance.
(6) Raise patient to sitting position by shifting weight from front to back leg.	Improves balance, overcomes inertia, and transfers weight in direction you move patient.
(7) Push against bed using arm that is placed on bed surface.	Divides activity between arms and legs and protects back from strain. By bracing one hand against mattress and pushing against it as you lift patient, you transfer weight away from your back muscles through your arm onto mattress.

STEP 1b(1) Side-lying position.

STEP 1b(4) Proper foot placement.

STEP	RATIONALE
b. Assisting cooperative patient who can partially bear weight to sitting position on side of bed:	
(1) With bed flat and waist high, turn patient to a side-lying position with assistance of another caregiver if necessary. Patient needs to face nurse on side of bed that patient will be sitting (see illustration).	Decreases amount of work needed by nurse and patient.
(2) Raise head of bed 30 degrees.	Facilitates raising patient to sitting position and protects him or her from falling.
(3) Stand opposite patient's hips. Turn diagonally so you face patient and far corner of head of bed.	Places your center of gravity nearer patient. Reduces twisting of your body because you are facing direction of movement.
(4) Place feet apart with foot closest to bed in front of other foot (see illustration).	Increases balance and allows transfer of body weight as you move patient to a sitting position.
(5) Place arm nearer head of bed under patient's shoulders, supporting head and cervical vertebrae.	Maintains alignment of head and cervical vertebrae and allows for even lifting of patient's trunk.
(6) Place other arm over patient's thighs (see illustration).	Supports hip and prevents patient from falling backward during procedure.
(7) Move patient's lower legs and feet over side of bed. Pivot toward rear leg, allowing patient's upper legs to swing downward. At same time shift weight to back leg and elevate patient (see illustration).	Decreases friction and resistance. Weight of patient's legs when off bed allows gravity to lower legs, and weight of legs helps to pull to sitting position.
(8) Allow patient to dangle on side of bed for a few minutes. Have patient alternately flex and extend feet and move lower legs. Ask if patient feels dizzy. Have patient relax and take a few deep breaths until dizziness subsides and balance is gained.	Determines ability to tolerate standing. Dizziness that lasts more than 60 seconds may indicate orthostatic hypotension; return patient to bed (Myszenski, 2014). Recheck blood pressure.
c. Transferring cooperative patient who is partially weight bearing from bed to chair:	

CLINICAL DECISION: *Allow patient to transfer independently if able to fully bear weight. Stand by as needed to promote safe transfer (VISN8, 2015). If patient has partial weight bearing with upper-body strength and caregiver must lift more than 35 lbs (115.9 kg) of patient weight, use a stand-assist lift device and follow manufacturer instructions (Figure 39-23).*

STEP 1b(6) Nurse places arm over patient's thighs.

STEP 1b(7) Nurse shifts weight to rear leg and elevates patient.

FIGURE 39-23 Stand-assist device.

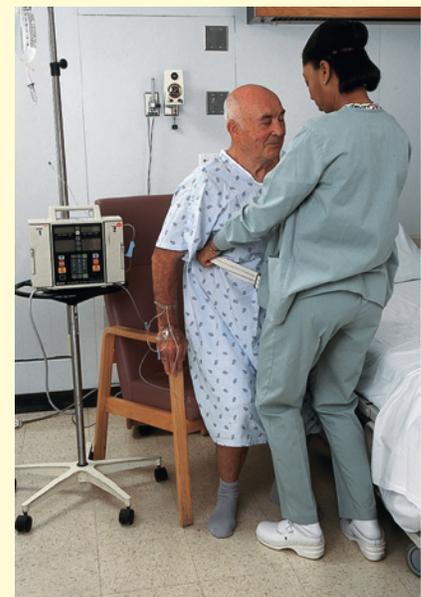
SKILL 39-1	USING SAFE AND EFFECTIVE TRANSFER TECHNIQUES—cont'd

STEP	RATIONALE
(1) Help patient to sitting position on side of bed (see Step 1b). Have chair placed next to bed at 45-degree angle on patient's strong side. Allow patient to sit on side of bed (dangling) for a few minutes before transferring. Ask if patient feels dizzy. Do not leave unattended while dangling.	Positions chair within easy access for transfer. Placing chair on patient's stronger side allows patient to help with transferring. Dangling helps equilibrate blood pressure, reducing risk for dizziness or fainting when standing.
(2) Apply transfer belt or other transfer aids. Be sure it completely circles patient's waist. Place the belt low and be sure it is snug. You may need to adjust belt once patient stands.	Transfer belt maintains stability of patient during transfer and reduces risk for falling (Pierson and Fairchild, 2013; VISN8, 2015). Patient's arm needs to be in sling if flaccid paralysis is present.
(3) Ensure that patient has stable nonskid shoes. Weight-bearing or strong leg is forward, with weak foot back.	Nonskid soles decrease risk of slipping during transfer. Always have patient wear shoes during transfer; bare feet increase risk of falls. Patient stands on stronger, or weight-bearing, leg.
(4) Spread feet apart.	Ensures balance with wide base of support.
(5) Flex hips and knees, aligning knees with patient's knees (see illustration).	Flexing knees and hips lowers center of gravity to object to be raised; aligning knees with those of patient allows for stabilization of knees when patient stands.
(6) Grasp transfer belt from underneath along patient's sides.	Provides movement of patient at center of gravity. Never lift patients with upper-extremity paralysis or paresis by or under arms (VISN8, 2006).

CLINICAL DECISION: *Use a transfer belt or walking belt with handles in place of the under-axilla technique. The under-axilla technique is physically stressful for nurses and uncomfortable for patients (Pierson and Fairchild, 2013).*

STEP	RATIONALE
(7) Rock patient up to standing position on count of 3 while straightening hips and legs and keeping knees slightly flexed (see illustration). Unless contraindicated, instruct patient to use hands to push up if applicable.	Rocking motion gives patient's body momentum and requires less muscular effort to lift him or her.
(8) Maintain stability of patient's weak or paralyzed leg with knee.	Often patient maintains ability to stand on paralyzed or weak limb with support of knee to stabilize (Pierson and Fairchild, 2013).
(9) Pivot on foot farther from chair.	Maintains support of patient while allowing adequate space for patient to move.
(10) Instruct patient to use armrests on chair for support and ease into chair (see illustration).	Increases patient stability.

STEP 1c(5) Nurse flexes hips and knees, aligning knees with patient's knees.

STEP 1c(7) Nurse rocks patient to standing position.


STEP 1c(10) Patient uses armrests for support.

STEP	RATIONALE
(11) Flex hips and knees while lowering patient into chair (see illustration).	Prevents injury to nurse from poor body mechanics.
(12) Assess patient for proper alignment for sitting position. Provide support for paralyzed extremities. Lapboard or sling supports flaccid arm. Stabilize leg with bath blanket or pillow.	Prevents injury to patient from poor body alignment.
(13) Praise patient's progress, effort, or performance.	Continued support and encouragement provide incentive for patient perseverance.
d. Using mechanical lift and full-body sling to transfer uncooperative patient who can bear partial weight or patient who cannot bear weight and is either uncooperative or does not have upper-body strength to move from bed to chair:	Mechanical lift devices prevent musculoskeletal injuries to health care workers (Pelczarski, 2012).
(1) Position lift properly at bedside (see equipment instructions).	Ensures safe elevation of patient off bed. (Before using lift, be thoroughly familiar with its operation.)
(2) Position chair near bed and allow adequate space to maneuver lift.	Prepares environment for safe use of lift and subsequent transfer.
(3) Raise bed to high position with mattress flat. Lower side rail.	Maintains nurses' alignment during transfer.
(4) Keep side rail up on side opposite from you.	Maintains patient safety.
(5) Roll patient away from you.	Positions patient for use of lift sling.
(6) Place sling under patient. Place lower edge under patient's knees (wide piece) and upper edge under patient's shoulders (narrow piece).	Allows positioning of patient on mechanical/hydraulic sling. Places sling under patient's center of gravity and greatest part of body weight.
(7) Roll patient to opposite side and pull body sling through.	Completes positioning of patient on mechanical/hydraulic sling.
(8) Roll patient supine onto canvas seat.	Sling needs to extend from shoulders to knees (hammock) to support patient's body weight equally.
(9) Remove patient's glasses if appropriate.	Swivel bar is close to patient's head and can break eyeglasses.
(10) If using a transportable hydraulic lift, place horseshoe-shaped base of lift under side of bed (on side with chair).	Positions hydraulic lift efficiently and promotes smooth transfer.
(11) Lower upper horizontal bar to sling level following manufacturer directions. Some lifts require valve to be locked.	Positions lift close to patient. Locking valve prevents injury to patient.
(12) Attach hooks on strap to holes in sling. Short straps hook to top holes of sling; longer straps hook to bottom of sling.	Secures hydraulic lift to sling.
(13) Elevate head of bed.	Positions patient in sitting position.
(14) Fold patient's arms over chest.	Prevents injury to paralyzed arms.
(15) Use lift to raise patient off bed (see illustration).	Moves patient off bed.
(16) Use steering handle to pull lift from bed and maneuver to chair.	Moves patient from bed to chair.
(17) Move lift to chair.	Positions lift in front of chair.

STEP 1c(11) Nurse eases patient into chair.

STEP 1d(15) Use mechanical lift to raise patient off bed.

SKILL 39-1	USING SAFE AND EFFECTIVE TRANSFER TECHNIQUES—cont'd

STEP	RATIONALE
(18) Position patient and lower slowly into chair following manufacturer guidelines (see illustration).	Safely guides patient into back of chair as seat descends.
(19) Remove straps and mechanical/hydraulic lift.	Prevents damage to skin and underlying tissues from canvas or hooks.
(20) Check patient's sitting alignment and correct if necessary.	Prevents injury from poor posture.
e. Transferring patient from bed to stretcher (bed at stretcher level):	
(1) Raise bed to height of stretcher.	Bed and stretcher need to be at same level to allow patient to slide from bed to stretcher.
(2) Lower head of bed as much as patient can tolerate. Cross patient's arms on chest. Ensure that bed brakes are locked.	Prevents injury to arms during transfer.
(3) Lower side rails. Two caregivers stand on side where stretcher will be; third caregiver stands on other side.	Minimizes caregivers' stretching. Prevents patient from falling out of bed and promotes safety.
(4) Two caregivers help patient roll onto side toward them (use of drawsheet is optional) with smooth, continuous motion.	Positions patient for placing friction-reducing lateral transfer device.
(5) Place slide board under drawsheet or follow manufacturer guidelines (see illustrations). Gently roll patient back onto slide board.	Patient needs to be placed on transfer device properly to allow safe transfer.
(6) Align stretcher alongside of bed. Lock wheels of stretcher once it is in place. Instruct patient not to move.	Positions stretcher in correct position for transfer and prevents patient from falling out of bed.
(7) All three caregivers place feet widely apart with one slightly in front of the other and grasp friction-reducing device.	Prepares for transfer. Wide base of support allows nurse to shift weight and minimizes back strain.

STEP 1d(18) Use mechanical lift to lower patient into chair.

STEP 1e(5) **A,** Two caregivers position slide board under patient. **B,** Two caregivers place air-assisted device under patient. **C,** Patient rolls to opposite side while other caregiver unrolls air-assisted device. **D,** Secure safety straps.

http://obgynebooks.com

STEP	RATIONALE
(8) On count of three, two caregivers pull drawsheet or patient from bed onto stretcher while third person holds slide board in place. Using the friction-reducing slide board, shift weight from front to back foot (see illustration). Position patient in center of stretcher.	Transfers patient smoothly and efficiently to the stretcher.
(9) Put up side rail of stretcher on side where caregivers are, roll stretcher away from side of bed, and put side rail up on that side.	Side rails prevent patient from falling off stretcher.
(10) Cover patient with sheet or blanket.	Promotes comfort and preserves patient dignity.
(11) Perform hand hygiene.	Reduces transmission of microorganisms.
(12) Following transfer, evaluate patient's body alignment.	Prompt identification of poor alignment reduces risks to patient's skin and musculoskeletal systems.
2. Perform hand hygiene.	Reduces transmission of microorganisms.

EVALUATION

1. Evaluate vital signs. Ask if patient feels tired or dizzy.	Evaluates patient's response to postural changes and activity.
2. Observe for correct body alignment and presence of pressure points on skin.	Minimizes risk for immobility complications.
3. Ask if patient experienced pain during transfer; measure current pain level.	Determines need for additional pain control or alteration of technique of transferring.
4. Use **Teach Back** to determine patient and family understanding about safe transfer techniques. State, "I want to be sure I explained how using the slide board prevents the risk for injury while we care for you. Can you explain to me the importance of using the slide board when we transfer you to a stretcher?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient and family are able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Patient sustains injury on transfer.
   - Evaluate incident that caused injury (e.g., assessment inadequate, change in patient status, improper use of equipment).
   - Complete occurrence report according to institution policy.
2. Patient's level of weakness does not permit active transfer.
   - Obtain help from additional nursing personnel.
   - Increase bed activity and exercise to heighten tolerance.
3. Patient transfers well on some occasions, poorly on others.
   - Assess patient for factors that affect ability to transfer (e.g., pain, fatigue, confusion) before transfer.
   - Allow for a rest period before transferring, medicate for pain if indicated, or reorient patient.

STEP 1e(8) **A,** Transfer of patient from bed to stretcher using slide board. **B,** Inflating air-assisted transfer device. **C,** Transfer of patient using air-assisted transfer device.

SKILL 39-1	USING SAFE AND EFFECTIVE TRANSFER TECHNIQUES—cont'd

RECORDING AND REPORTING

- Record procedure, including pertinent observations: weakness, ability to follow directions, weight-bearing ability, balance, ability to pivot, number of personnel needed to assist, and amount of assistance (muscle strength) required in nurses' notes.
- Report any unusual occurrence to nurse in charge. Report transfer ability and assistance needed to next shift or other caregivers. Report progress or transfer difficulties to rehabilitation staff (physical therapist or occupational therapist).
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- Teach family how to use safe patient–handling equipment if necessary.
- Teach patient and family about the importance of safety while helping patients with mobility.

KEY POINTS

- Exercise is physical activity for the purpose of conditioning the body, improving health, and maintaining fitness; it also is a therapeutic measure.
- Deconditioning is a particular risk for hospitalized patients who spend most of their time in bed even when they are able to walk.
- The best program of physical activity includes a combination of exercises that produces different physiological and psychological benefits.
- Body mechanics are the coordinated efforts of the musculoskeletal and nervous systems as the person moves, lifts, bends, stands, sits, lies down, and completes daily activities.
- Coordinated body movement requires integrated functioning of the skeletal system, skeletal muscles, and nervous system.
- Coordination and regulation of muscle groups depend on muscle tone and activity of antagonistic, synergistic, and antigravity muscles.
- The nervous system controls balance through the functions of the cerebellum and inner ear.
- You achieve body balance when there is a wide base of support, the center of gravity falls within the base of support, and a vertical line falls from the center of gravity through the base of support.
- Developmental changes, behavioral aspects, environmental issues, cultural origin, and family and social support influence the patient's perception and motivation to engage in physical activity and exercise.
- Use the nursing process to provide care for patients who are experiencing or are at risk for activity intolerance and impaired physical mobility.
- After identifying nursing diagnoses, plan and implement interventions to increase activity and exercise in collaboration with the patient when possible.
- ROM exercises incorporated into daily activities include one or all of the body joints.
- Apply proper algorithms when you transfer and lift patients.
- Assistive devices to promote walking include canes, walkers, and crutches.

CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

Mrs. Smith has experienced some success in losing weight. She states, "I feel like I should have lost more weight by now." However, she expresses concern about how to incorporate exercise into her daily routine to maintain weight and assist with future weight loss.

1. Mrs. Smith states, "It is hard for me to determine exactly how much exercise I get doing my usual activities." She also expresses feelings of overwhelming stress and excessive demands on her time. Which interventions do you suggest to Mrs. Smith to help assess her current level of exercise?
2. Recognizing the challenges Mrs. Smith has voiced in balancing the excessive demands on her time and incorporating an exercise program. Develop some strategies to help initiate and maintain daily exercise.
3. Develop a feedback method for Mrs. Smith, emphasizing her success in exercise and maintaining a healthy weight.

ⓔ *Answers to Clinical Application Questions can be found on the Evolve website.*

REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. A nurse is instructing a patient who has decreased leg strength on the left side how to use a cane. Which action indicates proper cane use by the patient?
    1. The patient keeps the cane on the left side of the body.
    2. The patient slightly leans to one side while walking.
    3. The patient keeps two points of support on the floor at all times.
    4. After the patient places the cane forward, he or she then moves the right leg forward to the cane.
2. The body alignment of the patient in the tripod position includes the following: (Select all that apply.)
    1. An erect head and neck
    2. Straight vertebrae
    3. Extended hips and knees
    4. Axillae resting on the crutch pads
    5. Bent knees and hips
3. A patient is experiencing some problems with joint stability. The doctor has prescribed crutches for the patient to use while still being allowed to bear weight on both legs. Which of the following gaits should the patient be taught to use?
    1. Four-point
    2. Three-point
    3. Two-point
    4. Swing-through

4. Which of the following *most* motivates a patient to participate in an exercise program?
   1. Providing a patient with a pamphlet on exercise
   2. Providing information to the patient when he or she is ready to change behavior
   3. Explaining the importance of exercise at the time of diagnosis of a chronic disease
   4. Providing the patient with a booklet with examples of exercises
   5. Providing the patient with a prescribed exercise program

5. Which of the following is a principle of proper body mechanics when lifting or carrying objects? (Select all that apply.)
   1. Keep the knees in a locked position.
   2. Bend at the waist to maintain a center of gravity.
   3. Maintain a wide base of support.
   4. Hold objects away from the body for improved leverage.
   5. Encourage patient to help as much as possible.

6. The nurse recognizes that the older adult's progressive loss of total bone mass and tendency to take smaller steps with feet kept closer together will most likely:
   1. Increase the patient's risk for falls and injuries.
   2. Result in less stress on the patient's joints.
   3. Decrease the amount of work required for patient movement.
   4. Allow for mobility in spite of the aging effects on the patient's joints.

7. A nurse plans to provide education to the parents of school-age children, which includes the increased prevalence of _____ as a result of children being less physically active outside of school.

8. A nursing assistive personnel asks for help to transfer a patient who is 125 lbs (56.8 kg) from the bed to a wheelchair. The patient is unable to help. What is the nurse's best response?
   1. "As long as we use proper body mechanics, no one will get hurt."
   2. "The patient only weighs 125 lbs. You don't need my assistance."
   3. "Call the lift team for additional assistance."
   4. "The two of us can lift the patient easily."

9. Which of the following statements made by an older adult reflects the best understanding of the need to exercise regardless of age?
   1. "You are never too old to begin an exercise program."
   2. "My granddaughter and I walk together around the high school track 3 times a week."
   3. "I purchased a subscription to a runner's magazine for my grandson for Christmas."
   4. "When I was a child, I exercised more than I see kids doing today."

10. Which is the correct gait when a patient is ascending stairs on crutches?
    1. A modified two-point gait. (The affected leg is advanced between the crutches to the stairs.)

2. A modified three-point gait. (The unaffected leg is advanced between the crutches to the stairs.)
    3. A swing-through gait
    4. A modified four-point gait. (Both legs advance between the crutches to the stairs.)

11. Before transferring a patient from the bed to a stretcher, which assessment data do the nurse need to gather? (Select all that apply.)
    1. Patient's weight
    2. Patient's level of cooperation
    3. Patient's ability to assist
    4. Presence of medical equipment
    5. Nutritional intake

12. A patient with a right knee replacement is prescribed no weight bearing on the right leg. You reinforce crutch walking knowing that which of the following crutch gaits is most appropriate for this patient?
    1. Two-point gait
    2. Three-point gait
    3. Four-point gait
    4. Swing-through gait

13. Which of the following indicates that additional assistance is needed to transfer the patient from the bed to the stretcher?
    1. The patient is 5 feet 6 inches and weighs 120 lbs.
    2. The patient speaks and understands English.
    3. The patient is returning to unit from recovery room after a procedure requiring conscious sedation.
    4. The patient received analgesia for pain 30 minutes ago.

14. The nurse encourages a patient with type 2 diabetes to engage in a regular exercise program primarily to improve the patient's:
    1. Gastric motility, thereby facilitating glucose digestion.
    2. Respiratory effort, thereby decreasing activity intolerance.
    3. Overall cardiac output, thereby resuming resting heart rate.
    4. Use of glucose and fatty acids, thereby decreasing blood glucose level.

15. Musculoskeletal disorders are the most prevalent and debilitating occupational health hazards for nurses. To reduce the risk for these injuries, the American Nurses Association advocates which of the following?
    1. Mandate that physical therapists do all patient transfers
    2. Require adequate staffing levels in health care organizations
    3. Require the use of assistive equipment and devices
    4. Require an adequate number of staff to be involved in all patient transfers

Answers: 1. 3; **2.** 1, 2, 3; **3.** 1; **4.** 2; **5.** 3, 5; **6.** 1; **7.** Childhood obesity; **8.** 3; **9.** 2; **10.** 2; **11.** 1, 2, 3, 4; **12.** 2; **13.** 3; **14.** 4; **15.** 3.

Personal hygiene affects patients' comfort, safety, and well-being. Hygiene care includes cleaning and grooming activities that maintain personal body cleanliness and appearance. Personal hygiene activities such as taking a bath or shower and brushing and flossing the teeth also promote comfort and relaxation, foster a positive self-image, promote healthy skin, and help prevent infection and disease. Healthy people are usually able to meet their own hygiene needs. However, physical or cognitive impairments and emotional challenges often cause individuals to need some degree of assistance with hygiene care. A variety of personal, social, and cultural factors influence hygiene practices.

In agency and home care settings, assess a patient's ability to perform self–hygiene care according to individual needs and preferences. Adaptations may be needed for hygiene techniques and approaches for patient care. Integrate nursing assessments and interventions during hygiene care with nursing activities such as range of motion (ROM), dressing changes, and inspection and care of intravenous (IV) sites. Because hygiene care requires close contact with your patients, use communication skills to build caring, therapeutic relationships. Provide any needed teaching or counseling for patients.

During hygiene care ensure privacy, convey respect, and provide safety and comfort.

SCIENTIFIC KNOWLEDGE BASE

Proper hygiene care requires an understanding of the anatomy and physiology of the skin, nails, oral cavity, eyes, ears, and nose. The skin and mucosal cells exchange oxygen, nutrients, and fluids with underlying blood vessels. The cells require adequate nutrition, hydration, and circulation to resist injury and disease. Good hygiene techniques promote the normal structure and function of these tissues.

Apply knowledge of pathophysiology to provide preventive hygiene care. Recognize disease states that create changes in the integument, oral cavity, and sensory organs. For example, diabetes mellitus often results in chronic vascular changes that impair healing of the skin and mucosa. In the early stages of acquired immunodeficiency syndrome (AIDS), fungal infections of the oral cavity are common. Paralysis of the trigeminal nerve (cranial nerve V) eliminates the blink reflex, causing risk of corneal drying. In the presence of conditions such as these, adapt hygiene practices to minimize injury. Use time spent

TABLE 40-1 **Function of the Skin and Implications for Care**	
Function/Description	**Implications for Care**
Protection Epidermis is a relatively impermeable layer that prevents entrance of microorganisms. Although microorganisms reside on skin surface and in hair follicles, relative dryness of surface of skin inhibits bacterial growth. Sebum removes bacteria from hair follicles. Acidic pH of skin further retards bacterial growth.	• Weakening of the epidermis occurs by scraping or stripping its surface (e.g., use of dry razors, tape removal, improper turning or positioning techniques). • Excessive dryness causes cracks and breaks in skin and mucosa that allow bacteria to enter. Emollients soften skin and prevent moisture loss, soaking skin improves moisture retention, and hydrating mucosa prevents dryness. • Constant exposure of skin to moisture causes maceration or softening, interrupting dermal integrity and promoting ulcer formation and bacterial growth. • Keep bed linen and clothing dry. • Misuse of soap, detergents, cosmetics, deodorant, and depilatories cause chemical irritation. Alkaline soaps neutralize the protective acid condition of skin. Cleaning skin removes excess oil, sweat, dead skin cells, and dirt, which promote bacterial growth.
Sensation Skin contains sensory organs for touch, pain, heat, cold, and pressure.	• Minimize friction to avoid loss of stratum corneum, which results in development of pressure ulcers. • Smooth linen out to remove sources of mechanical irritation. • Remove rings from fingers to prevent accidentally injuring patient's skin. • Make sure that bath water is not excessively hot or cold.
Temperature Regulation Radiation, evaporation, conduction, and convection control body temperature.	• Factors that interfere with heat loss alter temperature control. Wet bed linen or gowns interfere with convection and conduction. Excess blankets or bed coverings interfere with heat loss through radiation and conduction. Coverings promote heat conservation.
Excretion and Secretion Sweat promotes heat loss by evaporation. Sebum lubricates skin and hair.	• Perspiration and oil harbor microorganisms. • Bathing removes excess body secretions; although, if excessive, it causes dry skin.

providing hygiene care to identify abnormalities and initiate appropriate actions to prevent further injury to sensitive tissues.

The Skin

The skin serves several functions, including protection, secretion, excretion, body temperature regulation, and cutaneous sensation (Table 40-1). It consists of two primary layers: the epidermis and the dermis. Just beneath the skin lies the subcutaneous tissue (also known as the hypodermis), which shares some of the protective functions of the skin.

Several thin layers of epithelial cells comprise the outer layer, or **epidermis**; these cells shield underlying tissue against water loss and injury and prevent entry of disease-producing microorganisms. The innermost layer of the epidermis generates new cells to replace the dead cells that the outer surface of the skin continuously sheds. Bacteria commonly reside on the outer epidermis. These resident bacteria are normal flora (see Chapter 29) that do not cause disease but instead inhibit the multiplication of disease-causing microorganisms.

Bundles of collagen and elastic fibers form the thicker dermis that underlies and supports the epidermis. Nerve fibers, blood vessels, sweat glands, sebaceous glands, and hair follicles run through the dermal layers. Sebaceous glands secrete sebum, an oily, odorous fluid, into the hair follicles. Sebum softens and lubricates the skin and slows water loss from the skin when the humidity is low. More important, sebum has bactericidal action.

The subcutaneous tissue layer contains blood vessels, nerves, lymph, and loose connective tissue filled with fat cells. The fatty tissue functions as a heat insulator for the body. Subcutaneous tissue also supports upper skin layers to withstand stresses and pressure without

injury and anchors the skin loosely to underlying structures such as muscle. Very little subcutaneous tissue underlies the oral mucosa.

The skin often reflects a change in physical condition by alterations in color, thickness, texture, turgor, temperature, and hydration (see Chapter 31). As long as the skin remains intact and healthy, its physiological function remains optimal. Hygiene practices frequently influence skin status and can have beneficial and negative effects on the skin. For example, too-frequent bathing and use of hot water frequently leads to dry, flaky skin and loss of protective oils.

The Feet, Hands, and Nails

The feet, hands, and nails often require special attention to prevent infection, odor, and injury. The condition of a patient's hands and feet influences the ability to perform hygiene care. Without the ability to bear weight, ambulate, or manipulate the hands, the patient is at risk for losing self-care ability.

A wide range of dexterity exists in the hand because of the movement between the thumb and fingers. Any condition (e.g., arthritis, multiple sclerosis, traumatic hand injury) that interferes with hand movement (e.g., superficial or deep pain or joint inflammation) impairs a patient's self-care abilities. Foot pain often changes a patient's gait, causing strain on different joints and muscle groups. Discomfort while standing or walking limits self-care abilities.

The nails grow from the root of the nail bed, which is located in the skin at the nail groove, hidden by the fold of skin called the cuticle. A scalelike modification of the epidermis forms the visible part of the nail (nail body), which has a crescent-shaped white area known as the lunula. Under the nail lies a layer of epithelium called the *nail bed*. A normal healthy nail appears transparent, smooth, and convex, with a

pink nail bed and translucent white tip. Disease causes changes in the shape, thickness, and curvature of the nail (see Chapter 31).

The Oral Cavity

The oral cavity consists of the lips surrounding the opening of the mouth, the cheeks running along the sidewalls of the cavity, the tongue and its muscles, and the hard and soft palate. The mucous membrane, continuous with the skin, lines the oral cavity. The floor of the mouth and the undersurface of the tongue are richly supplied with blood vessels. Normal oral mucosa glistens and is pink, soft, moist, smooth, and without lesions. Ulcerations or trauma frequently results in significant bleeding. Several glands within and outside the oral cavity secrete saliva. Saliva cleanses the mouth, dissolves food chemicals to promote taste, moistens food to facilitate bolus formation, and contains enzymes that start breakdown of starchy foods. The effects of medications, exposure to radiation, dehydration, and mouth breathing impair salivary secretion in the mouth. Strong sympathetic nervous system stimulation almost completely inhibits the release of saliva and results in **xerostomia** or dry mouth.

The teeth lie in sockets in the gum-covered mandible and maxilla; they tear and grind ingested food so it can be mixed with saliva and swallowed for digestion. A normal tooth consists of the crown, neck, and root. The enamel-covered crown extends above the gingiva or gum, which normally surrounds the tooth like a tight collar. A constricted part of the tooth called the *neck* connects the crown and the root; the root is embedded in the jawbone. The periodontal membrane lies just below the gum margins, surrounds a tooth, and holds it firmly in place. Healthy teeth are white, smooth, shiny, and properly aligned.

Difficulty in chewing develops when surrounding gum tissues become inflamed or infected or when teeth are lost or become loosened. Regular oral hygiene helps to prevent **gingivitis** (i.e., inflammation of the gums) and **dental caries** (i.e., tooth decay produced by interaction of food with bacteria).

The Hair

Hair growth, distribution, and pattern indicate a person's general health status. Hormonal changes, nutrition, emotional and physical stress, aging, infection, and some illnesses affect hair characteristics. The hair shaft itself is lifeless, and physiological factors do not affect it directly. However, hormonal and nutrient deficiencies of the hair follicle cause changes in hair color or condition.

The Eyes, Ears, and Nose

When providing hygiene, the eyes, ears, and nose require careful attention because of sensitive anatomical structures. For example, the cornea of the eye contains many nerve endings sensitive to irritants such as soap. Chapter 31 describes the structure and function of these organs.

NURSING KNOWLEDGE BASE

A number of factors influence personal preferences for hygiene and the ability to maintain hygiene practices. Since no two individuals perform hygiene care in the same manner, you individualize patient care on the basis of learning about his or her unique hygiene practices and preferences. Individualized hygiene care requires knowing the patient and using therapeutic communication skills to promote a trusting therapeutic relationship. Use the opportunities provided during hygiene care to assess a patient's health promotion practices, emotional status, and health care education needs and then offer educational interventions. Be aware that developmental changes influence the need and preferences for type of hygiene care.

Factors Influencing Hygiene

Social Practices. Social groups influence hygiene preferences and practices, including the type of hygiene products used and the nature and frequency of personal care practices. An example is the choice by adolescent girls of the type of sanitary pads used during menstruation (Kamaljit et al., 2012). Parents and caregivers perform hygiene care for infants and young children. Family customs play a major role during childhood in determining hygiene practices such as the frequency of bathing, the time of day bathing is performed, and even whether certain hygiene practices such as brushing the teeth or flossing are performed. As children enter adolescence, peer groups and media often influence hygiene practices. For example, some young girls become more interested in their personal appearance and begin to wear makeup. During the adult years involvement with friends and work groups shapes the expectations that people have about personal appearance. Some older adults' hygiene practices change because of changes in living conditions and available resources.

Personal Preferences. Patients have individual preferences about when to perform hygiene and grooming care. Some patients prefer to shower, whereas others prefer to bathe. Patients select different hygiene and grooming products according to personal preferences. Knowing patients' personal preferences promotes individualized care. Culture plays a role in sensitivity to personal space and gender (see Box 40-1 and Chapter 9). Help a patient develop new hygiene practices when indicated by an illness or condition. For example, you may need to teach a patient with diabetes proper foot hygiene or a bariatric patient adaptive bathing methods. Safe and effective patient-centered nursing care improves patient satisfaction and health and reduces costs (Burman et al., 2013).

Body Image. Body image is a person's subjective concept of his or her body, including physical appearance, structure, or function (see Chapter 34). Body image affects the way in which individuals maintain personal hygiene. If a patient maintains a neatly groomed appearance, be sure to consider the details of grooming when planning care and consult with the patient before making decisions about how to provide hygiene. Patients who appear unkempt or uninterested in hygiene sometimes need education about its importance or further assessment regarding their ability to participate with daily hygiene.

Surgery, illness, or a change in emotional or functional status often affects a patient's body image. Discomfort and pain, emotional stress, or fatigue diminish the ability or desire to perform hygiene self-care and require extra effort to promote hygiene and grooming.

Socioeconomic Status. A person's economic resources influence the type and extent of hygiene practices used. Be sensitive in considering that a patient's economic status influences the ability to regularly maintain hygiene. He or she may not be able to afford desired basic supplies such as deodorant, shampoo, and toothpaste. A patient may need to modify the home environment by adding safety devices such as nonskid surfaces and grab bars in the bath to perform hygiene self-care safely. When patients lack socioeconomic resources, it becomes difficult for them to participate and take responsible roles in health promotion activities such as basic hygiene.

Health Beliefs and Motivation. Knowledge about the importance of hygiene and its implications for well-being influences hygiene practices. However, knowledge alone is not enough. Motivation also plays a key role in a patient's hygiene practices. Patient teaching is often needed to foster hygiene self-care. Provide information that focuses on a patient's personal health-related issues relevant to the desired hygiene

🌐 BOX 40-1   CULTURAL ASPECTS OF CARE

Hygiene Practices

Patients deserve a culturally congruent plan for hygiene care. For many patients culture influences hygiene practices, and hygiene care becomes a potential source of conflict and stress in the caregiving environment. Patient-centered care mandates that care be based on respect for an individual patient's cultural background (Douglas et al., 2014). A nurse must also consider other aspects of culture such as a patient's educational and developmental levels, extent of any physical disabilities, and geographical location of home when delivering hygiene.

Implications for Patient-Centered Care

- Maintain privacy, especially for women from cultures that value female modesty (e.g., Asian, Muslim, Hispanic, Nigerian) (Giger, 2013).
- Avoid uncovering the lower torso and exposing the arms of Middle Eastern and East Asian women.
- Allow family members to participate in care if desired by adapting the schedule of hygiene activities.
- Provide gender-congruent caregivers as needed or requested.
- Recognize that some cultures prohibit or restrict touching. Incorporate awareness that people from different cultural backgrounds have differing preferences regarding personal space. In some cases touch is considered magical and healing; others view it as evil or anxiety producing (Giger, 2013).
- Do not cut or shave hair without prior discussion with patient or family because of cultural or religious beliefs (e.g., Muslims) (Giger, 2013).
- Be aware that toileting practices vary by culture (Giger, 2013).
- Recognize that different cultures (e.g., Hindu, Asians, Hispanics) have preferences about hot and cold water and their effects on healing or diseases (Giger, 2013).

care behaviors. Patient perceptions of the benefits of hygiene care and the susceptibility to and seriousness of developing a problem affect the motivation to change behavior (Pender et al., 2011). For example, do patients perceive that they are at risk for dental disease, or that dental disease is serious, and that brushing and flossing are effective in reducing risk? When they recognize that there is a risk and that they can take reasonable action without negative consequences, they are more likely to be receptive to nurses' counseling and teaching efforts.

Cultural Variables. Cultural beliefs and personal values influence hygiene care (Box 40-1). People from diverse cultural backgrounds (e.g., level of education, gender preference, geographic location) frequently follow different self-care practices (see Chapter 9). For example, maintaining cleanliness does not hold the same importance for some ethnic or social groups as it does for others (Giger, 2013). In North America many are fortunate to be able to bathe or shower daily and use deodorant to prevent body odors. However, people from some socioeconomic or cultural groups are not sensitive to body odors, prefer to bathe less frequently, and do not use deodorant. Do not express disapproval when caring for patients whose hygiene practices differ from yours. Avoid forcing changes in hygiene practices unless the practices affect a patient's health. In these situations use tact, provide information, and allow choices. Some homeless people may be reluctant to remove shoes for bathing or to check for skin breakdown. Their feet may be edematous or have neuropathic symptoms (Chen et al., 2014).

Religious beliefs associated with culture sometimes influence hygiene practices. Middle Eastern practices encourage one hand to be kept clean at all times. Muslim patients often remove their shoes and assume different positions for prayer. This increases the risk of developing foot pathology such as calluses on the toes and lateral ankles. When caring for Muslim patients who have diabetes mellitus, you need to be supportive of religious practices while also stressing the need to be diligent in inspecting the feet after prayer sessions for any blisters or calluses.

Developmental Stage.   The normal process of aging affects the condition of body tissues and structures. A patient's developmental stage affects the ability of a patient to perform hygiene care and the type of care needed.

Skin.   The neonate's skin is relatively immature at birth. The epidermis and dermis are bound together loosely, and the skin is very thin. Friction against the skin layers causes bruising. Handle a neonate carefully during bathing. Any break in the skin easily results in an infection.

A toddler's skin layers become more tightly bound together. Thus the child has a greater resistance to infection and skin irritation. However, because of his or her more active play and the absence of established hygiene habits, parents and caregivers need to provide thorough hygiene and teach good hygiene habits.

During adolescence the growth and maturation of the integument increases. In girls estrogen secretion causes the skin to become soft, smooth, and thicker with increased vascularity. In boys male hormones produce an increased thickness of the skin with some darkening in color. Sebaceous glands become more active, predisposing adolescents to acne (i.e., active inflammation of the sebaceous glands accompanied by pimples). Sweat glands become fully functional during puberty. Adolescents usually begin to use antiperspirants. More frequent bathing and shampooing also become necessary to reduce body odors and eliminate oily hair.

The condition of the adult's skin depends on bathing practices and exposure to environmental irritants. Normally the skin is elastic, well hydrated, firm, and smooth. When an adult bathes frequently or is exposed to an environment with low humidity, it becomes dry and flaky. With aging the rate of epidermal cell replacement slows, and the skin thins and loses resiliency. Moisture leaves the skin, increasing the risk for bruising and other types of injury. As the production of lubricating substances from skin glands decreases, the skin becomes dry and itchy (Touhy and Jett, 2014). These changes warrant caution when bathing, turning, and repositioning older adults. Too-frequent bathing and bathing with hot water or harsh soap cause the skin to become excessively dry (American Academy of Dermatology, 2014).

Feet and Nails.   With aging and continued exposure to the trauma of walking and weight bearing, a patient is more likely to develop chronic foot problems compounded as a result of poor foot care, improper fit of footwear, and local abnormalities and systemic disease. For example, Morton's neuroma, a common condition in middle-age women, affects health-related quality of life by causing burning, numbness, and pain of the foot on weight bearing (Edwards et al., 2015). Painful feet in older adults result from a variety of congenital deformities, weak structure, and diseases such as diabetes and rheumatoid arthritis (Green, 2014).

Older adults do not always have the strength, flexibility, visual acuity, or manual dexterity to care for their feet and nails. Foot problems may be overlooked and impact a patient's comfort, mobility, and quality of life (Chan et al., 2012). Older adults frequently complain of foot pain. They also often have dry feet because of a decrease in sebaceous gland secretion and dehydration of epidermal cells. Common problems of the feet affecting older adults include corns, calluses,

bunions, hammertoes, maceration between toes, and fungal infections (Stolt et al., 2013).

The Mouth. At approximately 6 to 8 months of age, infants begin teething. The first permanent (secondary) teeth erupt at about 6 years of age (Hockenberry and Wilson, 2013). From adolescence, when all of the permanent teeth are in place, through middle adulthood, the teeth and gums remain healthy if a person follows healthy eating patterns and dental care. Avoiding fermentable carbohydrates and sticky sweets helps to keep the teeth free of caries. In addition, regular brushing (twice a day) and flossing reduce caries and periodontal disease.

As a person ages, numerous factors result in poor oral health, including age-related changes of the mouth, chronic disease such as diabetes, physical disabilities involving hand grasp or strength affecting the ability to perform oral care, lack of attention to oral care, and prescribed medications that have oral side effects. Gums lose vascularity and tissue elasticity, which may cause dentures to fit poorly.

Hair. Throughout life changes in the growth, distribution, and condition of the hair influence hair hygiene. As males reach adolescence, shaving becomes a part of routine grooming. Young girls who reach puberty often begin to shave their legs and axillae. With aging, as scalp hair becomes thinner and drier, shampooing is usually performed less frequently.

Eyes, Ears, and Nose. Chapter 49 addresses changes in hearing, vision, and olfaction across the life span as a result of growth and development. Alterations in sensory function often require modifications in hygiene care. Use your knowledge of developmental changes when planning hygiene care.

Physical Condition. Patients with certain types of physical limitations or disabilities associated with disease and injury lack the physical energy and dexterity to perform hygiene self-care safely. A patient whose arm is in a cast or who has an IV line needs help with hygiene care. A weakened grasp resulting from arthritis, stroke, or muscular disorders makes using a toothbrush, washcloth, or hairbrush difficult or ineffective. Sensory deficits not only alter a patient's ability to perform care but also place the patient at risk for injury. Safety is a priority for a patient with a sensory deficit. For example, the inability to feel that the water is too hot can lead to a burn injury during bathing.

Chronic illnesses such as cardiac, pulmonary, and neurological diseases; cancer; dementia; and some mental health illnesses often exhaust or incapacitate patients. Patients who become tired or short of breath frequently need to have complete hygiene care provided. Include periods of rest during care to allow patients who are tired the opportunity to participate in their care. Pain often accompanies illness and injury, limiting a patient's ability to tolerate hygiene and grooming activities or perform self-care. Pain frequently limits ROM, resulting in impaired use of the arms or hands or limited ability to move about in the environment, impairing the ability to perform hygiene self-care. Sedation and drowsiness associated with analgesics used for pain management also limit a patient's ability to safely participate in care.

Limited mobility caused by a variety of factors (e.g., obesity, physical injury, weakness, surgery, pain, prolonged inactivity, medication effect, and presence of medical devices [e.g., indwelling catheter, feeding tube, or IV line]) decreases a patient's ability to perform hygiene self-care activities safely. Individualized care considers a patient's ability to perform care, the amount of assistance needed, and the need for assistive and safety devices to facilitate safe hygiene care.

Acute and chronic cognitive impairments such as stroke, brain injury, psychoses, and dementia often result in the inability to perform self-care independently. When people with cognitive impairments are unaware of their hygiene and grooming needs, they become fearful

and agitated during hygiene care, resulting in aggressive behavior (Zimmerman et al., 2014). Safe, effective patient care takes the effect of cognitive impairment on hygiene care into consideration and allows for appropriate modifications.

CRITICAL THINKING

Effective critical thinking requires synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require you to anticipate the information necessary to analyze data and make decisions regarding care. A patient's condition is always changing, requiring ongoing critical thinking. During assessment consider all factors to include to make appropriate nursing diagnoses (Figure 40-1). Apply the elements of critical thinking as you use the nursing process to meet patients' hygiene needs.

Integrate nursing knowledge with knowledge from other disciplines. For example, a patient with diabetes mellitus has special needs

Knowledge
- Anatomy and physiology of integument, oral cavity, and sense organs
- Principles of comfort and safety
- Communication principles that convey caring
- Risk factors posing hygiene problems
- Knowledge of cultural variations in hygiene

Experience
- Prior experience caring for patients requiring assistance with hygiene
- Personal hygiene practices

ASSESSMENT
- Observe the patient's physical condition and integrity of integument, oral cavity, and sense organs
- Explore any developmental factors influencing the patient's hygiene needs
- Note the patient's self-care ability and hygiene practices
- Determine the patient's cultural preferences, values, and beliefs regarding hygiene

Standards
- Apply ADA's practice standards for foot care
- Apply WOCN and NPUAP guidelines on prevention and management of pressure ulcers
- Assess any skin alterations using accurate and consistent measurements

Attitudes
- Display curiosity; be thorough in assessing the condition of the patient's tissues; changes may indicate signs of disease
- Display humility; hygiene care should be patient-centered; know when to learn more about the patient's preferences

FIGURE 40-1 Critical thinking model for hygiene assessment. *ADA,* American Diabetes Association; *NPUAP,* National Pressure Ulcer Advisory Panel; *WOCN,* Wound, Ostomy and Continence Nurses Society.

for nail and foot care. Knowledge about the pathophysiology of diabetes and its potential effects on his or her peripheral circulation and sensory status provides the scientific knowledge base needed to implement safe and effective foot care. In addition, integrate knowledge about developmental and cultural influences as you identify and meet hygiene needs.

Be aware of the impact of critical thinking attitudes as you plan and implement care. For example, think creatively to help patients adapt existing hygiene practices or develop new ones when illness, loss of function, or decreased activity tolerance impairs self-care abilities. Be nonjudgmental and confident when providing care. Because of variations in individual patients' physical status and hygiene practices, you need to approach care with an attitude of flexibility. For example, when caring for a patient who is tired, you pace activities and plan rest periods during bathing to prevent exhaustion.

Draw on your own experiences as you help with your patients' hygiene care. Reflect on times when you helped family members or others close to you with their hygiene. Usually an early clinical experience involves providing or helping with hygiene care for a patient. Finally rely on professional standards such as those for skin and foot care from the American Diabetes Association (ADA) and specialty nursing groups such as the Wound Ostomy and Continence Nurses Society (WOCN) when planning care to meet a patient's hygiene needs. As your experience and knowledge grow, your comfort and expertise in meeting the individualized hygiene needs of your patients increase.

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care.

◆ Assessment

Thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe hygiene care. Assessment of a patient's hygiene status and self-care abilities requires you to complete a nursing history and perform a physical assessment (see Chapter 31). You do not assess all body regions routinely before providing hygiene. However, conduct a brief history to determine priority areas (e.g., an obese patient's skinfolds, a trauma patient's skin condition) and help you plan individualized hygiene care. Assessment of a patient's ability to provide hygiene self-care helps you make decisions about the kind and amount of hygiene care to provide and how much the patient can be encouraged to participate in care.

Through the Patient's Eyes. Providing safe, quality hygiene care requires a complete awareness of the patient's perspective. Because patients have varying expectations, you need to avoid making personal hygiene care a simple routine. Complete a nursing history that not only elicits personal preferences but also addresses the patient's cultural or religious customs and beliefs.

Explore a patient's viewpoint regarding hygiene care by asking him or her about preferred personal hygiene and grooming practices. Ask about personal care products desired and preferences such as frequency, time of day, and amount of assistance needed. Also ask questions such as, "To make you most comfortable and feel at home, how can I best perform your bath and personal care?" Determine the patient's awareness of any hygiene-related problems and his or her knowledge and ability to perform hygiene care measures (Box 40-2).

BOX 40-2   Nursing Assessment Questions

Cultural and/or Religious Practices
- Do you have preferences for how you bathe or clean your teeth?
- How comfortable are you with someone helping you, with how we care for you?
- In what way can I best help you with your bath, hair care. …?

Tolerance of Hygiene Activities
- Does bathing cause any symptoms such as shortness of breath, pain, or fatigue?
- What can I do to minimize these symptoms?
- Which aspects of bathing or toothbrushing cause discomfort or fatigue?

Assistance with Hygiene
- Do you use any aids to help you with your bath such as grab bars in your tub or shower?
- Do you prefer someone of the same gender to help in your hygiene care?
- Which parts of the bath, toothbrushing, and foot care can you do for yourself? With which parts of hygiene care do you need help?

Skin Care
- Which type of bath do you prefer?
- How often and when do you usually bathe?
- What kind of soap and lotion do you use?
- Have you noticed any skin changes or irritation?
- Do you have any known allergies or reactions to soaps, cosmetics, or skin care products?

Mouth Care
- Do you have any mouth pain or toothaches, have you noticed any sores in your mouth, do your gums bleed during brushing or flossing?
- Do you wear dentures or a partial plate?

Foot and Nail Care
- How do you usually care for your feet and nails? Do you soak your feet?
- Do you file or trim your own fingernails and toenails?

Hair and Scalp Care
- Have you recently experienced itching of the scalp or noticed flaking or dandruff?
- Have you noticed any changes in the texture or thickness of your hair?

Learning a patient's expectations and applying them in practice fosters a caring relationship. Fully individualizing hygiene care shows your respect for the patient's needs. As you learn what the patient expects, you incorporate this information into a plan of care.

Assessment of Self-Care Ability. Assess a patient's physical status as it relates to ability to perform or assist with hygiene care safely and efficiently; include assessment of the patient's muscle strength, flexibility, balance, visual acuity, and ability to detect thermal and tactile stimuli. Determine your patient's mental status, including orientation and cognitive function (see Chapter 31). A patient with impaired cognitive function may be unaware of hygiene care needs or less able to follow instructions and help with care. Observe the patient performing hygiene care, noting complaints or physical manifestations that suggest activity intolerance. Assess respiratory rate and effort, skin color, and pulse rate. Ask questions to assess the patient for dizziness, weakness, or fatigue. To determine the amount of assistance the patient needs, observe him or her performing care activities such as brushing teeth or combing hair (Figure 40-2). Patients who have limited

FIGURE 40-2 Nurse observes patient brushing teeth. During such observations the nurse can determine how much assistance the patient may need.

upper-extremity mobility, reduced vision, fatigue, or inability to grasp small objects require help. Patients having difficulty with manual dexterity and cognitive function are likely to show deterioration in physical or oral health (Burns, 2012). Also note the presence of medical devices such as feeding tubes, IV lines, or urinary catheters. These devices require special hygiene measures.

When patients have self-care limitations, family may help with care. Determine how the family can help the patient, how often they can provide this assistance, and their feelings about being caregivers. In addition, assess the home environment and its influence on the patient's hygiene practices. Are there barriers in the home that affect his or her self-care abilities (e.g., water faucets that are too tight to adjust easily, bathtubs with high sides, a bathroom too small to fit a chair in front of a sink, and lack of adjustable bed or adaptive equipment available for assisting with bathing).

Assessment of the Skin. Perform an assessment of the skin (see Chapter 31), noting color, texture, thickness, turgor, temperature, and hydration. In the healthy person the skin is smooth, warm, and supple with good turgor. Pay special attention to the presence and condition of any lesions. Note dryness indicated by flaking, redness, scaling, and cracking. Also carefully inspect the skin in contact with any medical device at least daily (e.g., skin under an oxygen cannula or the nasal mucosa under an endotracheal or feeding tube) (NPUAP, 2013). Look for edema under the sites. Discovering manifestations of common skin problems influences how you administer hygiene care (Table 40-2).

Determine the degree of cleanliness by observing the appearance of the skin and detecting body odors that can indicate inadequate cleansing or excessive perspiration caused by fever or pain. Inspect less obvious or difficult-to-reach skin surfaces such as under the breasts or scrotum, around the female patient's perineum, or in the groin for redness, excessive moisture, and soiling or debris. Separate skinfolds for observation and palpation. Cornstarch may be used to decrease friction and absorb moisture (Cowell and Radley, 2014).

Be attentive to characteristics of skin problems most influenced by hygiene measures. Is the skin dry from too much bathing or from use of hot water or irritating soap? Does the patient have a rash caused by an allergic reaction to a skin care product? Certain conditions place patients at risk for impaired skin integrity (Table 40-3). Because of increased risk be particularly alert when assessing patients with reduced sensation, impaired circulation, nutrition or hydration alterations, body secretions, incontinence, altered cognition, external medical

devices, and decreased mobility. Patients may be unaware of skin problems because they are unable to feel pain or pressure or see their skin in some places (e.g., the back or the feet). Carefully assess the skin under orthopedic devices (braces, splints, casts) and beneath items such as antiembolic stockings and tape. Assess the condition and cleanliness of the perineal and anal areas during hygiene care and when the patient requires toileting assistance. When prolonged contact of urine or feces occurs such as with diarrhea or incontinence, skin breakdown often results. Most people consider these areas private; therefore be sensitive in your approach (Touhy and Jett, 2012).

When caring for patients with dark skin pigmentation, be aware of assessment techniques and skin characteristics unique to highly pigmented skin (Ball et al., 2015). Carefully assess the skin in dark-skinned patients at risk for pressure ulcers (see Chapter 48).

Assessment of the Feet and Nails. A variety of common foot and nail problems can be caused by inadequate hygiene and are actually detected during hygiene care. Problems sometimes result from abuse or poor care of the feet and hands such as nail biting or trimming nails improperly, exposure to harsh chemicals, and wearing poorly fitting shoes. Question the patient to determine type of footwear and usual foot and nail care practices.

Examine all skin surfaces of the feet, including the areas between the toes and over the entire sole of the foot. Poorly fitting shoes often irritate the heels, soles, and sides of the feet. Inspection of the feet for lesions includes noting areas of dryness, inflammation, or cracking. Chronic foot problems are common in older adults who often experience dry feet because of a decrease in sebaceous gland secretion, dehydration, or poor condition of footwear.

People are often unaware of foot or nail problems until pain or discomfort occurs. Assess patients with diseases that affect peripheral circulation and sensation for the adequacy of circulation and sensation of the feet. Foot ulceration is the most common single precursor to lower-extremity amputations among people with diabetes (Jarrett, 2013). Daily inspection and preventive foot care help maintain ulcer-free feet. Palpate the dorsalis pedis and posterior tibial pulses and assess for intact sensation to light touch, pinprick, and temperature (Ball et al., 2015).

Observe a patient's gait. Painful foot disorders or decreased sensation cause limping or an unnatural gait. Ask whether the patient has foot discomfort and determine factors that aggravate the pain. Foot problems sometimes result from bone or muscular alterations or wearing poorly fitting footwear.

Inspect the condition of the fingernails and toenails, looking for lesions, dryness, inflammation, or cracking, which are often associated with a variety of common foot and nail problems (Table 40-4). The cuticle that surrounds the nail can grow over it and become inflamed if nail care is not performed correctly and periodically. Ask women whether they polish their nails and use polish remover frequently because chemicals in these products cause excessive nail dryness. Disease changes the shape and curvature of the nails (Ball et al., 2015). Inflammatory lesions and fungus of the nail bed cause thickened, horny nails that separate from the nail bed.

Assessment of the Oral Cavity. The condition of the oral cavity reflects overall health and also indicates oral hygiene needs. Inspect all areas of the mouth carefully for color, hydration, texture, and lesions (see Chapter 31). Patients frequently develop common oral problems as a result of inadequate oral care or disease (e.g., oral malignancy) or as a side effect of treatments such as radiation and chemotherapy. These problems include receding gum tissue, inflamed gums (gingivitis), a coated tongue, **glossitis** (inflamed tongue), discolored teeth

TABLE 40-2 Common Skin Problems		
Characteristics	**Implications**	**Interventions**
Dry Skin		
Flaky, rough texture on exposed areas such as hands, arms, legs, or face	Skin becomes infected if epidermal layer cracks.	Bathe less frequently. Rinse body of all soap because residue left on skin can cause irritation and breakdown. Add moisture to air with use of humidifier. Increase fluid intake when skin is dry. Use moisturizing cream to aid healing. (Cream forms protective barrier and helps maintain fluid within skin.) Use creams to clean skin that is dry or allergic to soaps and detergents.
Acne		
Inflammatory, papulopustular skin eruption, usually involving bacterial breakdown of sebum; appears on face, neck, shoulders, and back	Infected material within pustule spreads if area is squeezed or picked. Permanent scarring can result.	Wash hair and skin thoroughly each day with warm water and soap to remove oil. Use cosmetics sparingly. Oily cosmetics or creams accumulate in pores and make condition worse. Implement dietary restrictions if necessary. (Eliminate foods that aggravate condition from diet.) Use prescribed topical antibiotics for severe forms of acne.
Skin Rashes		
Skin eruptions that result from overexposure to sun or moisture or from allergic reaction (flat or raised, localized or systemic, pruritic or nonpruritic)	If skin is scratched continually, inflammation and infection may occur. Rashes also cause discomfort.	Wash area thoroughly and apply antiseptic spray or lotion to prevent further itching and aid in healing process. Apply warm or cold soaks to relieve inflammation if indicated.
Contact Dermatitis		
Inflammation of skin characterized by abrupt onset with erythema; pruritus; pain; and appearance of scaly, oozing lesions (seen on face, neck, hands, forearms, and genitalia)	Dermatitis is often difficult to eliminate because person is usually in continual contact with substance causing skin reaction. Substance is often hard to identify.	Avoid causative agents (e.g., cleansers and soaps).
Abrasion		
Scraping or rubbing away of epidermis that results in localized bleeding and later weeping of serous fluid	Infection occurs easily because of loss of protective skin layer.	Be careful not to scratch patient with jewelry or fingernails. Wash abrasions with mild soap and water; dry thoroughly and gently. Observe dressing or bandage for retained moisture because it increases risk of infection.

(particularly along gum margins), **cheilitis** (cracked lips), dental caries, missing teeth, and **halitosis** (foul-smelling breath). Localized pain and infection commonly accompany oral problems. Apply clean gloves to palpate any tender areas or lesions. Observe for cleanliness and use olfaction to detect halitosis. If you identify any oral problems, notify the patient's health care provider. Early identification of poor oral hygiene practices and common oral problems reduces the risk for gum disease and dental caries (USDHHS, 2015). If the older adult becomes **edentulous** (i.e., without teeth) and wears complete or partial dentures, include an assessment of underlying gums and palate.

Assessment of the Hair and Hair Care. Assess the condition of a patient's hair and scalp before performing hair care. Findings help determine the frequency and type of care needed. You can anticipate certain patients who might require a more focused assessment such as a patient who has had head trauma or a homeless patient not able to perform regular hygiene. Normally the hair is clean, shiny, and untangled; and the scalp is clear of lesions. Table 40-5 summarizes hair and scalp problems with implications and interventions.

Observe a patient's ability to perform hair care. A person's appearance and feeling of well-being often are related to the way the hair looks and feels. Illness, disability, and conditions such as arthritis, fatigue, obesity, and the presence of physical barriers (e.g., cast or IV access) alter a patient's ability to maintain daily hair care.

In community health and home care settings it is particularly important to inspect the hair for lice so you can provide appropriate hygienic treatment. If you suspect **pediculosis capitis** (head lice), guard against self-infestations by hand hygiene and using gloves or tongue blades to inspect the patient's hair.

The loss of hair (**alopecia**) results from the effects of chemotherapy medications, hormonal changes, or improper hair care practices. Alopecia often appears as brittle and broken hair in the hair line that progresses to bald patches. If noted, be sure to question the patient about specific hair care practices, especially the use of chemicals and heat application during hair care.

Assessment of the Eyes, Ears, and Nose. Examine the condition and function of the eyes, ears, and nose (see Chapter 31). The

TABLE 40-3   Risk Factors for Hygiene Care

Risks	Hygiene Implications
Oral Problems	
Inability to use upper extremities because of paralysis, weakness, or restriction (e.g., cast, dressing)	Patient lacks upper-extremity strength or dexterity needed to brush teeth (Lewis et al., 2014).
Dehydration, inability to take fluids or food by mouth (NPO)	Dehydration causes excess drying and fragility of mucosa; increases accumulation of secretions on tongue and gums.
Presence of nasogastric or oxygen tubes; mouth breathers	Tubes cause pressure, friction, and drying of mucosa and/or lips.
Chemotherapeutic drugs	Drugs kill rapidly multiplying cells, including normal cells lining oral cavity. Ulcers and inflammation develop.
Lozenges, cough drops, antacids, and chewable over-the-counter vitamins	Medications contain large amounts of sugar. Repeated use increases sugar or acid content in mouth, causing dental caries.
Radiation therapy to head and neck	Radiation therapy reduces salivary flow and lowers pH of saliva; leads to stomatitis and tooth decay (Lewis et al., 2014).
Oral surgery, trauma to mouth, placement of oral airway	These cause trauma to oral cavity with swelling, ulcerations, inflammation, and bleeding.
Immunosuppression; altered blood clotting	These predispose to inflammation and bleeding gums.
Diabetes mellitus	Patients are prone to dryness of mouth, gingivitis, periodontal disease, and loss of teeth.
Endotracheal intubation with mechanical ventilation	Potential for ventilator-associated pneumonia (VAP) exists. Use of chlorhexidine gluconate (CHG) reduces risk of VAP. CHG is an inexpensive effective agent for reducing VAP, especially in patients who have heart surgery (Nicolosi et al., 2014).
Dialysis	Oral problems commonly found in these patients include halitosis, xerostomia (dry mouth), gingivitis, stomatitis, tooth decay, tooth loss, and jaw problems. Causes may include elevated blood sugar, weight control, and smoking (Genco, 2014).
Skin Problems	
Immobilization	Dependent body parts are exposed to pressure from underlying surfaces. The inability to turn or change position increases risk for pressure ulcers.
Bariatric patient	Patient cannot visualize skin properly and keep it clean and dry. Excessive adipose tissue creates pressure from weight, lack of air circulation, and an increase in moisture with poor tissue perfusion (Cowell and Radley, 2014).
Reduced sensation caused by stroke, spinal cord injury, diabetes, local nerve damage	Patient unable to sense skin injury. Does not receive normal transmission of nerve impulses when applying excessive heat or cold, pressure, friction, or chemical irritants to skin.
Altered cognition resulting from dementia, psychological disorders, or temporary delirium	Patient unable to verbalize skin care needs. Does not realize effect of pressure or prolonged contact with excretions or secretions, requiring more vigilant assessment.
Limited protein or caloric intake and reduced hydration (e.g., fever, burns, gastrointestinal alterations, poorly fitting dentures)	Predispose to impaired tissue synthesis. Skin becomes thinner, less elastic, and smoother with loss of subcutaneous tissue. Poor wound healing results. Reduced hydration impairs skin turgor.
Excessive secretions or excretions on skin from perspiration, urine, watery fecal material, and wound drainage	Moisture is medium for bacterial growth and causes local skin irritation, softening of epidermal cells, and skin maceration.
Presence of external medical devices (e.g., cast, restraint, bandage, dressing)	Devices such as casts, cloth restraints, bandages, tubing, and orthopedic devices exert pressure or friction against surface of skin.
Vascular insufficiency	Arterial blood supply to tissues is inadequate, or venous return is impaired, causing decreased circulation to extremities. Tissue ischemia and breakdown often occur. Risk for infection is high.
Foot Problems	
Patient unable to bend over or has reduced visual acuity	Patient is unable to fully visualize entire surface of each foot, impairing ability to adequately assess condition of skin and nails.
Eye Care Problems	
Reduced dexterity and hand coordination	Physical limitations create inability to safely insert or remove contact lenses.

TABLE 40-4   Common Foot and Nail Problems

Characteristics	Implications	Interventions
Callus Thickened part of epidermis consists of mass of horny, keratotic cells. Callus is usually flat, painless, and found on undersurface of foot or palm of hand.	Local friction or pressure causes callus formation, which causes discomfort when wearing tight shoes.	Recommend soft-sole shoes with insoles. Advise patient to wear gloves when using tools or objects that create friction on palmar surfaces. Advise patients, especially with callus formation, not to self-treat but seek interventions from a podiatrist.
Corns Friction and pressure from ill-fitting or loose shoes cause keratosis. It is seen mainly on or between toes, over bony prominence. Corn is usually cone shaped, round, and raised. Soft corns are macerated.	Compresses the underlying dermis, making it thin and tender. Pain is aggravated when wearing tight shoes. Tissue becomes attached to bone if allowed to grow. Resultant pain causes an alteration in gait.	Surgical removal is necessary, depending on severity of pain and size of corn. Avoid use of oval corn pads, which increase pressure on toes and reduce circulation. Warm water soaks soften corns before gentle rubbing with a callus file or pumice stone. (Consult with health care provider. Not allowed with patients with diabetes.) Wider and softer shoes, with wider toe box, are helpful.
Plantar Warts Fungating lesion appears on sole of foot and is caused by papilloma virus.	Some warts are contagious. They are painful and make walking difficult.	Treatment ordered by health care provider often includes applications of salicylic acid, electrodessication (burning with electrical spark), or freezing with solid carbon dioxide.
Athlete's Foot (Tinea Pedis) Athlete's foot is fungal infection of foot; scaling and cracking of skin occurs between toes and on soles of feet. Small blisters containing fluid appear.	Athlete's foot spreads to other body parts, especially hands. It is contagious and frequently recurs.	Make sure that feet are well ventilated. Drying feet well after bathing and applying powder help prevent infection. Wearing clean socks or stockings reduces incidence. Health care provider orders application of griseofulvin, miconazole, or tolnaftate.
Ingrown Nails Toenail or fingernail grows inward into soft tissue around nail. Ingrown nail often results from improper nail trimming.	Ingrown nails cause localized pain when pressure is applied.	Treatment is frequent warm soaks in antiseptic solution and removal of part of nail that has grown into skin. Instruct patient in proper nail-trimming techniques and refer to podiatrist.
Foot Odors Foot odors are result of excess perspiration, promoting microorganism growth.	Condition causes discomfort because of excess perspiration.	Frequent washing, use of foot deodorants and powders, and wearing clean footwear prevent or reduce problem.

healthy eye is not inflamed and is without drainage. The presence of redness indicates allergic or infectious conjunctivitis, which can be highly contagious. The crusty drainage associated with conjunctivitis easily spreads from one eye to the other. Wear clean gloves to examine the eyes and perform proper hand hygiene before and after the examination. Determine if a patient wears contact lenses, especially when he or she enters the health care agency in an unresponsive or confused state. To determine if a contact lens is present, stand to the side of the patient's eyes and observe the corneas for the presence of a soft or rigid lens. Also observe the sclera because the lens may have shifted off the cornea. An undetected contact lens causes corneal injury when left in place too long.

Assessment of the external ear structures includes inspection of the auricle and external ear canal (see Chapter 31). Observe for the presence of accumulated **cerumen** (earwax) or drainage in the ear canal and local inflammation. Question patients about tenderness on palpation or the presence of pain and ask how they usually clean their ears.

Inspect the nares for signs of inflammation, discharge, lesions, edema, and deformity (see Chapter 31). The nasal mucosa is normally pink and clear and has little or no discharge. Allergies cause a clear, watery discharge. If patients have any form of tubing exiting the nose

(e.g., nasogastric), observe for edema, skin ulceration, localized tenderness, inflammation, drainage, and bleeding where the tubing comes in contact with the nares.

Use of Sensory Aids. For patients who wear eyeglasses, contact lenses, artificial eyes, or hearing aids, assess their knowledge and methods used for care and have them describe the typical approach used in routine care. When possible observe a patient perform care. Compare information gathered from him or her with the proper care technique for these devices. Any difference between patient and standard practice provides an opportunity for patient education.

Assessment of Hygiene Care Practices. Assessment of hygiene practices reveals a patient's preferences for grooming. For example, a patient chooses to groom the hair in a certain style or trim nails in a certain way. When a patient has a physical disability, special precautions may be necessary to perform grooming without injury. For example, teach patients with loss of sensation to file nails instead of clipping. By observing a patient perform hygiene care, you can detect any needed areas of teaching or assistance while maintaining the patient's maximal level of independence.

TABLE 40-5 Hair and Scalp Problems

Characteristics	Implications	Interventions
Dandruff Scaling of scalp is accompanied by itching. In severe cases dandruff is on eyebrows.	Dandruff causes embarrassment. If it enters eyes, conjunctivitis often develops.	Shampoo regularly with medicated shampoo. In severe cases obtain health care provider's advice.
Ticks Small, gray-brown parasites burrow into skin and suck blood.	Ticks transmit several diseases to people. Most common are Rocky Mountain spotted fever, tularemia, and Lyme disease.	Using blunt tweezers, grasp tick as close to the head as possible and pull upward with even, steady pressure. Hold until tick pulls out, usually for about 3-4 minutes. Save tick in plastic bag and put in freezer if it is necessary to identify type of tick.
Pediculosis (Lice) *Pediculosis Capitis (Head Lice)* Parasite resides on scalp attached to hair strands. Eggs look like oval particles, similar to dandruff. Bites or pustules may be observed behind ears and at hairline.	Head lice are difficult to remove and spread to furniture and other people if not treated. They do not carry disease, cannot fly or jump, and are carried by animals.	Wearing gloves, check entire scalp by using tongue depressor or special lice comb. Use medicated shampoo for eliminating lice. *Caution against use of products containing lindane because the ingredient is toxic and known to cause adverse reactions* (CDC, 2015). Manual removal is best option when treatment has failed. Vacuum infested areas of home.
Pediculosis Corporis (Body Lice) Parasites tend to cling to clothing; thus they are not always easy to see. Body lice suck blood and lay eggs on clothing and furniture.	Patient itches constantly. Scratches seen on skin become infected. Hemorrhagic spots appear on skin where lice are sucking blood.	Bathe or shower thoroughly. After skin is dried, apply recommended pediculicide lotion. After 12 to 24 hours take another bath or shower. Bag infested clothing or linen until laundered in hot water. Vacuum rooms thoroughly and throw away bag after completion.
Pediculosis Pubis (Crab Lice) Parasites are in pubic hair. Crab lice are gray-white with red legs.	Lice spread through bed linen, clothing, or furniture or between people via sexual contact.	Shave hair off affected area. Clean as for body lice. If lice were sexually transmitted, notify partner.
Hair Loss (Alopecia) Alopecia occurs in all races. Balding patches are in periphery of hair line. Hair becomes brittle and broken.	Patches of uneven hair growth and loss alter patient's appearance.	Stop hair care practices that damage hair. Use of hair curlers, hair picks, tight braiding, and hot comb contributes to hair-loss condition.

Assessment of Cultural Influences. Ask what makes a patient feel most comfortable during a bath or other hygiene measures. Perhaps he or she prefers a partial instead of a full bath from a nurse, with a family member completing the bathing of more private body parts. Some patients also defer part of hygiene. If you believe that hygiene is critical to prevent developing or worsening problems such as skin breakdown, take the time to understand the patient's concerns and then offer an explanation that helps him or her accept your intervention. For example, many institutions are using chlorhexidine gluconate (CHG) for daily bathing. CHG can leave the skin feeling sticky. If patients complain about its use, you need to explain their vulnerability to infection and how CHG helps reduce occurrence of health care–associated infection. Consider a patient's level of literacy and be sure that you have adapted your assessment questions to a level the patient can understand.

Patients at Risk for Hygiene Problems. Some patients present risks that require more attentive and rigorous hygiene care (see Table 40-3). These risks result from side effects of medications or other medical therapy; a lack of knowledge; immobilization; an inability to perform hygiene; or a physical condition that potentially injures the skin, mouth, feet and nails, or hair. Anticipate whether a patient is predisposed to risks and follow through with a complete assessment. For example, if a patient is receiving cancer chemotherapy, there is a risk of the medication producing mouth ulcerations, which are painful and create a risk for infection and impaired nutrition because of reluctance to eat and drink. A patient who receives broad-spectrum antibiotics may develop an opportunistic infection when the normal flora of the mouth is disrupted by the antibiotic. Be thorough and detailed during the oral examination, checking all surfaces of the tongue and mucosa. For a bariatric patient or a patient who is diaphoretic, provide special attention to body areas such as beneath the woman's breasts and in the groin, skinfolds, and perineal area, where moisture collects and irritates skin surfaces (Cowell and Radley, 2014). Assessment should include a review of a patient's medical and surgical history, medications, and the specific risk factors that the patient presents.

◆ Nursing Diagnosis

Thorough assessment of a patient's hygiene status and self-care abilities identifies clusters of risk factors or defining characteristics that support actual or at-risk hygiene-related diagnoses. Identification of the defining characteristics or risk factors leads you to select the NANDA

BOX 40-3 **Nursing Diagnostic Process**

Bathing Self-Care Deficit

Assessment Activities	Findings/Defining Characteristics
Observe patient attempt to bathe self.	Patient is unable to wash lower body, back, or perineal area.
Assess patient's upper-extremity strength and range of motion.	Patient has restricted upper-extremity range of motion and weakness. Patient has difficulty turning in bed by self or reaching items needed. Patient is unable to turn water faucets on and off.
Observe patient's ability to move from bed to bathroom and maneuver in bathroom.	Patient cannot transfer from bed to chair without assistance, cannot ambulate, relies on wheelchair to move around, is unable to maneuver wheelchair in bathroom without help or transfer to shower seat unassisted. Patient may need lift equipment for transfers.

International diagnostic label (Herdman and Kamitsuru, 2014) that best communicates the individual patient's situation. For example, when caring for an older adult with degenerative arthritis, you observe swollen joints, weakness, and limited ROM in the dominant hand along with a generally unkempt appearance. Closer review of data reveals defining characteristics of an inability to wash body parts and difficulty turning and regulating a water faucet. The nursing diagnosis of *Bathing Self-Care Deficit* becomes part of the plan of care. Accurate selection of nursing diagnoses requires critical thinking to identify actual or potential problems. Be thorough in assessment to reveal all appropriate defining characteristics or risk factors so you can make an accurate diagnosis (Box 40-3).

Use a patient's actual alteration (e.g., *Impaired Tissue Integrity*) or the alteration for which the patient is at risk (e.g., *Risk for Infection*) to determine the focus of nursing interventions. A patient with an actual alteration requires extensive hygiene care, often more thorough than routine hygiene. For example, if a patient has skin breakdown, initiate care more frequently to keep skin surfaces clean and dry and eliminate factors such as moisture or drainage. Also provide care to promote healing of injured skin surfaces (see Chapter 48). If a patient is at risk for a problem, take preventive measures. For example, if a patient is at risk for developing an infection in his or her mouth and has the nursing diagnosis *Risk for Infection,* keep the mucosa well hydrated, minimize foods irritating to tissues, and provide cleaning that soothes and reduces tissue inflammation.

Completing a nursing diagnosis requires identification of the related factor (for an actual diagnosis or optional for a risk diagnosis), which will guide your selection of nursing interventions. A diagnosis of *Impaired Oral Mucous Membrane related to malnutrition* and a diagnosis of *Impaired Oral Mucous Membrane related to chemical trauma* require different interventions. When poor nutrition is a causal factor, you need to consult with a dietitian for appropriate dietary supplements and incorporate patient education into the plan. When chemotherapy injures the oral mucosa, you follow cancer nursing guidelines regarding care for oral **mucositis** (i.e., painful inflammation of oral mucous membranes), including frequent gentle brushing with a soft toothbrush, flossing, rinsing with bland rinse, limiting diet to soft foods, and applying water-based moisturizer to lips (USDHHS, 2015). Although many possible nursing diagnoses apply to patients in need

Knowledge
- Principles of comfort and safety
- Patient's usual routines and preferences
- Adult learning principles to apply when educating the patient and family
- Services available through community agencies

Experience
- Care of previous patients who required adaptation of hygiene approaches

PLANNING
- Involve the patient and family in planning and adapting approaches, as well as in hygiene instruction
- Know community resources applicable for the patient's needs
- Consider the timing of other care activities when choosing the best time for hygiene care

Standards
- Individualize hygiene care to meet patient preferences
- Apply standards of safety and promotion of patient dignity

Attitudes
- Be creative when adapting approaches to any self-care limitations the patient might have
- Take responsibility for following standards of good hygiene practice

FIGURE 40-3 Critical thinking model for hygiene planning.

of supportive hygiene care, the following list represents examples of diagnoses commonly associated with these problems:

- *Activity Intolerance*
- *Bathing Self-Care Deficit*
- *Dressing Self-Care Deficit*
- *Impaired Physical Mobility*
- *Impaired Oral Mucous Membrane*
- *Ineffective Health Maintenance*
- *Risk for Infection*
- *Risk for Impaired Skin Integrity*

◆ **Planning**

During planning synthesize information from multiple resources (Figure 40-3). Critical thinking ensures that a patient's plan of care integrates all that is known about the individual patient and key critical thinking elements. In many situations patients present with multiple nursing diagnoses. Use a concept map (Figure 40-4) to visualize and understand how nursing diagnoses interrelate. Rely on knowledge, experience, and established standards of care when developing a care plan. Remember critical thinking attitudes such as creativity when developing a patient-centered plan for hygiene care. Consciously include the patient in this important step of the nursing process. Partner with a patient to identify patient goals and outcomes, set priorities for care, and select evidence-based interventions. Consider continuity of care and involve other health care team members (e.g., occupational or physical therapy) when developing the plan.

Previous experience with other patients is useful in knowing how to adapt hygiene techniques for special needs. Professional standards

CONCEPT MAP

Nursing diagnosis: Bathing: self-care deficit
- Decreased ROM
- Unable to bathe self, wash hair or care for feet
- BMI 40

Interventions
- Preserve independence and dignity
- Control pain and fatigue prior to bathing
- Assess ROM and strength
- Use adaptive equipment—bath sponge, brush, long handle cloth
- Assist patient with equipment—provide care where needed

Nursing diagnosis: Risk for infection
- Diabetic neuropathy
- Recent surgery
- BMI 40

Interventions
- Assess postoperative wound
- Keep skin folds clean and dry
- Provide proper nutrition/fluids
- Turn and position every 2 hours
- Assess for pressure areas on skin

Primary health problem: Recent colon resection, bariatric patient, immobility, diabetic neuropathy
Priority assessments: Pain, functional assessment for ADLs/bathing, ROM

Nursing diagnosis: Impaired skin integrity
- Related to excessive skin folds and pressure from weight
- Recent surgical incision

Interventions
- Teach patient to assess skin with mirror
- Obtain bariatric bed
- Turn and position every 2 hours
- Check tubes, lines, drains for pressure areas when repositioning patient
- Conduct Braden skin assessment per agency policy
- Use bath-aides, towels, emollients, moisturizer, powders

Nursing diagnosis: Impaired physical mobility
- Related to BMI 40, inability to stand or walk unassisted, or turn self in bed

Interventions
- Assess for adequate staff and proper equipment before moving patient
- Use correct size bed and wheelchair
- Consult PT and OT to assist with evaluation of adaptive equipment
- Identify areas to wash in different positions
- Initiate fall precautions

——— Link between medical diagnosis and nursing diagnosis   - - - - Link between nursing diagnoses

FIGURE 40-4 Concept map for Mrs. White. *ADLs,* Activities of daily living; *BMI,* body mass index; *OT,* occupational therapist; *PT,* physical therapist; *ROM,* range of motion.

guide selection of the most effective nursing interventions. These standards often establish evidence-based guidelines for care.

Goals and Outcomes. Partner with the patient and family to identify goals and expected outcomes to develop a mutually agreed-on plan of care based on the patient's nursing diagnoses (see the Nursing Care Plan). For example, establish goals with the patient's self-care abilities and resources in mind and focus on maintaining or improving the condition of the skin and oral cavity. Make outcomes measurable and achievable within patient limitations. In addition, work with the patient to select individualized hygiene measures.

When providing patient hygiene, you will care for a variety of patients with different self-care abilities and needs. For example, a

nurse and a patient who has one-sided paralysis following a cerebral vascular accident develop the following goal: "Patient will be able to groom self (dress and bathe) before discharge." The nurse establishes realistic, individualized expected outcomes to measure the patient's progress toward meeting this goal. These outcomes may include the following:
- Patient is able to bathe in front of sink.
- Patient uses assist devices (bathing mitt and long handled sponge) for bathing.
- Patient dresses self, using dressing stick and sock aid.

Setting Priorities. A patient's condition influences your priorities for hygiene care. Set priorities based on the necessary assistance

⊚ **NURSING CARE PLAN**

Bathing Self-Care Deficit

ASSESSMENT

Mrs. White is a 70-year-old female admitted with abdominal pain and a change in bowel habits. She is now post op day 2 after a colon resection. Mrs. White has been transferred out of the intensive care unit (ICU) onto the surgical unit. She has become progressively weaker since her surgery. Her mobility is limited because of her abdominal discomfort and obesity, although she can walk short distances. Mrs. White has diabetes, a history of hypertension, and body mass index of 40. She prefers staying in bed because she states that she feels tired, weak, and sore. However, the physician has ordered ambulation to begin, and physical therapy is helping her learn to use a walker. Mrs. White states that her buttocks, thigh, and skinfolds feel inflamed with a pain score of 7/10. She lives alone, but her grand-daughter is going to nursing school and has offered to help her at home.

Assessment Activities	*Findings/Defining Characteristics**
Ask Mrs. White what hygiene care is important this morning.	Mrs. White says, "I want to **feel clean** and **smell good."**
Assess Mrs. White's skin condition.	On visual inspection the student nurse observes **redness at elbows and under breasts and thighs.** The abdominal incision is dry and pink, and the sutures are well approximated.
Assess Mrs. White's ability to bathe, including an assessment of her range of motion (ROM) and upper- and lower-extremity strength.	Mrs. White is unable to gather bath supplies because of her immobility. She can stand and walk to the bathroom sink but is unable to wash her entire body. Mrs. White states that she has **difficulty visualizing areas of her body.** She perspires easily. Her **arms are restricted with decreased ROM** and have **decreased sensation** because of her **diabetic neuropathy.** Mrs. White states that her pain level is 7/10 when moving side to side in bed since her surgery.

*Defining characteristics** are shown in bold type.

NURSING DIAGNOSIS: Bathing self-care deficit related to immobility associated with obesity; body mass index (BMI) 40, limited ROM, diabetic neuropathy, and pain score of 7/10

PLANNING

Goals	*Expected Outcomes (NOC)[†]*
	Self-Care: Bathing
Mrs. White will remain free of body odor.	Mrs. White self-reports feeling clean and refreshed after bathing each day.
Mrs. White will maintain intact skin during hospitalization.	Skin is clean and dry skin without skin breakdown between skinfolds.
	Mrs. White describes personal risk factors for impaired skin integrity.
Mrs. White will describe best method to bathe using adaptive devices by discharge.	Mrs. White states two ways to use adaptive equipment during her bath by discharge. She bathes herself, using a bath mitt and mirror.
Mrs. White will accept help from a family caregiver to assist with hygiene care within the next week.	Mrs. White reports satisfaction with assistance in bathing by family caregiver.

[†]Outcome classification labels from Moorhead S et al: *Nursing outcomes classification (NOC),* ed 5, St Louis, 2013, Mosby.

INTERVENTIONS (NIC)[‡]	**RATIONALE**
Self-Care Assistance: Bathing/Hygiene	
Administer prn ordered oral analgesic before bath; begin bath 30 minutes later.	Patient participation in bathing or other self-care activities will improve with pain control. Give prn pain medication before pain is severe (Bulechek et al., 2013).
Help patient shower and place her on a shower seat. Demonstrate for patient use of wash mitt with soap pocket. Offer a mirror with long handle to improve view of foot surfaces. Stay close by to prevent an accidental fall.	Using a wash mitt with a soap pocket or a wall-mounted soap dispenser minimizes difficulty of manipulating soap and a washcloth. A shower seat or bath bench makes it easier for patient to focus on washing rather than on balance required for standing (Sokol-McKay, 2013).
Bathing Option: Consider using prepackaged bath/chlorhexidine gluconate (CHG) wipes for bed bath if patient cannot tolerate shower.	Bath wipes are easy to use and disposable and require no rinsing. Skin can air dry. Daily bathing with CHG wipes decreases hospital-acquired infections (Singh and Subhashni, 2013).
	Keeping skin clean and dry helps to avoid risk of friction and shearing and decreases moisture from sweat glands that become blocked, causing bacteria and fungi infections on skin to occur (Cowell and Radley, 2014).
Teach Mrs. White reasons that she is vulnerable for impaired skin integrity: perspiration, obesity, effects of diabetes, immobility, and changes in skin from aging.	Self-efficacy (i.e., a person's judgment about what one thinks one can accomplish with knowledge and skills) (Bandura, 1997) affects self-care performance, especially if tasks and circumstances are not ambiguous.
Teach patient and granddaughter (as needed) how to use adaptive equipment for bathing and safe patient-handling skills and how to perform skin assessments. Have Mrs. White plan hygiene schedule with granddaughter.	Family members who are taught methods to meet patient's bathing needs increase patient satisfaction, making the experience safe, easy, less stressful. Appropriate assistive devices encourage independence. Return demonstration identifies problem areas and increases self-confidence. Teach Back ensures that patient and family understand the importance of skin integrity and infection control to minimize risks for the obese patient with diabetes (Cowell and Radley, 2014). Individuals in supportive social relationships are happier and healthier than those socially isolated. Providing help that addresses the needs and desires of a patient is uplifting to a caregiver (Schulz and Sherwood, 2008).

[‡]Intervention classification labels from Bulechek GM et al: *Nursing interventions classifications (NIC),* ed 6, St Louis, 2013, Mosby.

⊚ **NURSING CARE PLAN**

Bathing Self-Care Deficit—cont'd

EVALUATION

Nursing Actions	*Patient Response/Finding*	*Achievement of Outcome*
Ask Mrs. White why it is important for her to inspect skin and have regular bathing. Inspect Mrs. White's skin after she bathes in shower and assess for any remaining body odor.	Mrs. White states that she now knows she is at risk for infection because she is overweight and has diabetes. She also knows her risk for infection is higher in the hospital. Mrs. White's skin is clear without irritation under breasts and perineum. Had difficulty cleansing back and bottom of feet, but no signs of irritation. No apparent odor. Patient expresses sense of feeling clean. Because Mrs. White is older, she has learned that she need not bathe daily. She and granddaughter have planned to have a bath every 3 days in the evening after granddaughter returns from work. Granddaughter is able to explain correct technique for helping patient with walker and transferring to and from shower chair.	Mrs. White is able to identify her personal risk factors for infection if she does not bathe properly. Mrs. White requires assistance with bathing in areas of body she could not reach. Will refer to occupational therapy for an appropriate assistive device with long handle. Mrs. White has a realistic plan for bathing at home. Granddaughter demonstrates knowledge of safe patient handling. Consultation note will be written for home health nurse to check granddaughter's skin assessment skills.

required by the patient, the extent of the hygiene-related problems, and the nature of the patient's nursing diagnoses. For example, a seriously ill patient usually needs a daily bath because body secretions accumulate and the patient is unable to maintain cleanliness independently. Some older patients at home require a visit from a home care aide to help with a tub bath or shower. Patients who are normally inactive during the day and have skin that tends to be dry may need to bathe only twice a week, whereas a patient with urinary and bowel incontinence needs perineal cleaning with each episode of soiling. Plan to help patients who are weakened or possess poor coordination. For example, a patient who is partially paralyzed and has difficulty getting out of a tub needs a tub chair, handrails, or extra personnel available for help.

Timing is also important in planning hygiene care. Being interrupted in the middle of a bath often frustrates and embarrasses a patient. Assess for cultural preferences on time of day or who may help patient with hygiene care.

Teamwork and Collaboration. If a patient is hospitalized, plan care before discharge to home, a rehabilitation facility, or extended care. Provide clear directions for family caregivers or staff who will be assuming the patient's care so the appropriate equipment and hygiene supplies can be used. Be sure that caregivers know any physical or cognitive limitations that will affect their ability to provide safe, effective hygiene care. For example, does the patient require assistance to get into a tub or shower, does the patient have reduced sensation making him or her at risk for burns from hot water, and can the patient remember steps to follow for proper foot care? Collaborate with other health team members as indicated (e.g., work with physical and occupational therapy to enhance the patient's independence with self-care activities).

When a patient needs assistance as a result of a self-care limitation and family members are the ones to provide it, proper education and preparation should be included in the plan of care. Family members also need guidance in adapting techniques to fit patient limitations. Be aware of equipment and procedures used in the agency so the patient and family are knowledgeable about the care, have the skills needed to provide it, and have access to necessary equipment. Depending on a patient's limitations, some insurance plans provide home care assistants to help with basic hygiene needs. Explore this option with the patient and family members.

Collaborate with community agencies as needed. For example, the nurse involved in the care of a homeless patient needs to be aware of the location of clothing distribution centers for basic hygiene supplies, a shelter where bathing facilities are available, and any organization

that offers free health care or reduced fees. Partner with social workers or staff in local area churches, not-for-profit organizations, and schools to be sure that patients have the resources they need to maintain hygiene.

◆ **Implementation**

Hygiene is a part of basic patient care. When you use caring practices to perform hygiene measures, you reduce the patient's anxiety and promote comfort and relaxation. For example, use a gentle approach when giving patients their baths and changing gowns as you turn and reposition them. A soft, gentle voice when conversing with patients relieves fears or concerns. For patients suffering symptoms such as pain or nausea, administering medications to relieve the symptoms before providing hygiene helps to maintain patient comfort during procedures.

Consider the stress that hygiene care can cause and be alert for any cues of embarrassment or anxiety. Some patients fear pain or are frightened about falling or sustaining injury associated with hygiene care.

Implementation also focuses on assisting and preparing patients to be able to perform as much of their hygiene care as they can independently. Teach patients proper hygiene techniques and how their use is associated with better health. Discuss any signs and symptoms of hygiene problems. Inform patients about available resources in the community for dealing with these problems if they arise. Always use Teach Back during instruction to confirm their understanding.

Health Promotion. In primary health care situations educate and counsel patients and caregivers on why proper hygiene techniques are necessary. For example, a new mother needs to learn how to bathe her newborn to reduce risk of skin irritation and infection, whereas an older adult needs information on the importance of regular ear care to avoid accumulated cerumen and hearing impairment. The hygiene skills described throughout this chapter provide standards for excellent physical care. When caring for patients in primary health care settings, maintain these standards and incorporate adaptations as needed to meet the patient's lifestyle, functional status, living arrangements, and preferences. Key points when teaching patients about hygiene include the following:

- Make any instruction relevant on the basis of your assessment of the patient's knowledge, motivation, preferences, and health beliefs. For example, when teaching a patient with diabetes, include how circulation to the feet is impaired and how this causes poor healing and infection, especially when the skin is

injured or broken. Use the Teach Back method to ensure that the patient understands skin care.

- Adapt instruction to a patient's personal bathing facilities and resources. Not all patients have the ideal situation that exists in a health care setting (e.g., easily accessible shower or a bedside table to place over a bed). Adapt available resources so the patient can reach and use needed items comfortably and safely. For example, a young mother has more room and believes that bathing her infant is safer if she uses her kitchen sink and counter rather than her bathroom sink.
- Teach patients ways to avoid injury. Almost any hygiene procedure poses risks (e.g., cutting a nail too close to the skin or failing to adjust the water temperature of the bath). Include safety risks and tips with all instructions.
- Reinforce infection control practices. Damage to the skin, mucosa, eyes, or other tissues creates an immediate risk for infection. Determine that a patient understands the relationship among healthy and intact skin and tissues, hand hygiene practices, and the prevention of infection.

Acute, Restorative, and Continuing Care. Nursing knowledge and skills needed for performing hygiene care are consistent across all health care settings. In addition, some of the skills in this section are applicable in areas of health promotion. The variety, frequency, and timing of hygiene measures vary across health care settings and according to individual patient needs. In the acute care setting factors such as more frequent diagnostic and treatment plans and the need for more extensive hygiene care resulting from acute illness or injury affect scheduling. In extended care facilities and nursing homes, bathing may be scheduled less frequently.

Bathing and Skin Care. Consider a patient's normal grooming routines, including type of hygiene products used and the time of day when hygiene is routinely performed. Individualize your care on the basis of the patient's preferences. The extent, type, and timing or frequency of bathing and the methods used depend on a patient's physical abilities, health problems, and the degree of hygiene required (Boxes 40-4 and 40-5). In addition to cleansing baths, the health care provider may prescribe therapeutic baths, including sitz baths. Medicated baths (e.g., oatmeal, cornstarch, or Aveeno) may be recommended in the home setting. A sitz bath cleans and reduces pain and inflammation of perineal and anal areas (see Chapter 48). Medicated baths relieve skin irritation and create an antibacterial and drying effect.

If a patient is physically dependent or cognitively impaired, increase the frequency of skin assessment and provide skin care directed toward reducing the risk for skin breakdown. When bathing patients with cognitive impairments, consider their special needs and challenges. These patients easily become afraid. Patients with dementia often refuse, withdraw, or fight during a bath or shower. It can be difficult managing their physical and verbally aggressive behaviors. If possible, learn the triggers that routinely cause these behaviors (Warchol, 2010). For example, unmanaged pain; being cold; feeling frightened, vulnerable, and exposed; feeling embarrassed; feeling a loss of control; or not understanding what is happening often causes aggressive behavior. Adapt your bathing procedures and the environment to reduce the triggers. For example, administer any ordered analgesic 30 minutes before a bath and be gentle in your approach. Keep the patient's body as warm as possible with warm towels and be sure that the room temperature is comfortable. Reduce fear by making sure that all safety devices (e.g., grab bars in a shower, bath mats) are available. Ask for permission to conduct the bath and give the patient options for making

---

BOX 40-4 Hygiene Care Schedule in Acute and Long-Term Care Settings

Early Morning Care
Nursing personnel on the night shift provide basic hygiene to patients getting ready for breakfast, scheduled tests, or early morning surgery. "AM care" includes offering a bedpan or urinal if the patient is not ambulatory, washing the patient's hands and face, and helping with oral care.

Routine Morning Care
After breakfast help by offering a bedpan or urinal to patients confined to bed; provide a full or partial bath or a shower, including perineal care and oral, foot, nail, and hair care; give a back rub; change a patient's gown or pajamas; change the bed linens; and straighten a patient's bedside unit and room. This is often referred to as "complete AM care."

Afternoon Care
Hospitalized patients often undergo many exhausting diagnostic tests or procedures in the morning. In rehabilitation centers patients participate in physical therapy in the morning. Afternoon hygiene care includes washing the hands and face, helping with oral care, offering a bedpan or urinal, and straightening bed linen.

Evening, or Hour-before-Sleep, Care
Before bedtime offer personal hygiene care that helps patients relax and promotes sleep. "PM care" often includes changing soiled bed linens, gowns, or pajamas; helping patients wash the face and hands; providing oral hygiene; giving a back massage; and offering the bedpan or urinal to nonambulatory patients. Some patients enjoy a beverage such as juice; check diet to determine which beverages are allowed.

BOX 40-5 Types of Baths

Complete bed bath: Bath administered to totally dependent patient in bed (see Skill 40-1).

Partial bed bath: Bed bath that consists of bathing only body parts that would cause discomfort if left unbathed such as the hands, face, axillae, and perineal area. Partial bath may also include washing back and providing back rub. Provide a partial bath to dependent patients in need of partial hygiene or self-sufficient bedridden patients who are unable to reach all body parts.

Sponge bath at the sink: Involves bathing from a bath basin or sink with patient sitting in a chair. Patient is able to perform part of the bath independently. Assistance is needed for hard-to-reach areas.

Tub bath: Involves immersion in a tub of water that allows more thorough washing and rinsing than a bed bath. Commonly used in long-term care. A patient may require the nurse's help. Some institutions have tubs equipped with lifting devices that facilitate positioning dependent patients in the tub.

Shower: Patient sits or stands under a continuous stream of water. The shower provides more thorough cleaning than a bed bath but can cause fatigue.

Bag bath/travel bath: Contains several soft, nonwoven cotton cloths that are premoistened in a solution of no-rinse surfactant cleanser and emollient. The bag bath offers an alternative because of the ease of use, reduced time bathing, and patient comfort.

Chlorhexidine gluconate (CHG) bath: This antimicrobial bath wipe is used to decrease the frequency of hospital-acquired infections on skin, invasive lines, and catheters.

decisions (e.g., choice of soap, timing of when to wash face). Use comforting words during bathing to enhance a patient's relaxation. Collaborate and communicate to teach family members how to help bathe dependent or cognitively impaired patients for optimal outcomes once the patient is discharged (Hardin, 2012).

Complete Bed Bath. A **complete bed bath** (see Skill 40-1 on pp. 854-862), tub bath, or shower often exhausts a patient. Turning during a complete bed bath and receiving back care increase oxygen consumption and demand. Getting out of a low tub requires considerable exertion. Assess and be alert for a patient's activity intolerance during hygiene care. Assessing heart rate before, during, and after a bath provides a measure of his her physical tolerance. Provide a **partial bed bath** (see Skill 40-1) to patients who are aging, dependent, in need of only partial hygiene, or bedridden and unable to reach all body parts. Wear gloves when there is a risk of coming in contact with body fluids. Control environmental factors that alter skin integrity, including moisture, heat, and external sources of pressure such as wrinkled bed linen and improperly placed drainage tubing.

Traditionally baths have been given using soap and warm water. The question of whether to use bath basins with soap and water is an issue because bath basins provide a reservoir for bacteria and are a possible source of transmission of hospital-acquired infections (Johnson et al., 2009). There is a link between waterborne pathogens and the development of biofilm (multiple colonies of microorganisms attached to a surface such as a bath basin). The formation of a biofilm combined with transmission of organisms through contact with unwashed hands can create a reservoir of bacteria. The bacteria can be transferred to and maintained in a patient's bath basin. In contrast, the use of CHG 4% solution in place of standard soap and water in wash basins has been shown to decrease bacterial growth in basins (Powers et al., 2012) and reduce critical care unit–acquired methicillin-resistant *Staphylococcus aureus* (MRSA) (Petlin et al., 2014). It is important to air-dry bath basins completely and not to use a basin for storing supplies.

Another option to using CHG in bath basins is the use of CHG 2% in impregnated washcloths (Box 40-6). The CHG in the cloths is fast acting, has broad-spectrum microorganism coverage, continues antimicrobial activity up to 24 hours after application, and is rinse free and disposable (AHRQ, 2013). Daily bathing with 2% CHG-impregnated cloths versus nonantimicrobial washcloths has been shown to reduce the acquisition of multidrug-resistant organisms (MDROs) (Climo et al., 2013). The cost of implementation of CHG cloths has reduced hospital infection rates and improved outcomes for a shorter patient hospitalization (Rubin et al., 2013). The one factor that may result in health care settings choosing 4% CHG solution versus the 2% CHG cloths is the fact that the 2% cloths are more costly but not any more effective. Daily bathing with some form of CHG is becoming more of a standard practice across hospitals.

- When using CHG solution in bath water or impregnated cloths, use a clean CHG washcloth/cloth for each area of the body. Do not use above a patient's jawline as it can be irritating to the eyes and ears (AHRQ, 2013). Use a regular washcloth moistened in warm water for the face. It is necessary not to rinse the CHG off to maintain its antibacterial effects. Patients often describe their skin as feeling a bit sticky. Be sure to explain to patients the importance of using CHG to protect them against serious infection.
- There are precautions to follow in using CHG. CHG is safe to use on superficial wounds, abrasions, and rashes (AHRQ, 2013). In the case of open or deep wounds such as stage III or IV pressure ulcers, bathe with CHG around a dressing or wound. Do not use CHG on third- or fourth-degree burns (AHRQ, 2013).

BOX 40-6 EVIDENCE-BASED PRACTICE

Reducing Hospital-Acquired Infections Using Bathing Techniques

PICO Question: Do adult hospitalized patients using chlorhexidine gluconate (CHG) wipes for bathing compared to soap and water have a decrease in hospital-acquired infections (HAIs) during their hospital stay?

Evidence Summary

Patient's hospital bath basins are a known source of microorganisms that can lead to infection. These reservoirs for bacteria have been associated with HAI. Research studies have indicated that CHG solutions used for daily bathing decrease the incidence of HAIs. Evidence-based research indicates that use of CHG may also reduce culture growth of bacteria on central line catheters leading to bloodstream infections and decrease multiresistant organisms on skin and at surgical sites (Powers et al., 2012). This is especially important for patients who are immunocompromised or susceptible to infections. Further studies are needed on different types of organisms affected by CHG and water contaminates (Rubin et al., 2013). The long-term effects on neonates and the elderly should also be researched.

Application to Nursing Practice

- The Joint Commission (TJC) has recommended that there is a need for evidence-based practices to help prevent HAIs (Rubin et al., 2013).
- Handwashing and personal protective equipment (PPE) may not be enough to prevent nosocomial infections during hospitalization (TJC, 2016). Check patient for allergies before using on skin. Packaged wipes are convenient and easy to use. They decrease time for bathing. Always check with the patient for sensitivity or allergy. Use wipes as directed on package—one wipe per each area of the body (see Skill 40-1).
- CHG wipes are easy to use and accessible for older patients and bariatric patients, offering a no-rinse or drying procedure. The Centers for Disease Control and Prevention (CDC, 2012; 2009) has suggested using CHG wipes along with proper hand hygiene and isolation precautions to decrease multidrug-resistant HAIs. Reductions in rates of bloodstream infections with the use of CHG wipes are being seen in immunocompromised patients, patients prone to skin infections, patients with central line catheters, and patients in intensive care settings (Climo et al., 2013).

Use a tub bath or shower (see Skill 40-1) to give a more thorough bath than a bed bath. CHG 4% solution can be used in showers, but instruct patients to exit the shower after application and do not rinse the CHG off. Implement safety measures to prevent fall injuries because the surface of the tub or shower stall is slippery. In some settings a health care provider's order for a shower or tub bath is necessary. Place a chair in the shower for patients with weakness or poor balance. Both tubs and showers need to have grab bars for patients to hold during entry and exit and maneuvering during the bath or shower. Patients vary in how much help they need.

Regardless of the type of bath a patient receives, use the following guidelines:

- *Provide privacy.* Close the door and/or pull room curtains around the bathing area. While bathing a patient, expose only the areas being bathed by using proper draping.
- *Maintain safety.* Keep side rails up when away from a patient's bedside when patients are dependent or unconscious. NOTE: When side rails serve as a restraint, you need a health care provider's order (see agency-specific policy for restraint usage) (see Chapter 27). Place the call light in the patient's reach if leaving the bedside even temporarily.

- *Maintain warmth.* Keep the room warm because the patient is partially uncovered and easily chilled. Wet skin causes an excessive loss of heat through evaporation. Control drafts and keep windows closed. Keep the patient covered. Expose only the body part being washed during the bath.
- *Promote independence.* Encourage the patient to participate in as much of the bathing activities as possible. Offer assistance when needed.
- *Anticipate needs.* Bring a new set of clothing and hygiene products to the bedside or bathroom.

Teach patients to follow a few general rules for skin health. Encourage them to routinely inspect their skin for changes in color or texture and report abnormalities to their health care provider. Instruct them to handle the skin gently, avoiding excessive rubbing. Patients with excessively dry skin are predisposed to skin impairment. If patients use bar soap at home, recommend that they choose one that contains emollients to hydrate dry skin. Avoid overly hot water because it can dry the skin by removing natural oils. Lubricate the skin with emollient lotions to reduce dryness.

Also encourage patients to eat nutritious foods from all food groups, including those rich in vitamins and minerals, and to consume adequate fluids. Stress safety concerns such as failing to adjust or check the water temperature, cutting nails too close to the skin, and slipping on wet surfaces. Ensure that patients understand that healthy and intact skin and tissues protect them from infection. Reinforce infection control practices, including proper hand hygiene.

Perineal Care. Cleansing patients' genital and anal areas is called **perineal care**. It usually occurs as part of a complete bed bath; however, it must be provided at least once a day and more often (see agency policy) if a patient has a urinary catheter (see Skill 40-1). Patients most in need of perineal care include those at greatest risk for acquiring an infection (e.g., uncircumcised males, patients who have indwelling urinary catheters, or those who are recovering from rectal or genital surgery or childbirth). In addition, women who are having a menstrual period require perineal care. CHG is safe to use on the perineum and external mucosa for thorough cleansing (AHRQ, 2013).

When the patient's condition allows, encourage the patient to perform perineal care. Sometimes you are embarrassed about providing perineal care, particularly to patients of the opposite sex. Similarly the patient may feel embarrassed. Do not let embarrassment cause you to overlook the patient's hygiene needs. When staffing levels permit, use a gender-congruent caregiver. A professional, dignified, and sensitive approach reduces embarrassment and helps put the patient at ease.

If a patient performs self-care, various problems such as vaginal and urethral discharge, skin irritation, and unpleasant odors often go unnoticed. Stress the importance of perineal care in preventing skin breakdown and infection. Be alert for complaints of burning during urination or localized soreness, excoriation, or pain in the perineum. Inspect vaginal and perineal areas and the patient's bed linen for signs of discharge and use your sense of smell to detect abnormal odors. Risk factors for skin breakdown in the perineal area include urinary or fecal incontinence, rectal and perineal surgical dressings, indwelling urinary catheters, and morbid obesity.

Back Rub. A back rub or back massage usually follows a patient's bath. It promotes relaxation, relieves muscular tension, and decreases perception of pain. **Effleurage** (i.e., long, slow, gliding strokes of a massage) is associated with reduced measured anxiety, heart rate, and respiratory rate. Studies show that slow-stroke back massages of 3 minutes and hand massages of 10 minutes significantly improve both physiological and psychological indicators of relaxation in older people (Touhy and Jett, 2012).

When providing a back rub, enhance relaxation by reducing noise and ensuring that the patient is comfortable. It is important to ask whether a patient would like a back rub, because some individuals dislike physical contact. Consult the medical record for any contraindications to a massage (e.g., fractured ribs, burns, heart surgery).

Foot and Nail Care. Incorporate foot and nail care into a person's regular hygiene routine. Routine care involves soaking the hands and feet to soften cuticles and layers of horny cells, thorough cleaning, drying, and proper nail trimming. The one exception is patients with diabetes mellitus or peripheral vascular disease, who are at risk for tissue ulceration or infection because soaking causes skin softening or **maceration** of tissue.

When providing nail care, have the patient remain in bed or sit in a chair (see Skill 40-2 on pp. 862-865). In some settings or with specific patients such as a person with diabetes mellitus, you need a health care provider's order to trim toenails. Before implementing nail care, check agency policy to determine if an order is necessary.

Take time during the procedure to teach the patient and family proper techniques for cleaning and nail trimming. Stress the importance of how thorough nail care prevents infection and promotes good circulation. Patients must learn to protect the feet from injury, never walk barefoot, keep feet clean and dry, and wear footwear that fits properly. Instruct patients in the proper way to inspect all surfaces of the feet and hands for redness, lesions, dryness, or signs of infection. Teach foot care to family caregivers for patients who need regular foot care and have peripheral vascular disease, visual difficulties, physical constraints preventing movement, or cognitive problems.

Certain conditions place patients with diabetes at increased risk for amputation (ADA, 2015). These factors include peripheral neuropathy, limited joint mobility, bony deformity, peripheral vascular disease, and a history of skin ulcers or previous amputation. Observe for changes that indicate peripheral neuropathy or vascular insufficiency (Box 40-7). Advise patients to use the following guidelines in a routine foot and nail care program (Sheridan, 2012):

- Inspect the feet daily, including the bottoms and tops, heels, and areas between the toes. Use a mirror to help inspect the feet thoroughly or ask a family member to check daily.
- Wash feet daily in lukewarm water. Dry thoroughly, especially between the toes. Avoid harsh chemicals or long soaks, which can cause skin softening or maceration of tissue, causing ulceration or infection.
- Wear well-fitting shoes and clean, dry socks at all times; never go barefoot. Check inside shoes before wearing them for rough areas or objects that may rub against the foot.

BOX 40-7   Signs of Peripheral Neuropathy or Vascular Insufficiency

Peripheral Neuropathy
- Muscle wasting of lower extremities
- Absence of deep tendon reflexes
- Foot deformities
- Infections
- Abnormal gait

Vascular Insufficiency
- Decreased hair growth on legs and feet
- Absent or decreased pulses
- Infection in the foot
- Poor wound healing
- Thickened nails
- Shiny appearance of the skin
- Blanching of skin on elevation

Data from Ball J et al: *Seidel's guide to physical examination,* ed 8, St Louis, 2015, Mosby.

- Keep skin soft and smooth by applying an emollient lotion over all surfaces of the feet but not between the toes.
- If you can see and reach your toenails, trim them straight across and square file the edges smooth.
- Keep the blood flowing to your feet by putting them up when sitting and wiggling your toes and moving your ankles up and down for 5 minutes, 2 or 3 times a day. Do not cross your legs for long periods and don't smoke.
- Protect the feet from hot and cold. Do not use heating pads or electric blankets and always wear shoes at the beach or on hot pavement.

Oral Hygiene. Regular oral hygiene, including brushing, flossing, and rinsing, prevents and controls plaque-associated oral diseases. Evidence relates poor oral health to risk of impaired nutrition, stroke, poor blood sugar control in diabetes, and nursing home–acquired pneumonia (Barnes, 2014). Inadequate oral care and some medications diminish salivary production, which in turn reduces the ability of the oral environment to help fight effects of pathogens. Older adults in particular require good oral care (Box 40-8).

Brushing cleans the teeth of food particles, plaque, and bacteria. It also massages the gums and relieves discomfort resulting from unpleasant odors and tastes. Flossing removes tartar that collects at the gum line. Rinsing removes dislodged food particles and excess toothpaste. Complete oral hygiene enhances well-being and comfort and stimulates the appetite.

When patients become ill, many factors influence their need for oral hygiene such as their ability to take fluids orally, presence of oral lesions or trauma, and level of consciousness. Patients in hospitals or long-term care facilities do not always receive the aggressive oral care they need. Base the frequency of care on the condition of the oral cavity, risk for aspiration of saliva, and the patient's level of comfort. Some patients (e.g., stroke, trauma to oral cavity, patient with endotracheal tube) require oral care as often as every 1 to 2 hours.

Acidic fruits in a patient's diet reduce plaque formation. A well-balanced diet contributes to the integrity of oral tissues. To prevent tooth decay, patients sometimes need to change eating habits (e.g., reducing intake of carbohydrates, especially sweet snacks between meals). Advise patients of all ages to visit a dentist regularly for check-ups. Education about common gum and tooth disorders and methods of prevention may motivate patients to follow good oral hygiene practices.

Brushing. The American Dental Association guidelines (2014) for effective oral hygiene include brushing the teeth at least twice a day with American Dental Association–approved fluoride toothpaste. Fluoride and antimicrobial mouth rinses help prevent tooth decay. Do not use fluoride rinse in children ages 6 or under because of the risk of swallowing the rinse. Use antimicrobial toothpastes and 0.12% CHG oral rinses for patients at increased risk for poor oral hygiene (e.g., older adults and patients with cognitive impairments and who are immunocompromised) (Garcia and Caple, 2014). The toothbrush needs to have a straight handle and a brush small enough to reach all areas of the mouth. Rounded soft bristles stimulate the gums without causing abrasion and bleeding. Any patient who has decreased dexterity as a result of a medical condition or the aging process requires an enlarged handle with an easier grip.

Brush all tooth surfaces thoroughly (Box 40-9). Commercially made foam swabs are ineffective in removing plaque (Garcia and Caple, 2014). Electric or battery-powered toothbrushes improve the quality of cleaning and may be easier to use than manual brushes when nurses provide care for dependent patients. Do not use lemon-glycerin sponges because they dry mucous membranes and erode tooth enamel.

To prevent cross-contamination, teach patients to avoid sharing toothbrushes with family members or drinking directly from a bottle of mouthwash. Disclosure tablets or drops to stain the plaque that collects at the gum line are useful for showing patients how effectively they brush. Instruct patients to obtain a new toothbrush every 3 months or following a cold or upper respiratory infection to minimize growth of microorganisms on the brush surfaces (American Dental Association, 2014).

Flossing. Dental flossing removes plaque and tartar between teeth. Flossing involves inserting waxed or unwaxed dental floss between

---

BOX 40-8 **FOCUS ON OLDER ADULTS**

Oral Health

- Many older adults are edentulous (without teeth), and the teeth that are present are often diseased or decayed (Touhy and Jett, 2014).
- The periodontal membrane weakens with aging, making it more prone to infection. Periodontal disease predisposes older adults to systemic infection.
- Dentures or partial plates do not always fit properly, causing pain and discomfort, which in turn affects digestive processes, enjoyment of food, and nutritional status.
- An age-related decline in saliva secretion and some medications (e.g., antihypertensives, diuretics, antiinflammatories, antidepressants) cause dry mouth (Touhy and Jett, 2014).
- Financial limitations and the belief that dentures eliminate the need for routine dental care are some of the reasons why older adults do not seek dental care (Touhy and Jett, 2014).

BOX 40-9 **PROCEDURAL GUIDELINES**

Providing Oral Hygiene

Delegation Considerations

The skill of performing oral hygiene can be delegated to nursing assistive personnel (NAP).

However, the nurse is responsible for assessing the patient's gag reflex to determine risk for aspiration. Direct the NAP to:
- Position the patient to avoid aspiration.
- Immediately report to the nurse excessive patient coughing or choking during or after oral hygiene.
- Report bleeding of oral mucosa or gums, patient report of pain, and any types of changes in oral mucosa (e.g., open areas or lesions)

Equipment

Soft-bristle toothbrush; nonabrasive fluoride toothpaste; dental floss; tongue depressor; water glass with cool water, normal saline, or an essential oil-antiseptic mouth rinse *(optional depending on patient preference);* emesis basin; face towel; paper towels; clean gloves; penlight; linen bag or hamper

Steps

1. Review medical record and identify presence of common oral hygiene problems: dental caries—chalky white discoloration of tooth or presence of brown or black discoloration; gingivitis—inflammation of gums;

BOX 40-9   **PROCEDURAL GUIDELINES**

Providing Oral Hygiene—cont'd

periodontitis—receding gum lines, inflammation, gaps between teeth; halitosis—bad breath; cheilitis—cracked lips; dry, cracked, and coated tongue.

2. Perform hand hygiene and apply clean gloves.

3. Identify patient using two identifiers (e.g., name and birthday or name and medical record) according to agency policy.

4. Using tongue depressor and pen light, inspect integrity of lips, teeth, buccal mucosa, gums, palate, and tongue; also assess for gag reflex and ability to swallow (see Chapter 31).

5. Confirm presence of common oral problems.

6. Determine patient's oral hygiene practices such as frequency of brushing and flossing, type of toothpaste and mouthwash used, last and frequency of dental visits.

7. Remove gloves and perform hand hygiene.

8. Explain procedure to patient, discussing preferences and willingness to help with oral care.

9. Assess patient's ability to grasp and manipulate toothbrush.

10. Place paper towels on over-bed table and arrange other equipment within easy reach.

11. Provide privacy by closing room doors and drawing room divider curtain. Raise bed to comfortable working position. Raise head of bed (if allowed) and lower near side rail. Move patient or help him or her move closer to side. Place patient in side-lying position if needed (if aspiration risk). Place towel over patient's chest.

12. Apply clean gloves.

13. Apply enough toothpaste to brush to cover length of bristles. Hold brush over emesis basin. Pour small amount of water over toothpaste.

14. Patient may help with brushing. Hold toothbrush bristles at 45-degree angle to gum line (see illustration). Be sure that tips of bristles rest against and penetrate under gum line. Brush inner and outer surfaces of upper and lower teeth by brushing from gum to crown of each tooth. Clean biting surfaces of teeth by holding top of bristles parallel with teeth and brushing gently back and forth (see illustration). Brush sides of teeth by moving bristles back and forth (see illustration).

15. Have patient lightly brush over surface and sides of tongue. Avoid initiating gag reflex.

16. Allow patient to rinse mouth thoroughly by taking several sips of cool water, swishing water across all tooth surfaces, and spitting into emesis basin. Use this time to observe patient's brushing technique and teach importance of regular hygiene.

17. Have patient rinse mouth with antiseptic rinse for 30 seconds. Then have him or her spit rinse into emesis basin. Help wipe his or her mouth.

18. Floss or allow patient to floss between all teeth (see illustration).

19. Allow patient to rinse mouth thoroughly with cool water and spit into emesis basin. Help wipe his or her mouth.

20. Inspect oral cavity to determine effectiveness of oral hygiene and rinsing. Ask patient if mouth feels clean or if there are any sore or tender areas. Remove towel and place in linen bag.

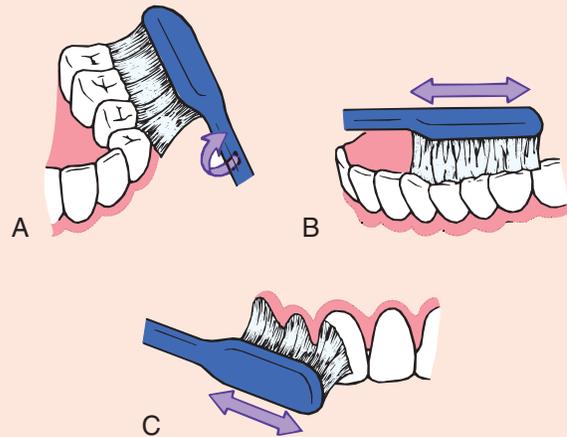
21. Use **Teach Back** to determine patient's and family's understanding about oral care. State, "I want to be sure you know how often to brush your teeth and floss. Can you explain that for me?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.

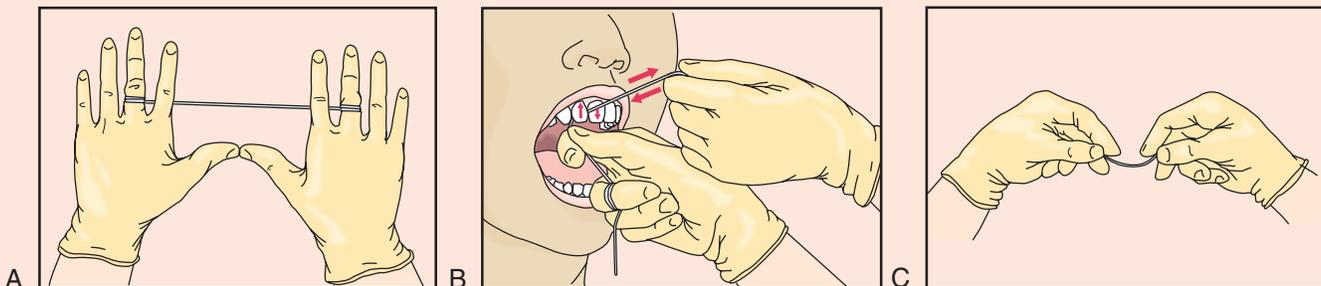
22. Remove gloves. Help patient to comfortable position, raise side rail, and lower bed to original position.

23. Perform hand hygiene. Apply clean gloves to clean and dry emesis basin before returning basin and nondisposable supplies.

24. Remove gloves and perform hand hygiene.

25. Record procedure. Note condition of oral cavity, amount of care patient could perform, and whether additional instruction is needed on oral care in nurse's notes.

26. Report bleeding, pain, or presence of lesions to nurse in charge or health care provider.


STEP 14 Direction for toothbrush placement. **A,** 45-degree angle brushes gum line. **B,** Parallel position brushes biting surfaces. **C,** Lateral position brushes sides of teeth.


STEP 18 Flossing. **A,** Dental floss held between middle fingers to floss upper teeth. **B,** Floss moved in up-and-down motion between teeth. **C,** Floss held with index fingers to floss lower teeth.

all tooth surfaces, one at a time. The seesaw motion used to pull floss between teeth removes plaque and tartar from tooth enamel. Use unwaxed floss and avoid vigorous flossing near the gum line on patients who are receiving chemotherapy, radiation, or anticoagulant therapy to prevent bleeding. If toothpaste is applied to the teeth before flossing, fluoride comes in direct contact with tooth surfaces, aiding in cavity prevention. According to American Dental Association recommendations (2014), flossing once a day is sufficient. Because it is important to clean all teeth surfaces thoroughly, do not rush to complete flossing. Placing a mirror in front of a patient helps you demonstrate the proper method for holding the floss and cleaning between the teeth. Flossing a patient's teeth is not realistic or appropriate in all care settings.

Patients with Special Needs. Some patients require special oral hygiene methods. For example, patients with diabetes mellitus and who are on chemotherapy frequently experience periodontal disease. Therefore they need to visit a dentist every 3 to 4 months, clean their teeth up to 4 times a day, and handle oral tissues gently with a minimum of trauma. Xerostomia, bruxism, and dental caries may be present with patients who are methamphetamine users. Cravings for sugary sweets may cause decay and gum disease.

Patients may depend on their caregivers for oral care. Being unconscious or having an artificial airway (e.g., endotracheal or tracheal tubes) increases the susceptibility for patients to have drying of salivary secretions because they are unable to eat or drink, unable to swallow, and frequently breathe through the mouth. Unconscious patients cannot swallow salivary secretions that accumulate in the mouth. These secretions often contain gram-negative bacteria that cause pneumonia if aspirated into the lungs. While providing hygiene, protect the patient from choking and aspiration and use topical CHG, especially in ventilated patients (see Skill 40-3 on pp. 865-867). Current evidence shows that use of CHG with oral hygiene reduces the risk for ventilator-associated pneumonia (Wiech et al., 2012).

Patients with decreased levels of consciousness need special attention because they often do not have a gag reflex. Proper oral hygiene requires keeping the mucosa moist and removing secretions that contribute to infection. Pooling of salivary secretions in the back of the throat harbors microorganism growth. When providing oral hygiene to an unconscious patient, you need to protect him or her from choking and aspiration. Have two nurses provide the care; turn the patient's head toward you, and place the bed in semi-Fowler's position. You can delegate nursing assistive personnel to participate. One nurse does the actual cleaning, and the other caregiver removes secretions with suction equipment. Some agencies use equipment that combines a mouth swab with the suction device; you can use this equipment safely by yourself. While cleansing the oral cavity, use a small oral airway or a padded tongue blade to hold the mouth open. Never use your fingers to hold a patient's mouth open. A human bite contains multiple pathogenic microorganisms. Even though the patient is not awake or alert, explain the steps of mouth care and the sensations that he or she will feel. Also tell the patient when the procedure is completed.

Some treatments such as chemotherapy, immunosuppressive agents, head and neck radiation, and nasogastric intubation place patients at higher risk of experiencing stomatitis or inflammation of the oral mucosa. **Stomatitis** causes burning, pain, and change in food and fluid tolerance. When caring for patients with stomatitis, brush with a soft toothbrush and floss gently to prevent bleeding of the gums. In some cases flossing needs to be omitted temporarily from oral care. Advise patients to avoid alcohol and commercial mouthwash and stop smoking. Normal saline rinses (approximately 30 mL) on awaking in the morning, after each meal, and at bedtime help clean the oral cavity. Patients can increase the rinses to every 2 hours if necessary. Consult with the health care provider to obtain topical or oral analgesics for pain control.

Denture Care. Encourage patients to clean their dentures on a regular basis to avoid gingival infection and irritation. When patients become disabled, someone else assumes responsibility for denture care (Box 40-10). Dentures are a patient's personal property and must be handled with care because they break easily. They must be removed at night to rest the gums and prevent bacterial buildup. To prevent warping, keep dentures covered in water when they are not worn and always store them in an enclosed, labeled cup with the cup placed in the patient's bedside stand. Discourage patients from removing their dentures and placing them on a napkin or tissue because they could easily be thrown away.

Implement measures to prevent denture-induced stomatitis when caring for patients who wear dentures. Poorly fitting dentures, wearing dentures while sleeping, and poor dental hygiene habits contribute to denture-induced stomatitis (Martori et al., 2014). Signs and symptoms range from redness and swelling under the dentures to painful red sores on the roof of the mouth and infection with the yeast *Candida albicans*. Some patients deny pain, and others complain of pain worsened by wearing dentures. To prevent denture-induced stomatitis, rinse the mouth and dentures after meals, clean them carefully and regularly, remove and soak them overnight, brush and floss (if appropriate) any remaining teeth, and visit a dentist regularly for examination (American Dental Association, 2014).

Hair and Scalp Care. A person's appearance and feeling of well-being often depend on the way the hair looks and feels. Illness or disability often prevents a patient from maintaining daily hair care. When patients are immobilized, their hair soon becomes tangled. Some dressings or diagnostic procedures leave sticky residue on the hair. Basic hair and scalp care includes brushing, combing, and shampooing.

Brushing and Combing. Frequent brushing helps keep hair clean and distributes oil evenly along hair shafts. Combing prevents hair from tangling. Encourage patients to maintain routine hair care and provide help for patients with limited mobility or weakness and those who are confused or weakened by illness. Patients in a hospital or extended care facility appreciate the opportunity to have their hair brushed and combed before being seen by others.

When caring for patients from different cultures, learn as much as possible from them or their family about preferred hair care practices. For example, the hair of African-Americans tends to be quite dry. Use special lanolin conditioners for conditioning. Cultural preferences also affect how hair is combed and styled and whether it can be cut.

Long hair becomes matted easily when a patient is confined to bed, even for a short period. When lacerations or incisions involve the scalp, blood and topical medications also cause tangling. Frequent brushing and combing keep long hair neatly groomed. Braiding helps to avoid repeated tangles; however, patients need to unbraid hair periodically and comb it to ensure good hygiene. Braids that are too tight lead to bald patches. Obtain permission from the patient before braiding the hair.

To brush hair part it into two sections and separate each section into two more sections. Brushing from the scalp toward the hair ends minimizes pulling. Moistening the hair with water or an alcohol-free detangle product makes it easier to comb. Never cut a patient's hair without consent.

Patients who develop head lice require special considerations in the way combing is performed (Box 40-11). The lice are small, about

---

BOX 40-10   PROCEDURAL GUIDELINES

Care of Dentures

Delegation Considerations

The skill of denture care can be delegated to nursing assistive personnel (NAP). Instruct the NAP to:

- Inform the nurse if there are cracks in dentures.
- Inform the nurse if the patient complains of oral discomfort.
- Inform the nurse of any lesions in the mouth.

Equipment

Soft-bristle toothbrush or denture toothbrush, denture-cleaning agent or tooth-paste, denture adhesive *(optional),* glass of water, emesis basin or sink, wash-cloth, clean gloves, denture cup (if dentures are to be stored after cleaning)

Steps

1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.
2. Ask patient if dentures fit and if there is any gum or mucous membrane tenderness or irritation.
3. Ask patient about preferences for denture care and products used. If patient is unable to care for own dentures, provide this care. Clean dentures for patient during routine mouth care.
4. Perform hand hygiene. Apply clean gloves. Fill emesis basin with tepid water; or, if using sink, place washcloth in bottom of sink and fill sink with 2.5 cm (1 inch) of water.
5. Remove dentures: If patient is unable to do this independently, grasp upper plate at front with thumb and index finger wrapped in gauze and pull downward. To remove lower denture, gently lift it from jaw and rotate one side downward. Place dentures in emesis basin or sink.
6. Apply cleaning agent to brush and brush surfaces of dentures (see illustration). Hold dentures close to water. Hold brush horizontally and use

back-and-forth motion to clean biting surfaces. Use short strokes from top of denture to biting surfaces to clean outer and inner teeth surfaces. Hold brush vertically and use short strokes to clean inner tooth surfaces. Hold brush horizontally and use back-and-forth motion to clean undersurface of dentures.

STEP 6 Brushing dentures.

7. Some patients use an adhesive to seal dentures in place. Apply a thin layer to undersurface before inserting.
8. If patient needs help inserting dentures, moisten upper denture and press firmly to seal it in place. Insert moistened lower denture. Ask if dentures feel comfortable.
9. Some patients prefer to have their dentures stored to rest the gums and reduce risk of infection. Keeping dentures moist prevents warping and facilitates easier insertion. Store in secure place to prevent loss.
10. Remove and discard gloves and perform hand hygiene.

BOX 40-11   Hygiene Care for Head Lice

- Perform hand hygiene and apply disposable gown and gloves.
- Use a grooming comb or hairbrush to remove tangles.
- Divide patient's hair in sections and fasten off hair that is not being combed.
- Comb out from scalp to the end of the hair (special combs are available in drug stores).
- Dip comb in a cup of water or use a paper towel to remove lice between each passing.
- After combing look through hair carefully for attached lice; you can catch live lice with a tweezers or comb.
- After combing thoroughly, move to next section of hair.
- Instruct family to clean the comb with an old toothbrush and dental floss. Then boil the comb. The ideal is to discard the comb after each use, but some patients' financial situations prevent purchase of multiple combs.
- Instruct family to comb and screen for lice daily.
- Instruct family to contain patient's clothes and wash them in hot water.
- Instruct family to vacuum the home and patient's room and immediately empty vacuum bag or bagless collection device.
- Instruct caregivers on how to prevent transmission of lice: Do not share bed linens or hair care products. Avoid placing bare hand on patient's head. Immediately wash hands after providing hair care.

the size of a sesame seed; thus you need bright light or natural sunlight to see them. Thorough combing is more effective than use of pediculicidal shampoos, which are often toxic and ineffective against resistant lice.

If a pediculicidal shampoo is ordered, review pertinent information and instruct the patient and caregiver in its proper use. Use with caution because these shampoos may have severe neurological side effects. Make sure to thoroughly rinse shampoo from hair to avoid itching.

Shampooing. Frequency of shampooing depends on a person's daily routines and the condition of the hair. Remind patients in hospitals or extended care facilities that staying in bed, excess perspiration, or treatments that leave blood or solutions in the hair require more frequent shampooing. In some agencies you need a health care provider's order to shampoo a patient who is dependent or has limited mobility because it is challenging to find ways to shampoo the hair without causing injury.

The patient who can shower or tub bathe usually shampoos the hair without difficulty. A shower or tub chair facilitates shampooing for patients who are ambulatory and weight bearing and become tired or faint. Handheld shower nozzles allow patients to easily wash the hair in the tub or shower. Some patients allowed to sit in a chair choose to be shampooed in front of a sink or over a washbasin; however, certain conditions (e.g., eye surgery or neck injury) limit bending. In these situations teach the patient and family the degree of bending allowed.

If a patient is unable to sit but can be moved, transfer him or her to a stretcher for transportation to a sink or shower equipped

BOX 40-12 PROCEDURAL GUIDELINES

Shampooing Hair of Patient Who is Bed Bound

Delegation Considerations

The skill of shampooing hair can be delegated to nursing assistive personnel (NAP). Instruct the NAP:

- About any precautions needed in positioning the patient.
- To inform the nurse if the patient reports neck pain.
- To inform the nurse of any new skin lesions.

Equipment

Brush, comb, shampoo board, shampoo, conditioner *(optional),* hydrogen peroxide *(optional),* towels (three or more), waterproof pad, hair dryer, basin of very warm water, clean gloves (if needed) or shampoo cap

Steps

1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.
2. Before washing patient's hair, determine that there are no contraindications to procedure (e.g., neck injury).
3. Perform hand hygiene and apply gloves if needed. Inspect hair and scalp before initiating procedure to determine presence of any conditions that require use of special shampoos or treatments (e.g., for dandruff or the removal of dried blood).
4. Place waterproof pad under patient's shoulders, neck, and head. Position patient supine, with head and shoulders at top edge of bed. Place plastic trough under patient's head and washbasin at end of trough (see illustration). Be sure that trough spout extends beyond edge of mattress.

STEP 4 Patient positioned for shampoo. (Copyright © Mosby's Clinical Skills: Essentials Collection.)

5. Place rolled towel under patient's neck and bath towel over patient's shoulders.
6. Brush and comb patient's hair.
7. Obtain warm water.
8. Offer patient the option of holding face towel or washcloth over eyes.
9. Slowly pour water from water pitcher over hair until it is completely wet (see illustration). If hair contains matted blood, put on gloves, apply peroxide to dissolve clots, and rinse hair with saline. Apply small amount of shampoo.

STEP 9 Wetting patient's hair. (Copyright © Mosby's Clinical Skills: Essentials Collection.)

10. Work up lather with both hands. Start at hairline and work toward back of neck. Lift head slightly with one hand to wash back of head. Shampoo sides of head. Massage scalp by applying pressure with fingertips.
11. Rinse hair with water. Make sure that water drains into basin. Repeat rinsing until hair is free of soap.
12. Apply conditioner or cream rinse if requested and rinse hair thoroughly.
13. Wrap patient's head in bath towel. Dry patient's face with cloth used to protect eyes. Dry off any moisture along neck or shoulders.
14. Dry patient's hair and scalp. Use second towel if first becomes saturated.
15. Comb hair to remove tangles and dry with dryer if desired.
16. Apply oil preparation or conditioning product to hair if desired by patient.
17. Help patient to comfortable position and complete styling of hair.

---

with a handheld nozzle. Use caution when positioning the patient's head and neck, particularly in patients with any form of head or neck injury.

If a patient is unable to sit in a chair or be transferred to a stretcher, shampoo the hair with him or her in bed (Box 40-12). Position a special shampoo trough under his or her head to catch water and suds. After shampooing, patients like having their hair styled and dried. Most health care centers have portable hair dryers. Dry shampoos that reduce the need to wet the patient's hair are also available but are not highly effective. Shampoo caps provide a warm, wet massage to the scalp while cleaning the hair (Box 40-13).

Shaving. Shave a patient's facial hair after the bath or shampoo. Some women prefer to shave their legs or axillae while bathing. When helping a patient, take care to avoid cutting him or her with the razor blade. Patients prone to bleeding (e.g., those receiving anticoagulants or high doses of aspirin or those with low platelet counts) need to use their personal electric razor. Before using an electric razor, check for frayed cords or other electrical hazards. Use razor blades on only one patient because of infection control considerations.

When using a razor blade for shaving, soften the skin to prevent pulling, scraping, or cuts. Moisten the skin with lukewarm water and apply shaving cream. Bar soap may leave a film on the blade, resulting in a poorer-quality shave. You need to shave patients when they are unable to shave themselves independently. To avoid causing discomfort or razor cuts, gently pull the skin taut and use long, firm razor strokes in the direction the hair grows (Figure 40-5). Short downward strokes work best to remove hair over the upper lip or chin. A patient usually explains the best way to move the razor across the skin. Facial hair of African-Americans tends to be curly and becomes ingrown unless shaved close to the skin.

Mustache and Beard Care. Mustaches or beards require daily grooming. Grooming keeps food particles and mucus from collecting in the hair. If a patient is unable to carry out self-care, do so at his or her request. Comb out beards gently and obtain the patient's permission before trimming or shaving off a mustache or beard.

Care of the Eyes, Ears, and Nose. Give special attention to cleaning the eyes, ears, and nose during a routine bath and when

BOX 40-13 Shampooing Using Disposable Shampoo Product

1. Perform hand hygiene; apply gloves as needed.
2. Patient can be sitting on a chair or in bed.
3. Comb hair to remove tangles or debris.
4. Heat package in microwave according to agency policy and instructions.
5. Open package; apply cap with all hair underneath for correct fit (see illustration).

STEP 5 Patient wearing disposable shampoo cap.

6. Massage head through cap 2-4 minutes.
7. Discard cap into garbage; do not dispose in toilet because it may clog plumbing.
8. Towel-dry hair.
9. Brush or comb patient's hair.
10. Remove gloves if applicable; perform hand hygiene.

FIGURE 40-5 Shave using short, firm strokes in direction of hair growth.

drainage or discharge accumulates. This aspect of hygiene not only makes a patient more comfortable but also improves sensory reception (see Chapter 49). Care focuses on preventing infection and maintaining normal sensory function. In addition, care of the eyes, ears, and nose requires approaches that consider the patient's special needs.

Medical Devices. If a patient has oxygen tubing, a feeding tube, or a nasotracheal tube, it is essential you care for the area of the skin around the nose or ears underlying the device. The National Pressure Ulcer Advisory Panel (NPUAP, 2013) recommends the following: cushion and protect the skin with dressings in high-risk areas (e.g., nasal bridge) (see Chapter 48); do not place device(s) over sites of prior or existing pressure ulceration; and be sure to gently cleanse a potential area of irritation that underlies a device at least daily.

Basic Eye Care. Cleaning the eyes involves simply washing with a clean washcloth moistened in water (see Skill 40-1). Soap may cause burning and irritation. Never apply direct pressure over the eyeball because it causes serious injury. When cleaning a patient's eyes, obtain a clean washcloth and clean from inner to outer canthus. Use a different section of the washcloth for each eye. Remember, never use CHG solution or cloths to clean the eyes, ears, or face.

Unconscious patients require more frequent eye care. A complication of sedation and coma is that some patients are unable to maintain effective eye closure (Werli-Alvarenga et al., 2013). Thus these patients lose their natural protective mechanisms to protect the cornea. When unprotected, there is an increased risk of corneal dehydration, abrasion, perforation, and infection. Normal protective mechanisms include blinking with lubrication of the eye (Douglas and Berry, 2011). Blinking provides a mechanical barrier to injury and prevents dehydration. Secretions collect along the lid margins and inner canthus when the blink reflex is absent or when the eye does not close completely. When an eye does not close completely, you may need to place an eye patch over it to prevent corneal drying and irritation. Apply lubricating eyedrops according to the health care provider's orders.

Eyeglasses. Eyeglasses are expensive. Be careful when cleaning glasses and protect them from breakage or other damage when they are not worn. Put them in a case in a drawer of the bedside table when not in use. Cool water sufficiently cleans glass lenses. Prevent scratching by using a soft cloth for drying; do not use paper towels. Plastic lenses in particular scratch easily; special cleaning solutions and drying tissues are available.

Contact Lenses. A contact lens is a thin, transparent, circular disk that fits directly over the cornea of the eye. Contact lenses correct refractive errors of the eye or abnormalities in the shape of the cornea. In outpatient or home settings instruct patients on the routines to follow for regular cleansing and care (Box 40-14). Explain that all contact lenses must be removed periodically to prevent ocular infection and corneal ulcers or abrasions from infectious agents such as *Pseudomonas aeruginosa* and staphylococci. Pain, tearing, discomfort, and redness of the conjunctivae indicate lens overwear. Encourage patients to report persistence of these symptoms even after lens removal to their health care provider.

When patients are admitted to the hospital or agency in an unresponsive or confused state, determine if they normally wear contact lenses and if the lenses are in place. If a patient wears contact lenses and no one detects this, severe corneal injury can result. If you find that your patient is wearing contact lenses and cannot remove them, seek help. Once the lenses are removed, document the removal, the condition of the patient's eyes following removal, and the storage of the lenses.

Artificial Eyes. Patients with artificial eyes have had an **enucleation** (i.e., removal) of an entire eyeball as a result of tumor growth, severe infection, or eye trauma. Some artificial eyes are implanted

BOX 40-14   PATIENT TEACHING

Contact Lens Care

Objective
- Patient verbalizes and/or demonstrates proper care for contact lenses and common warning signs of problems associated with contact lens wear.

Teaching Strategies
- Instruct patients on the following:
  - Do not use fingernail on lens to remove dirt or debris.
  - Do not use tap water to clean soft lenses.
  - Follow recommendations of lens manufacturer or eye care practitioner when inserting, cleaning, and disinfecting lenses.
  - Keep lenses moist or wet when not worn.
  - Use fresh solution daily when storing and disinfecting lenses.
  - Thoroughly wash and rinse lens storage case on a daily basis. Clean periodically with soap or liquid detergent, rinse thoroughly with warm water, and air dry.
  - If lens is dropped, moisten finger with cleaning or wetting solution and gently touch it to pick it up. Then clean, rinse, and disinfect it.
- To avoid mix-up, always start with the same lens when removing or inserting lenses.
- Throw away disposable or planned replacement lenses after prescribed wearing period.
- Encourage patient to remember the acronym RSVP: *R*edness, *S*ensitivity, *V*ision problems, and *P*ain. If one of these problems occurs, remove contact lenses immediately. If problems continue, contact a vision care specialist (Lewis et al., 2014).

Evaluation
- Ask patient to state warning signs of corneal irritation and eye infection.
- Ask patient to describe methods of contact lens care that lead to infection.
- Ask patient to demonstrate cleaning and storing contact lenses.

FIGURE 40-6 Removal of prosthetic eye.

permanently, whereas others must be removed for cleaning. Patients with artificial eyes usually prefer to care for their own eyes. Respect the patient's wishes and help by assembling needed equipment.

At times patients require help to remove and clean prosthesis. To remove an artificial eye, retract the lower eyelid and exert slight pressure just below the eye (Figure 40-6). This action causes the artificial eye to rise from the socket because the suction holding the eye in place has been broken. You can also use a small, rubber bulb syringe or medicine-dropper bulb to create a suction effect. Place the bulb tip directly over the eye and squeeze it to create suction needed to lift the eye from the socket.

An artificial eye is usually made of glass or plastic. Warm normal saline cleans the prosthesis effectively. Clean the edges of the eye socket and surrounding tissues with soft gauze moistened in saline or clean tap water. Report signs of infection immediately because bacteria can spread to the neighboring eye, underlying sinuses, or even brain tissue. To reinsert the eye, retract the upper and lower lids and gently slip the eye into the socket, fitting it neatly under the upper eyelid. Store an artificial eye in a labeled container filled with tap water or saline.

Ear Care. Routine ear care involves cleaning the ear with the end of a moistened washcloth rotated gently into the ear canal. Gentle, downward retraction at the entrance of the ear canal usually causes visible cerumen to loosen and slip out. Instruct patients never to use objects such as bobby pins, toothpicks, paper clips, or cotton-tipped applicators to remove earwax. These objects can injure the ear canal and rupture the tympanic membrane. They may also cause cerumen to become impacted within the ear canal.

Children and older adults commonly have impacted cerumen. You can usually remove excessive or impacted cerumen by irrigation, which requires a health care provider's order. Review the order for type of solution and ear(s) to receive the irrigation. Before irrigation question the patient for history of perforated eardrum and inspect his or her tympanic membrane to be sure that it is intact; a perforated tympanic membrane contradicts performing irrigation. Visually inspect the pinna and external meatus for redness, swelling, drainage, and presence of foreign objects. Also determine the patient's ability to hear in the affected ear before irrigation.

To irrigate the ear, have the patient sit or lie on the side with the affected ear up. For adults and children over 3 years of age, gently pull the pinna up and back. In children 3 years of age or younger, the pinna should be pulled down and back. Using a bulb-irrigating syringe or a Water Pik set on No. 2 setting, gently wash the ear canal with warm solution (37° C or 98.6° F), being careful to not occlude the canal, which results in pressure on the tympanic membrane. Direct the fluid slowly and gently toward the superior aspect of the ear canal, maintaining the flow in a steady stream. Periodically during the irrigation ask if the patient is experiencing pain, nausea, or vertigo. These symptoms indicate that the solution is too hot or too cold or is being instilled with too much pressure. After the canal is clear, wipe off any moisture from the ear with cotton balls and inspect the canal for remaining earwax.

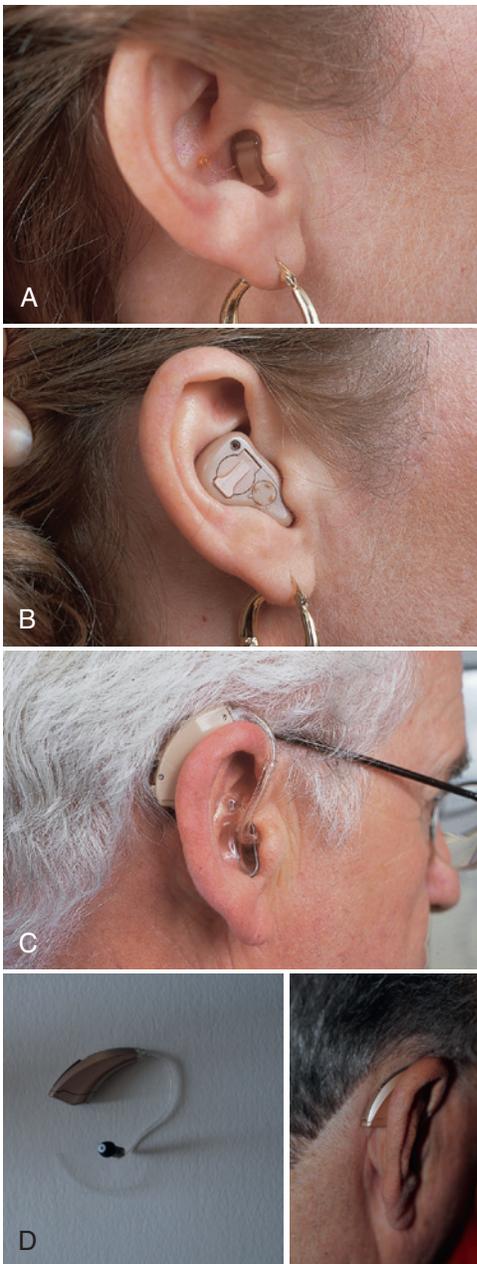
Hearing Aid Care. A hearing aid amplifies sounds in a controlled manner; the aid receives normal low-intensity sound inputs and delivers them to a patient's ear as louder outputs. Hearing aids come in a


FIGURE 40-7 Common types of hearing aids. **A,** Completely-in-canal (CIC). **B,** In the ear (ITE). **C,** Behind the ear (BTE). **D,** Digital hearing aid.

variety of types. The new class of hearing aids reduces background noise interference. Computer chips placed in the aids allow for fine adjustments to the specific patient's hearing needs.

There are several popular types of hearing aids. A completely-in-canal (CIC) aid (Figure 40-7, *A*) is the newest, smallest, and least visible and fits entirely in the ear canal. It is used for patients with moderately severe hearing loss. It has cosmetic appeal, is easy to manipulate and place in the ear, and does not interfere with wearing eyeglasses or using the telephone; and the patient can wear it during most physical exercise. However, it requires adequate ear diameter and depth for proper fit. It does not accommodate progressive hearing loss; and it requires manual dexterity to operate, insert, remove, and change batteries. In addition, cerumen tends to plug this model more than the others.

An in-the-ear (ITE, or intraaural) aid (Figure 40-7, *B*) fits into the external auditory canal and allows for finer tuning. It is more

powerful and stronger and therefore is useful for mild-to-severe hearing loss than the ITC aid. It is easy to position and adjust and does not interfere with wearing eyeglasses. However, it is more noticeable than the ITC aid and is not for people with moisture or skin problems in the ear canal.

A behind-the-ear (BTE, or postaural) aid (Figure 40-7, *C*) hooks around and behind the ear. It is connected by a short, clear, hollow plastic tube to an earmold inserted into the external auditory canal. A BTE aid allows for fine tuning. It is the largest aid and is useful for patients with mild to profound hearing loss or manual dexterity difficulties or for those who find partial ear occlusion intolerable. The larger size of this type of aid can make use of eyeglasses and phones difficult; it is more difficult to keep in place during physical exercise.

Digital hearing aids (Figure 40-7, *D*) analyze sounds to remove background noise. This aid is beneficial for people with mild to severe hearing loss. Digital hearing aids program for low-frequency and high-frequency sounds and must be programmed and adjusted by a licensed audiologist. Box 40-15 reviews guidelines for the care and cleaning of hearing aids.

Nasal Care. A patient usually removes secretions from the nose by gently blowing into a soft tissue. Caution the patient against harsh blowing that creates pressure capable of injuring the eardrum, nasal mucosa, and even sensitive eye structures. Bleeding from the nares is a sign of harsh blowing. If a patient is unable to remove nasal secretions, help by using a wet washcloth or a cotton-tipped applicator moistened in water or saline. Never insert the applicator beyond the length of the cotton tip. You can remove excessive nasal secretions by gentle suctioning.

When nasogastric, feeding, or endotracheal tubes are inserted through a patient's nose, change the tape anchoring the tube at least once a day. When tape becomes moist from nasal secretions, the skin and mucosa easily become macerated. Friction from a tube causes tissue sloughing and eventual ulceration. After carefully removing the

tape, maintain hold of the tubing and thoroughly clean and dry the nasal surface.

Patient's Room Environment. Attempt to make a patient's room as comfortable as the home. It needs to be safe and large enough to allow the patient and visitors to move about freely. Removal of barriers along walkways reduces risk of falls. Control room temperature, ventilation, noise, and odors. Keeping the room neat and orderly also contributes to the patient's sense of well-being.

Maintaining Comfort. What makes a comfortable environment depends on a patient's age, severity of illness, and level of normal daily activity. Depending on age and physical condition, maintain the room temperature between 20° and 23° C (68° and 73.4° F). Infants, older adults, and the acutely ill often need a warmer room. However, certain ill patients benefit from cooler room temperatures to lower the metabolic demands of the body.

An effective ventilation system keeps stale air and odors from lingering in a room. Protect the acutely ill, infants, and older adults from drafts by ensuring that they are dressed adequately and covered with a lightweight blanket. Always empty and rinse commodes, bedpans, and urinals promptly. Room deodorizers help remove many unpleasant odors. Before using room deodorizers determine that the patient is not allergic or sensitive to the deodorizer itself. Thorough hygiene measures provide the best control of body or breath odors.

Ill patients seem to be more sensitive to noises and lighting commonly found in health care settings. Try to control the noise level, especially when a patient is trying to sleep. Explain the source of unfamiliar noises such as an IV pump or pulse oximeter alarms. Proper lighting provides for safety and comfort. A brightly lit room usually stimulates, whereas a darkened room promotes rest and sleep. Adjust room lighting by closing or opening drapes, regulating over-bed and floor lights, and closing or opening room doors. When entering a patient's room at night, refrain from abruptly turning on an overhead light unless necessary.

Room Equipment. Although there are variations across health care settings, a typical hospital room contains the following basic pieces of furniture: over-bed table, bedside stand, chairs, and bed (Figure 40-8). Long-term care and rehabilitation facilities often have similar equipment. You can adjust the over-bed table, which rolls on wheels, to various heights over the bed or a chair. The table provides ideal working space for performing procedures. It also provides a surface on which to place meal trays, toiletry items, and objects frequently used by a patient. Clean the top of the over-bed table with an antiseptic cleaner before using it for meals. Do not place the bed pan or urinal on the over-bed table. The bedside stand is for storing the patient's personal possessions and hygiene equipment. The telephone, water pitcher, and drinking cup are usually on top of the bedside stand.

Most hospital rooms contain an armless straight-backed chair or an upholstered lounge chair with arms. Straight-backed chairs are convenient when temporarily transferring patients from a bed such as during bed making. Lounge chairs tend to be more comfortable when a patient is willing and able to sit for an extended period.

Each room usually has an over-bed light and floor level night lighting. Position movable lights that extend over the bed from the wall for easy reach but move them aside when not in use. Additional portable lighting provides extra light during bedside procedures. Some facilities have permanent examination lights mounted in the ceiling or wall.

Other equipment usually found in a patient's room includes a call light, a television set, a wall-mounted blood pressure gauge, oxygen and vacuum wall outlets, and personal care items. Special equipment designed for comfort or positioning patients includes foot boots and special mattresses (see Chapter 48). Whenever you use comfort and

FIGURE 40-8 Typical hospital room.

positioning equipment, check agency policy and manufacturer directions before application.

Beds. Seriously ill patients often remain in bed for a long time. Because a bed is the piece of equipment used most by a hospitalized patient, it is designed for comfort, safety, and adaptability for changing positions. A typical hospital bed has a firm mattress on a metal frame that you can raise and lower horizontally. More and more hospitals are converting the standard hospital bed to one in which the mattress surface can be adjusted electronically for safety and comfort. For example, low beds are being used to prevent falls, and beds that regulate pressure in the mattress help to reduce pressure ulcers. Different bed positions promote patient comfort, minimize symptoms, promote lung expansion, and improve access during certain procedures (Table 40-6).

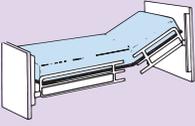
You usually change the position of a bed by using electrical controls incorporated into the patient's call light and in a panel on the side or foot of the bed (Figure 40-9). Know how to use the bed controls. Ease in raising and lowering a bed and changing position of the head and foot eliminates undue musculoskeletal strain. Also instruct patients and family members in the proper use of controls and caution them against raising the bed to a position that causes the patient harm. Maintain the bed height at the lowest horizontal position when a patient is unattended.

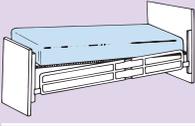
Beds contain safety features such as locks on the wheels or casters. Lock wheels when a bed is stationary to prevent accidental movement. Side rails allow patients to move more easily in bed and prevent accidents. Do not use side rails to restrict a patient from moving in bed. When using side rails as a restraint, you need a health care provider's order (see Chapter 27). You can remove the headboard and footboard from most beds. This is important when the medical team needs to have easy access to the patient such as during cardiopulmonary resuscitation.

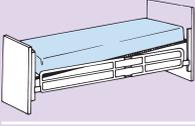
Bed Making. Keep a patient's bed clean and comfortable. This requires frequent inspection to be sure that linen is clean, dry, and free of wrinkles. When patients are diaphoretic, have draining wounds, or are incontinent, check more frequently for wet or soiled linen.

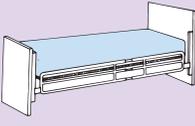
Usually you make the bed in the morning after a patient's bath or while he or she is bathing, in a shower, sitting in a chair eating, or out of the room for procedures or tests. Throughout the day straighten linen that is loose or wrinkled. Also check the bed linen for food particles after meals and for wetness or soiling. Change any linen that becomes soiled or wet.

TABLE 40-6   Common Bed Positions

Position	Description	Uses
Fowler's	Head of bed raised to angle of 45 degrees or more; semi-sitting position; foot of bed may also be raised at knee	While patient is eating During nasogastric tube insertion and nasotracheal suction Promotes lung expansion Eases difficult breathing
Semi-Fowler's	Head of bed raised approximately 30 degrees; inclination less than Fowler's position; foot of bed may also be raised at knee	Promotes lung expansion, especially with ventilator-assisted patients Used when patients receive oral care and for gastric feedings to reduce regurgitation and risk of aspiration
Trendelenburg's	Entire bedframe tilted with head of bed down	Used for postural drainage Facilitates venous return in patients with poor peripheral perfusion
Reverse Trendelenburg's	Entire bedframe tilted with foot of bed down	Used infrequently Promotes gastric emptying Prevents esophageal reflux
Flat	Entire bedframe horizontally parallel with floor	Used for patients with vertebral injuries and in cervical traction Used for patients who are hypotensive Patients usually prefer for sleeping








When changing bed linen, follow principles of medical asepsis by keeping soiled linen away from the uniform (Figure 40-10). Place soiled linen in special linen bags before placing in a hamper. To avoid air currents that spread microorganisms, never shake the linen. To avoid transmitting infection, do not place soiled linen on the floor. If clean linen touches the floor or any unclean surface, immediately place it in the dirty-linen container.

During bed making use safe patient-handling procedures (see Chapter 28). Always raise the bed to the appropriate height before changing linen so you do not have to bend or stretch over the mattress. Move back and forth to opposite sides of the bed while applying new linen. Body mechanics and safe handling are important when turning or repositioning a patient in bed.

When patients are confined to bed, you must make an occupied bed. Organize bed-making activities to conserve time and energy (Box 40-16). The patient's privacy, comfort, and safety are all important when making a bed. Using side rails to aid positioning and turning, keeping call lights within the patient's reach, and maintaining the proper bed position help promote comfort and safety. After making a bed, return it to the lowest horizontal position and verify that the wheels are locked to prevent accidental falls when the patient gets in and out alone.

When possible, make the bed while it is unoccupied (Box 40-17). Use judgment to determine the best time for a patient to sit in a chair so you can make the bed. When making an unoccupied bed, follow the same basic principles as for occupied bed making.

An unoccupied bed can be made as an open or closed bed. In an open bed the top covers are folded back so it is easy for a patient to get into bed. Draw up the top sheet, blanket, and bedspread to the head of the mattress and place a pillow at the top to make a closed bed. A closed bed is prepared in a hospital room before a new patient is admitted to that room. A surgical, recovery, or postoperative bed is a modified version of the open bed. The top bed linen is arranged for easy transfer of the patient from a stretcher to the bed. The top sheets and spread are not tucked or mitered at the corners. Instead they are folded to one side or to the bottom third of the bed (Figure 40-12). This makes patient transfer into the bed easier.

Linens. Many agencies have "nurse servers" either within or just outside a patient's room to store a daily supply of linen. Because of the importance of cost control in health care, avoid bringing excess linen into a patient's room. Once you bring linen into a patient's room, if

FIGURE 40-9 Nurse instructing patient in use of call light and bed controls.

FIGURE 40-10 Holding linen away from uniform prevents contact with microorganisms.

BOX 40-16 PROCEDURAL GUIDELINES

Making an Occupied Bed

Delegation Considerations

The skill of making an occupied bed can be delegated to nursing assistive personnel (NAP). The nurse reviews any precautions or activity restrictions. Instruct the NAP about:

- Any activity or positioning restrictions for the patient, including need to use equipment for lifting and positioning patient.
- Looking for wound drainage, dressing materials, drainage tubes, or intravenous tubing that becomes dislodged or is found in linens.
- What to do if patient becomes tired.

Equipment

Linen bag(s), mattress pad *(optional depending on facility practice; needs to be changed only when soiled)*, bottom sheet (flat or fitted), drawsheet, top sheet, blanket *(optional depending on patient preference)*, bedspread, waterproof pads and/or bath blankets *(optional)*, pillowcases, bedside chair or table, clean gloves *(optional)*, paper towels or washcloth, disinfectant (Figure 40-11).

Old cotton drawsheet

Old plastic drawsheet (optional)

Old bottom sheet and mattress pad

Clean bottom sheet and mattress pad

Clean plastic drawsheet (optional)

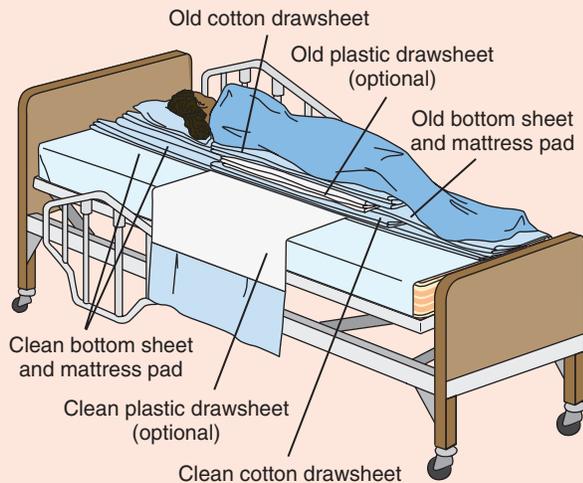
Clean cotton drawsheet


FIGURE 40-11 Equipment for making occupied bed.

Steps

1. Check chart for orders or specific precautions concerning patient movement and positioning.
2. Gather needed supplies, being sure not to let clean linen touch your uniform.
3. Explain procedure to patient, including that he or she will be asked to turn on side and roll over linen.
4. Perform hand hygiene and apply clean gloves (wear gloves only if old linen is soiled or there is risk for contact with body).
5. Assess potential for patient incontinence or excess drainage on bed linen.
6. Arrange equipment on bedside chair or over-bed table. Remove unnecessary equipment such as a dietary tray or items used for hygiene. Pull curtain and close door.
7. Adjust bed height to comfortable working position with bed flat if patient can tolerate. Lower raised side rail on one side of bed. Remove call light.
8. Loosen top linen at foot of bed.
9. Remove bedspread and blanket separately. If spread and blanket are soiled, place them in linen bag. Keep soiled linen away from uniform.
10. If blanket and spread are to be reused, fold them by bringing the top and bottom edges together. Fold farthest side over onto nearer bottom edge. Bring top and bottom edges together again. Place folded linen over back of chair.

11. Cover patient with bath blanket in the following manner: unfold bath blanket over top sheet. Ask patient to hold top edge of bath blanket. If patient is unable to help, tuck top of bath blanket under shoulders. Grasp top sheet under bath blanket at patient's shoulders and bring sheet down to foot of bed. Remove sheet and discard in linen bag.
12. Help patient turn toward far side of bed, turned onto side and facing away from you. Be sure that side rail in front of patient is up. Adjust pillow under patient's head.
13. Loosen bottom linens, moving from head to foot. With seam side down (facing the mattress), fanfold soiled drawsheet and bottom sheet toward patient. Tuck edges of linen just under buttocks, back, and shoulders. Do not fanfold mattress pad if it is to be reused (see illustration).

STEP 13 Old linen tucked under patient.

14. Wipe off any moisture on exposed mattress with paper towel and appropriate disinfectant. Make sure that mattress surface is dry before applying linens.
15. Apply clean linen to exposed half of bed:
   a. Place clean mattress pad on bed (if used) by folding it lengthwise with center crease in middle of bed. Fanfold top layer over mattress. (If pad is reused, simply smooth out any wrinkles.)
   b. If using flat sheet for bottom sheet, unfold sheet lengthwise so center crease is situated lengthwise along center of bed. Fanfold top layer of sheet toward center of bed alongside patient (see illustration). Smooth bottom layer of sheet over mattress and bring edge over closest side of mattress. If using fitted sheet, pull sheet smoothly over mattress ends.

STEP 15b Clean linen applied to bed.

Continued

BOX 40-16 PROCEDURAL GUIDELINES

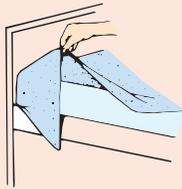
Making an Occupied Bed—cont'd

   c. Allow edge of flat unfitted sheet to hang about 25 cm (10 inches) over mattress edge. Make sure that lower hem of bottom flat sheet lies seam down and even with bottom edge of mattress.

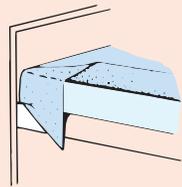
16. If flat sheet is used for bottom sheet, miter bottom flat sheet at head of bed:

   a. Face head of bed diagonally. Place hand away from head of bed under top corner of mattress, near mattress edge, and lift.

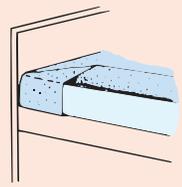
   b. With other hand tuck top edge of bottom sheet smoothly under mattress so side edges of sheet above and below mattress meet when brought together.

   c. Face side of bed and pick up top edge of sheet at approximately 45 cm (18 inches) from top of mattress (see illustration).


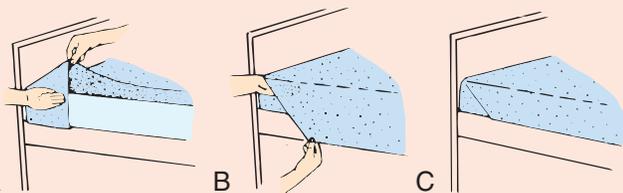
STEP 16c Top edge of sheet picked up.

   d. Lift sheet and lay it on top of mattress to form a neat triangular fold, with lower base of triangle even with mattress side edge (see illustration).


STEP 16d Sheet on top of mattress in a triangular fold.

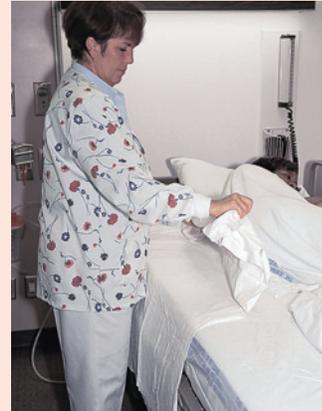
   e. Tuck lower edge of sheet, which is hanging free below the mattress, under mattress. Tuck with palms down without pulling triangular fold (see illustration).


STEP 16e Lower edge of sheet tucked under mattress.

   f. Hold part of sheet covering side of mattress in place with one hand. With the other hand, pick up top of triangular linen fold and bring it down over side of mattress. Tuck this part under mattress (see illustration).


STEP 16f A and B, Triangular fold placed over side of mattress. **C,** Linen tucked under mattress.

   g. Tuck remaining part of sheet under mattress, moving toward foot of bed. Keep linen smooth.

17. *Optional:* Open clean drawsheet so it unfolds in half. Lay centerfold along middle of bed lengthwise and position sheet so it is under patient's buttocks and torso (see illustration). Fanfold top layer of drawsheet toward patient with edge along patient's back. Smooth bottom layer out over mattress and tuck excess edge under mattress (keep palms down).


STEP 17 Optional drawsheet.

18. Place single waterproof pad over drawsheet *(optional)* with centerfold against patient's side. Fanfold top layer toward patient.

19. Advise patient that rolling over thick layer of linens is necessary and that he or she will feel a lump. Have patient roll slowly toward you over the layers of linen (rolling like a log). Have patient lie still and raise side rail on working side before going to other side of bed.

20. Lower side rail. Help patient to comfortable positioning on other side as needed. Loosen edges of soiled linen from under mattress (see illustration).

STEP 20 Helping patient to position after rolling over folds of linen.

21. Remove all soiled linen by folding it into a bundle or square with soiled side turned in. Discard in linen bag. If necessary, wipe mattress with antiseptic solution and dry mattress surface before unfolding and applying clean linen.

22. Pull clean, fanfolded linen smoothly over edge of mattress from head to foot of bed. Help patient roll back into supine position (if preferred). Reposition pillow.

BOX 40-16 **PROCEDURAL GUIDELINES**

Making an Occupied Bed—cont'd

23. If using a fitted sheet, pull it smoothly over mattress ends. If using a flat sheet, miter top corner of bottom sheet (see Steps 16 a-g). When tucking corner, be sure that sheet is smooth and free of wrinkles.

24. Facing side of bed, grasp remaining edge of bottom flat sheet. Lean back, keep back straight, and pull while tucking excess linen under mattress. Proceed from head to foot of bed. (Avoid lifting mattress during tucking to ensure fit.)

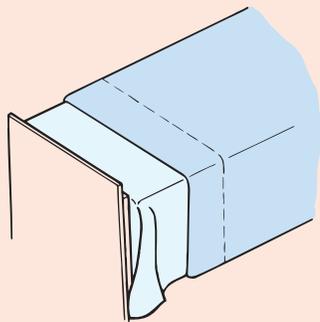
25. Smooth fanfolded drawsheet out over bottom sheet. Grasp edge of sheet with palms down, lean back, and tuck sheet under mattress. Tuck from middle to top and then to bottom.

26. Place top sheet over patient with centerfold lengthwise down middle of bed. Open sheet from head to foot and unfold over patient. Ask patient to hold clean top sheet or tuck sheet around his or her shoulders. Remove bath blanket and discard in linen bag.

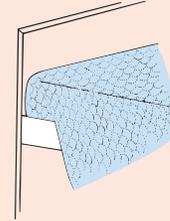
27. Place blanket on bed, unfolding it so crease runs lengthwise along middle of bed. Unfold blanket to cover patient. Make sure that top edge is parallel with edge of top sheet and 15 to 20 cm (6 to 8 inches) from edge of top sheet.

28. Place spread over bed according to Step 27. Be sure that top edge of spread extends about 2.5 cm (1 inch) above edge of blanket. Tuck top edge of spread over and under top edge of blanket.

29. Make cuff by turning edge of top sheet down over top edge of blanket and spread.

30. Standing on one side at foot of bed, lift mattress corner slightly with one hand and tuck sheet and blanket together under mattress. Be sure that lines are loose enough to allow movement of patient's feet. Making a horizontal toe pleat is an option (see illustration).


STEP 30 Optional toe pleat.

31. Make modified mitered corner with top sheet, blanket, and spread (follow Steps 16 a-e). After making the triangular fold, do not tuck tip of the triangle (see illustration) under the mattress.


STEP 31 Modified mitered corner.

32. Raise side rail. Make other side of bed; spread sheet, blanket, and bedspread out evenly. Fold top edge of spread over blanket and make cuff with top sheet (see Steps 28 and 29); make modified mitered corner (see Step 31)

33. Change pillowcase:
    a. Have patient raise head. While supporting neck with one hand, remove pillow. Allow patient to lower head.
    b. Remove soiled case by grasping pillow open end with one hand and pulling case back over pillow with other hand. Discard case in linen bag.
    c. Grasp clean pillowcase at center of closed end. Gather case, turning it inside out over the hand holding it. With same hand pick up middle of one end of pillow. Pull pillowcase down over pillow with other hand.
    d. Be sure that pillow corners fit evenly into corners of pillowcase. Place pillow under patient's head.

34. Place call light within patient's reach and return bed to comfortable position and height. Open room curtains and rearrange furniture. Place personal items within easy reach on over-bed table or bedside stand.

35. Place dirty linen in hamper or chute. Remove gloves (if worn); dispose and perform hand hygiene.

36. Ask if patient feels comfortable.

37. Use this time to inspect skin for areas of irritation.

Making an Unoccupied Bed

Delegation Considerations

The skill of making an unoccupied bed can be delegated to nursing assistive personnel (NAP).

Equipment

Linen bag, mattress pad (change only when soiled), bottom sheet (flat or fitted), drawsheet *(optional)*, top sheet, blanket, bedspread, waterproof pads *(optional)*, pillowcases, bedside chair or table, clean gloves (if linen is soiled), washcloth or paper towel, and antiseptic cleanser.

Steps

1. If patient has been incontinent or if excess drainage is on linen, gloves are necessary.
2. Assess activity orders or restrictions in mobility in planning if patient can get out of bed for procedure. Help to bedside chair or recliner.
3. Lower side rails on both sides of bed and raise bed to comfortable working position.
4. Remove soiled linen and place in laundry bag. Avoid shaking or fanning linen.
5. Reposition mattress and wipe off any moisture with a washcloth or paper towel moistened in antiseptic solution. Dry thoroughly.
6. Apply all bottom linen on one side of bed (before moving to opposite side):
   a. Be sure that fitted sheet is placed smoothly over mattress.
   b. To apply a flat unfitted sheet, allow about 25 cm (10 inches) to hang over sides of mattress edges. Make sure that lower hem of sheet lies seam down, even with bottom edge of mattress. Pull remaining top part of sheet over top edge of mattress.
7. While standing at head of bed, miter top corner of bottom sheet (see Box 40-16, Steps 16a-f).
8. Tuck remaining part of unfitted sheet under mattress from head to foot of bed.
9. *Optional:* Apply drawsheet, laying centerfold along middle of bed lengthwise. Smooth drawsheet over mattress and tuck excess edge under mattress, keeping palms down.
10. Move to opposite side of bed and spread bottom sheet smoothly over edge of mattress from head to foot of bed.

11. Apply fitted sheet smoothly over each mattress corner. For an unfitted sheet, miter top corner of bottom sheet (see Step 7), making sure that corner is taut.
12. Grasp remaining edge of unfitted bottom sheet and tuck tightly under mattress while moving from head to foot of bed.
13. Smooth folded drawsheet over bottom sheet and tuck under mattress, first at middle, then at top, and then at bottom.
14. If needed, apply single waterproof pad over bottom sheet or drawsheet.
15. Place top sheet over bed with vertical centerfold lengthwise down middle of bed. Open sheet out from head to foot, being sure that top edge of sheet is even with top edge of mattress.
16. Make horizontal toe pleat: stand at foot of bed and make fanfold in sheet 5 to 10 cm (2 to 4 inches) across bed. Pull sheet up from bottom to make fold approximately 15 cm (6 inches) from bottom edge of mattress.
17. Tuck in remaining part of sheet under foot of mattress. Place blanket over bed with top edge parallel to top edge of sheet and 15 to 20 cm (6 to 8 inches) down from edge of sheet. (*Optional:* Apply additional spread over bed.)
18. Make cuff by turning edge of top sheet down over top edge of blanket and spread.
19. Standing on one side at foot of bed, lift mattress corner slightly with one hand; with other hand tuck top sheet, blanket, and spread under mattress. Be sure that toe pleats are not pulled out.
20. Make modified mitered corner with top sheet, blanket, and spread. After making triangular fold, do not tuck tip of triangle (see Box 40-16, Step 31).
21. Go to other side of bed. Spread sheet, blanket, and spread out evenly. Make cuff with top sheet and blanket. Make modified corner at foot of bed.
22. Apply clean pillowcase (see Box 40-16, step 33).
23. Place call light within patient's reach on bedrail or pillow and return bed to height allowing for patient transfer. Help patient to bed.
24. Arrange patient's room. Remove and discard supplies. Perform hand hygiene.

FIGURE 40-12 Surgical or recovery bed.

unused, it must be laundered before being used. Excess linen lying around a patient's room creates clutter and obstacles for patient care activities.

Before making a bed, collect necessary bed linens and the patient's personal items. In this way all equipment is accessible to prepare the bed and room. When fitted sheets are not available, flat sheets usually are pressed with a center crease to be placed down the center of the bed. The linens unfold easily to the sides, with creases often fitting over the mattress edge. Apply clean linens whenever there is soiling.

Handle linen properly to minimize the spread of infection (see Chapter 29). Agency policies provide guidelines for the proper way to bag and dispose of soiled linen. After a patient is discharged, all bed linen goes to the laundry, and housekeeping cleans the mattress and bed before clean linen is applied.

◆ **Evaluation**

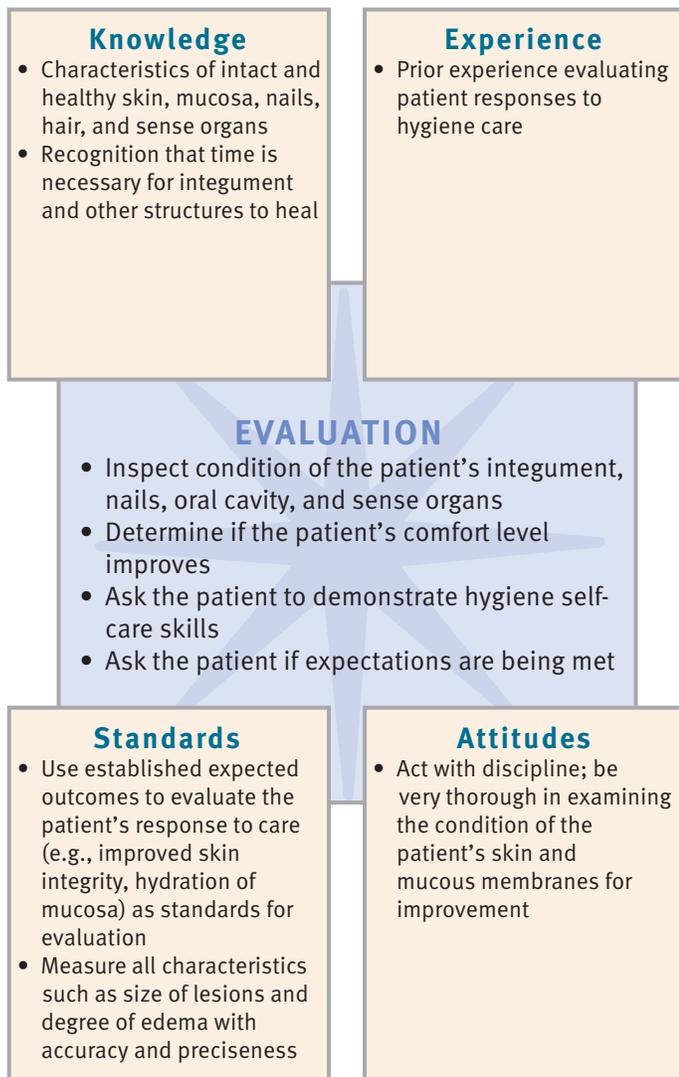
Through the Patient's Eyes. During assessment you collected information about a patient's expectations of care. Both during and after hygiene determine from the patient if care is being provided in an acceptable manner (Figure 40-13). For example, while bathing a


FIGURE 40-13 Critical thinking model for hygiene evaluation.

Knowledge
- Characteristics of intact and healthy skin, mucosa, nails, hair, and sense organs
- Recognition that time is necessary for integument and other structures to heal

Experience
- Prior experience evaluating patient responses to hygiene care

EVALUATION
- Inspect condition of the patient's integument, nails, oral cavity, and sense organs
- Determine if the patient's comfort level improves
- Ask the patient to demonstrate hygiene self-care skills
- Ask the patient if expectations are being met

Standards
- Use established expected outcomes to evaluate the patient's response to care (e.g., improved skin integrity, hydration of mucosa) as standards for evaluation
- Measure all characteristics such as size of lesions and degree of edema with accuracy and preciseness

Attitudes
- Act with discipline; be very thorough in examining the condition of the patient's skin and mucous membranes for improvement

patient, encourage him or her to verbalize any discomfort such as too-cool water or discomfort with movement. To evaluate a patient's satisfaction with your care, ask questions such as, "Do you think your bath helped you feel more comfortable?" "Are there ways we can make you feel less tired during your bath?" "Were you pleased with how we

cared for your foot?" Being aware of and addressing a patient's expectations and any concerns foster a caring therapeutic relationship.

Patient Outcomes. Evaluate patient responses to hygiene measures both during and after each particular hygiene intervention. For example, while bathing a patient inspect the skin carefully to see if soiling or drainage is effectively removed. Once a bath is completed, evaluate if the patient feels more comfortable by using a pain scale (see Chapter 44). Frequently it takes time for hygiene care to result in an improvement in a patient's condition. The presence of oral lesions, a scalp infestation, or skin excoriation often requires repeated measures and a combination of nursing interventions. Your knowledge base and experience provide important perspectives when analyzing ongoing evaluation data about a patient. For example, frequent observation of the skin helps to determine the effectiveness of hygiene practices. Does a rash clear or a pressure ulcer heal? Is the patient able to complete hygiene care using adaptive equipment?

To evaluate a patient's or family caregiver's ability to perform self-care hygiene measures use Teach Back. For example, "I want to be sure you are clear about why foot care is so important for you since you have diabetes. Tell me three things you can do to protect your feet from infection?" Another example, "We talked about ways to prevent your skin from drying. Describe them for me."

If outcomes established for the care plan are not met, revise it. Continue to apply critical thinking attitudes when considering all evaluation findings. When outcomes are not met, ask questions by involving the patient to determine appropriate changes in interventions. Examples of questions include:
- What is preventing you from being able to perform your foot care at home?
- Which further measures do you think are necessary to keep your mouth feeling clean?
- What do you think would help you be more independent with your hygiene?

> **QSEN: BUILDING COMPETENCY IN PATIENT SAFETY** Mrs. White is discharged to her home. Her granddaughter and a home care aide will provide care for her over the next few weeks. Mrs. White is making progress using the walker and bath-adaptive equipment that have been ordered for home care. Which assessments should be made for her following discharge from the hospital? What teaching needs to be provided to the family member to perform safe hygiene care for her grandmother?
>
> Answers to QSEN Activities can be found on the Evolve website.

SAFETY GUIDELINES FOR NURSING SKILLS

Ensuring patient safety is an essential role of the professional nurse. To ensure patient safety, communicate clearly with members of the health care team, assess and incorporate the patient's priorities of care and preferences, and use the best evidence when making decisions about your patient's care. When performing the skills in this chapter, remember the following points to ensure safe, individualized patient care.
- To implement patient safety for the practice setting, identify the patient using two identifiers (TJC, 2016).
- Always perform hygiene measures moving from the cleanest to less clean or dirty areas. This often requires you to change gloves and perform hand hygiene during care activities.
- Use clean gloves when you anticipate contact with nonintact skin or mucous membranes or when there will likely be contact with drainage, secretions, excretions, or blood during hygiene care.
- When using water or solutions for hygiene care, be sure to test the temperature to prevent burn injury.
- Use principles of body mechanics and safe patient handling to avoid injury when performing hygiene care and reduce risk of harm to self or others (QSEN, 2014).
- You are responsible and accountable for the care provided. Give proper direction to nursing assistive personnel to whom you delegate and be sure they are competent with hygiene measures.

SKILL 40-1	**BATHING AND PERINEAL CARE**	⏵

DELEGATION CONSIDERATIONS

The skill of bathing and perineal care can be delegated to nursing assistive personnel (NAP). Direct the NAP to:

- Avoid massaging reddened skin areas.
- Perform range-of-motion (ROM) exercises for patients able to tolerate.
- Report skin changes or early signs of impaired skin integrity, including redness or pale skin, to nurse.
- Properly position patients with musculoskeletal limitations and indwelling catheters or intravenous (IV) lines.
- Report patient fatigue, shortness of breath, or pain during hygiene care.

EQUIPMENT

- Washcloths and bath towels *(disposable cloths optional)*
- Bath blanket
- Soap and soap dish or liquid chlorhexidine gluconate (CHG) *(CHG cloths optional)*
- Toiletry items (deodorant, powder, lotion, cologne) **NOTE:** When using CHG soap, use a lotion that is hospital approved, such as Aloe Vesta.
- Toilet tissue or wipes
- Warm water
- Clean hospital gown or patient's own pajamas or gown
- Laundry bag
- Clean gloves (when risk for contacting body fluids)
- Washbasin *(optional when using CHG cloths)*

STEP	**RATIONALE**

ASSESSMENT

1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number, according to agency policy).

2. Assess patient's tolerance for bathing: activity tolerance, comfort level during movement, cognitive ability, musculoskeletal function, and presence of shortness of breath.

Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).

Determines patient's ability to perform or tolerate bathing and level of assistance required (e.g., tub bath, partial bed bath).

CLINICAL DECISION: *Patients with dementia may become agitated and aggressive during bathing activities. Consider using alternative bathing procedures such as bag wipes with these patients. Maintain a calm, nonthreatening, quiet environment using therapeutic communication.*

---

3. Assess patient's visual status, ability to sit without support, hand grasp, ROM of extremities.

4. Assess for presence of equipment (e.g., intravenous [IV] line, oxygen tubing, Foley catheter).

5. Assess for allergy or sensitivity to CHG.

6. Assess patient's bathing preferences: frequency and time of day preferred, type of hygiene products used, and other factors related to patient preferences.

7. Ask if patient has noticed any problems related to condition of skin and genitalia: excess moisture, inflammation, drainage or excretions from lesions or body cavities, rashes or other skin lesions.

8. Before or during bath assess condition of patient's skin. Note presence of dryness, indicated by flaking, redness, scaling, and cracking.

9. Assess patient's knowledge of skin hygiene in terms of its importance, preventive measures to take, and common problems.

Determines degree of assistance patient needs for bathing. ROM may be delegated to assistive personnel.

Affects how you plan bathing activities and positioning. Helps determine how to set up supplies.

When allergy or sensitivity is present, select another cleansing solution.

Patient participates in plan of care. Promotes patient's comfort and willingness to cooperate. Includes cultural or personal hygiene preferences into care.

Provides you with information to direct physical assessment of skin and genitalia during bathing. Also influences selection of skin care products.

Provides a baseline for comparison over time in determining if bathing improves condition of skin.

Determines patient's learning needs.

PLANNING

1. Review orders for specific precautions concerning patient's movement or positioning.

2. Check for health care provider's therapeutic bath order; if there is an order, note type of solution, length of time for bath, body part to be attended.

3. Explain procedure and ask patient for suggestions on how to prepare supplies. If partial bath, ask how much of bath patient wishes to complete. If using CHG, explain benefit of reducing infection and that solution leaves a sticky feeling.

4. Prepare equipment and supplies. If it is necessary to leave room, be sure that call light is within patient's reach.

Prevents injury to patient during bathing activities. Determines level of assistance required by patient.

Therapeutic baths are ordered for specific physical effect, which usually includes promotion of healing or soothing effects.

Promotes patient's cooperation and participation. Patients who prefer using their own bathing supplies may need to discuss benefits of CHG.

Avoids interrupting procedure or leaving patient unattended to retrieve missing equipment.

IMPLEMENTATION

1. Complete or partial bed bath

   a. Assess environment for safety (e.g., check room for spills, make sure that equipment is working properly and that bed is in locked, low position).

   b. Close room, door, and windows; draw room divider curtain. Offer patient bedpan or urinal. Provide toilet tissue.

   c. Perform hand hygiene. If patient has nonintact skin or skin is soiled with drainage, excretions, or body secretions, apply clean gloves. Ensure that patient is not allergic to latex.

Identifies safety hazards that could cause or potentially lead to harm (QSEN, 2014).

Provides for patient privacy.

Helps patient feel more comfortable after voiding.

Prevents interruption of bath.

Reduces transmission of microorganisms.

Prevents allergic reaction if latex gloves are used.

STEP	RATIONALE

d. Verify that bed is in locked position and raise bed to comfortable working height. Lower side rail closest to you and help patient into comfortable supine position, maintaining body alignment. Bring patient toward side closest to you.

Prevents bed from moving. Helps you reach patient without stretching and reaching across bed, thus minimizing strain on back muscles.

e. Place bath blanket over patient and loosen and remove top covers without exposing him or her. If possible, have patient hold top of bath blanket while you remove linen. Place soiled linen in laundry bag. Take care to not allow linen to touch your uniform. *Optional:* Use top sheet when bath blanket is not available or patient prefers.

Bath blanket provides warmth and privacy during bath.

f. Remove patient's gown or pajamas.

Provides full exposure of body parts during bathing.

   (1) If using gown with ties or snaps on sleeves for patient with IV line, upper-extremity injury, or limited ROM, simply unsnap or untie and remove gown.

   (2) If regular gown is used and patient has limited upper-extremity ROM or an IV access, remove gown from *unaffected side first*.

Undressing unaffected side first allows easier manipulation of gown over body part with reduced ROM.

   (3) Remove gown from arm with IV line (see illustrations A-C). Remove IV bag and tubing from pole and slide IV container and tubing through arm of patient's gown. Rehang IV container and check flow rate (see illustration D). Regulate if necessary.

Manipulation of IV tubing and container may disrupt flow rate. Do **not** delegate regulation of IV flow rate to NAP.

   (4) If IV pump is in use, turn pump off, clamp tubing, remove tubing from pump, and proceed as in Step (3). Reinsert tubing into pump, unclamp tubing, and turn pump on at correct rate. Observe flow rate and regulate if necessary. *Do not disconnect tubing.*

Regulation is necessary to prevent improper infusion of fluids. Do **not** delegate regulation of IV pump to NAP.

Disconnecting IV tubing places patient at risk of introduction of microorganisms into the IV line.

g. Pull side rail up. Lower bed temporarily to lowest position and raise to comfortable working height on return after filling washbasin two-thirds full with warm water. (*Option:* if using 4% CHG solution, pour entire single-use container into basin.) Place basin and supplies on over-bed table. Check water temperature and also have patient place fingers in water to test temperature tolerance. Place plastic container of bath lotion in bath water to warm if desired.

Raising side rail and lowering bed position maintain patient's safety while you leave bedside. Keeping bed at working height during bath prevents back strain. Warm water promotes comfort, relaxes muscles, and prevents unnecessary chilling. CHG is most effective at full strength. Testing temperature prevents accidental burns. Bath water warms lotion for application to patient's skin.

h. Lower side rail, remove pillow if tolerated, and raise head of bed 30 to 45 degrees if allowed. Place bath towel under patient's head. Place second bath towel over patient's chest.

Helps your access to patient. You do not have to reach across bed, thus minimizing strain on back muscles.

Removal of pillow makes it easier to wash patient's ears and neck. Placing towels prevents bed linen and bath blanket from getting soiled or wet.

STEP 1f(3) **A,** Remove patient's gown. **B,** Remove IV tubing from pole. **C,** Slide IV tubing through arm of patient's gown. **D,** Rehang IV bag.

SKILL 40-1	BATHING AND PERINEAL CARE—cont'd

STEP	RATIONALE

i. Wash face.

> **CLINICAL DECISION:** *If using CHG solution in bath water, do not use to wash face. Only use clear water or mild soap and water on the face.*

(1) Ask if patient is wearing contact lenses.

Prevents accidental injury to eyes.

(2) Fold washcloth around fingers of your hand to form a mitt (see illustration). Immerse mitt in water and wring thoroughly.

Mitt retains water and heat better than loosely held washcloth; keeps cold edges from brushing against patient and prevents splashing.

(3) Wash patient's eyes with plain warm water. Use different section of mitt for each eye. Move mitt from inner to outer canthus (see illustration). Soak any crusts on eyelid for 2 to 3 minutes with damp cloth before attempting removal. Dry eyes thoroughly but gently.

Soap irritates eyes. Use of separate sections of mitt reduces infection transmission. Bathing eye from inner to outer canthus prevents secretions from entering nasolacrimal duct. Pressure can cause internal injury.

(4) When using soap and water, ask if patient prefers to use soap on face. Otherwise wash, rinse, and dry forehead, cheeks, nose, neck, and ears without using soap. (Men may wish to shave at this point or wait until after bath.)

Soap tends to dry face, which is exposed to air more than other body parts.

j. Wash trunk and upper extremities.

(1) Remove bath blanket from patient's arm that is closest to you. Place bath towel lengthwise under arm. Bathe arm with soap and water using long, firm strokes from distal to proximal areas (fingers to axilla).

Towel prevents soiling of bed. Soap lowers surface tension and facilitates removal of debris and bacteria when friction is applied during washing. Long, firm strokes stimulate circulation; moving distal to proximal promotes venous return.

(2) Raise and support arm above head (if possible) to wash, rinse, and dry axilla thoroughly (see illustration). Apply deodorant or powder to underarms if desired or needed.

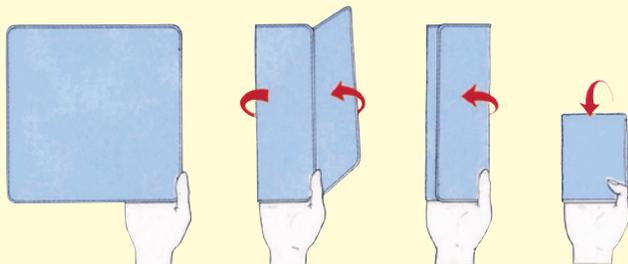
Movement of arm exposes axilla and exercises normal ROM of joint. Alkaline residue from soap discourages growth of normal skin bacteria. Drying prevents excess moisture, which can cause skin maceration or softening. Respect patient's preference for use of hygiene products.

(3) Move to other side of bed and repeat Steps (1) and (2) with other arm.

Provides for better access to patient and helps prevent back strain.

(4) Place bath towel across patient's chest so it covers chest and arms and fold bath blanket down to umbilicus. While lifting edge of towel away from chest with one hand, bathe chest with mitted washcloth on other hand using long, firm strokes. Take special care to wash skinfolds under female's breasts. It is often necessary to lift breast upward while bathing underneath it. Keep patient's chest covered between wash and rinse periods. Rinse and dry well.

Draping prevents unnecessary exposure of body parts. Towel maintains warmth and privacy. Secretions and dirt collect easily in areas of tight skinfolds. Skin under breasts is vulnerable to excoriation if not kept clean and dry.

k. Wash hands and nails.


STEP 1i(2) Steps for folding washcloth to form a mitt.

STEP 1i(3) Wash eye from inner to outer canthus.

STEP 1j(2) Positioning arm to wash axilla.

STEP	RATIONALE
(1) Fold bath towel in half and lay it on bed beside patient. Place basin on towel. Immerse patient's hand in water. Allow hand to soak for 2 to 3 minutes before washing hand and fingernails. Remove basin and dry hand well. Repeat for other hand.	Soaking softens cuticles and calluses of hand, loosens debris beneath nails, and enhances feeling of cleanliness. Thorough drying removes moisture between fingers.
l. Check temperature of bath water and change water when cool or soapy. (See agency policy regarding changing water when using CHG solution.)	Warm water maintains patient's comfort. Alkaline soap residue is irritating to skin and can decrease the normal protectiveness of acid ph.

CLINICAL DECISION: *If patient is at risk for falling, be sure that two side rails are up before obtaining fresh water. In addition, lower bed when it is necessary to leave bedside. NOTE: Having all side rails raised is considered a restraint. Check agency policy.*

---

m. Wash abdomen.	
(1) Place bath towel lengthwise over chest and abdomen. (Two towels may be needed.) Fold bath blanket down to just above pubic region. With one hand lift bath towel. With mitted hand bathe and rinse abdomen, giving special attention to umbilicus and skinfolds of abdomen and groin. Stroke from side to side. Keep abdomen covered between washing and rinsing. Rinse and dry well.	Draping prevents unnecessary exposure of body parts. Towel maintains warmth and privacy. Keeping skinfolds clean and dry helps prevent odor and skin irritation. Moisture and sediment that collect in skinfolds predispose skin to maceration.
(2) Apply clean gown or pajama top. If an extremity is injured or immobilized, dress affected side first. (This step may be omitted until completion of bath; gown should not become soiled during remainder of bath.)	Maintains patient's warmth and comfort. Dressing affected side first allows easier manipulation of gown over body part with reduced ROM.
n. Wash lower extremities.	
(1) Cover chest and abdomen with top of bath blanket. Cover legs with bottom of blanket. Expose near leg by folding blanket toward midline. Be sure to keep other leg and perineum draped.	Prevents unnecessary exposure.
(2) Place bath towel under leg, supporting leg at knee and ankle. If appropriate, place patient's foot in bath basin to soak while washing and rinsing. (Bend patient's leg at knee; and, while grasping patient's heel, elevate leg from mattress slightly and place bath basin on towel.) If patient is unable to support leg, you can clean by washing feet thoroughly with washcloth.	Towel prevents soiling of bed linen. Support of joint and extremity during lifting prevents strain on musculoskeletal structures. Sudden movement by patient could spill bath water. Soaking softens calluses and rough skin.

CLINICAL DECISION: *If patient has diabetes or peripheral vascular disease with impaired circulation and/or sensation, do not soak feet. Maceration of skin may predispose to infection.*

---

(3) Wash leg using long, firm strokes from ankle to knee and from knee to thigh (see illustration). Do not rub or massage back of calf. Rinse and dry well. Clean foot, making sure to bathe between toes. Rinse and dry toes and feet completely. Clean and clip nails as needed (see Skill 40-2). Remove and discard towel.	Promotes circulation and venous return. Excess massage of calf could loosen deep vein thrombus. Secretions and moisture may be present between toes, predisposing patient to maceration and breakdown. Avoid cutting nails of patient with diabetes. See agency policy for podiatrist care.

STEP 1n(3) Washing leg.

SKILL 40-1	BATHING AND PERINEAL CARE—cont'd

STEP	RATIONALE

(4) Raise side rail, move to opposite side of bed, lower side rail, and repeat Steps (2) and (3) for other leg and foot. If skin is dry, apply moisturizer. When finished, cover patient with bath blanket.

CLINICAL DECISION: *Do not use long, firm strokes to wash lower extremities of patients with history of deep vein thrombosis or blood-clotting disorders. Use short, light strokes instead.*

---

o. Cover patient with bath blanket, raise side rail for patient's safety, remove soiled gloves, and/or perform hand hygiene. Change bath water.

Decreased bath water temperature causes chilling. Clean water reduces microorganism transmission to perineal structures.

p. Provide perineal hygiene.

(1) If patient is able to maneuver and handle washcloth, allow him or her to clean perineum on own.

Maintains patient's dignity and self-care ability.

CLINICAL DECISION: *CHG is safe to use on the perineum and external mucosa (AHRQ, 2013).*

---

(2) Female patient

(a) Apply pair of clean gloves. Lower side rail. Help patient into dorsal recumbent position. Note restrictions or limitations in patient's positioning. Place waterproof pad under patient's buttocks. Drape patient with bath blanket placed in shape of a diamond. Lift lower edge of bath blanket to expose perineum (see illustration).

Provides full exposure of female genitalia. If patient is totally dependent, provide assistance to support her in side-lying position and raise leg as perineum is bathed. If position causes patient discomfort, reduce degree of abduction in her hips.

(b) Fold lower corner of bath blanket up between patient's legs onto abdomen. Wash and dry patient's upper thighs.

Keeping patient draped until procedure begins minimizes anxiety. Buildup of perineal secretions soils surrounding skin surfaces.

(c) Wash labia majora. Use nondominant hand to gently retract labia from thigh: with dominant hand wash carefully in skinfolds. Wipe in direction from perineum to rectum. Repeat on opposite side with separate section of washcloth. Rinse and dry area thoroughly.

Perineal care involves thorough cleaning of patient's external genitalia and surrounding skin. Skinfolds may contain body secretions that harbor microorganisms. Wiping front to back reduces chance of transmitting fecal organisms to urinary meatus.

(d) Gently separate labia with nondominant hand to expose urethral meatus and vaginal orifice. With dominant hand, wash downward from pubic area toward rectum in one smooth stroke (see illustration). Wash middle and both sides of perineum. Use separate section of cloth for each stroke. Clean thoroughly around labia minora, clitoris, and vaginal orifice. Avoid placing tension on indwelling catheter if present and clean area around it thoroughly.

Cleansing method reduces transfer of microorganisms to urinary meatus. (For menstruating women or patients with indwelling catheters, clean with cotton balls.)

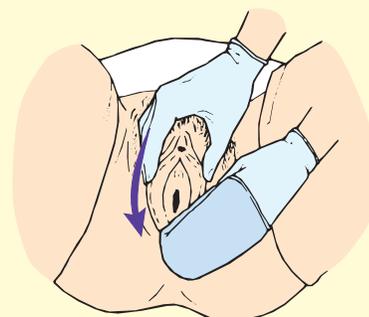
(e) Provide catheter care as needed (see Chapter 46).

Cleaning along catheter from exit site reduces incidence of health care–associated urinary infection.

(f) Rinse area thoroughly. May use bedpan and pour warm water over perineal area. Dry thoroughly from front to back.

Rinsing removes soap and microorganisms more effectively than wiping. Retained moisture harbors microorganisms.

(g) Fold lower corner of bath blanket back between patient's legs and over perineum. Ask patient to lower legs and assume comfortable position.

STEP 1p(2)(a) Drape patient for perineal care.


STEP 1p(2)(d) Cleanse from perineum to rectum (front to back).

STEP	RATIONALE

(3) Male patient

(a) Apply pair of clean gloves. Lower side rail. Help patient to supine position. Note any restriction in mobility.

Provides full exposure of male genitalia. Position patients who are unable to lie supine on their side.

(b) Fold lower half of bath blanket up to expose upper thighs. Wash and dry thighs.

Buildup of perineal secretions soils surrounding skin surfaces.

(c) Cover thighs with bath towels. Raise bath blanket up to expose genitalia. Gently raise penis and place bath towel underneath. Gently grasp shaft of penis. If patient is uncircumcised, retract foreskin (see illustration). If patient has an erection, defer procedure until later.

Draping minimizes patient anxiety. Towel prevents moisture from collecting in inguinal area. Gentle but firm handling of penis reduces chance of an erection. Secretions capable of harboring microorganisms collect underneath foreskin.

(d) Wash tip of penis at urethral meatus first. Using circular motion, clean from meatus outward (see illustration). Discard washcloth and repeat with clean cloth until penis is clean. Rinse and dry gently.

Direction of cleaning moves from area of least contamination to area of most contamination, preventing microorganisms from entering urethra.

(e) Return foreskin to its natural position. This is extremely important in patients with decreased sensation in their lower extremities.

Tightening of foreskin around shaft of penis causes local edema and discomfort. Patients with reduced sensation do not feel tightening of foreskin.

(f) Gently clean shaft of penis and scrotum by having patient abduct legs. Pay special attention to underlying surface of penis. Lift scrotum carefully and wash underlying skinfolds. Rinse and dry thoroughly.

Vigorous massage of penis may cause an erection. Underlying surface of penis is an area where secretions accumulate. Abduction of legs provides easier access to scrotal tissues. Secretions collect easily between skinfolds.

(g) Avoid placing tension on indwelling catheter if present and clean area around it thoroughly. Provide catheter care (see Chapter 46).

Cleaning along catheter from exit site reduces incidence of nosocomial urinary infection.

q. Remove soiled gloves and discard in trash; raise side rail before leaving bedside to dispose of water and obtain fresh water.

Prevents transmission of infection. Protects patient from injury.

r. Wash back. (This follows both female and male perineal care.)

(1) Perform hand hygiene and apply clean pair of gloves. Lower side rail. Help patient into prone or side-lying position (as applicable). Place towel lengthwise along patient's side and keep him or her covered with bath blanket.

Exposes back and buttocks for bathing while limiting exposure.

(2) Keep patient draped by sliding bath blanket over shoulders and thighs during bathing. Wash, rinse, and dry back from neck to buttocks using long, firm strokes.

Cleaning back before buttocks and anus prevents contamination of water.

(3) Next move from back to buttocks and anus. Have patient remain in prone or side-lying position and keep covered to avoid chilling. Clean anus and buttocks area.

Exposes back and buttocks for bathing while limiting exposure.

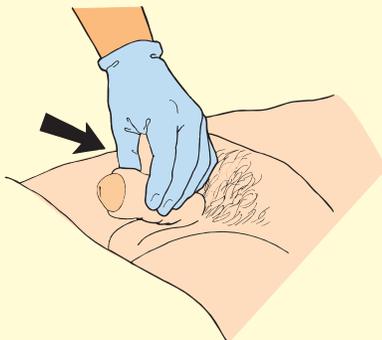
(4) If fecal material is present, enclose in fold of underpad or toilet tissue and remove with disposable wipes.

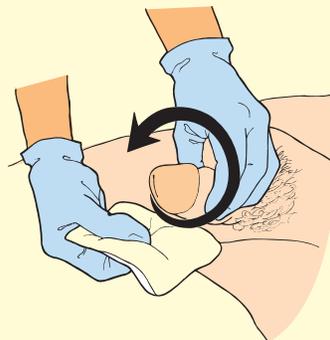
Skinfolds near buttocks and anus may contain fecal secretions that harbor microorganisms.

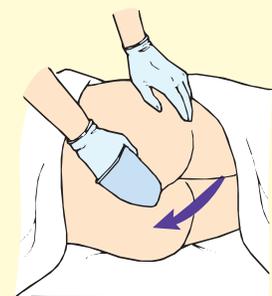
(5) Clean buttocks and anus, washing front to back (see illustration). Clean, rinse, and dry area thoroughly. If needed, place a clean absorbent pad under patient's buttocks. Remove contaminated gloves. Raise side rail and perform hand hygiene.

Cleaning motion prevents contaminating perineal area with fecal material or microorganisms.

(6) Return to bed and lower side rail; give a back rub.

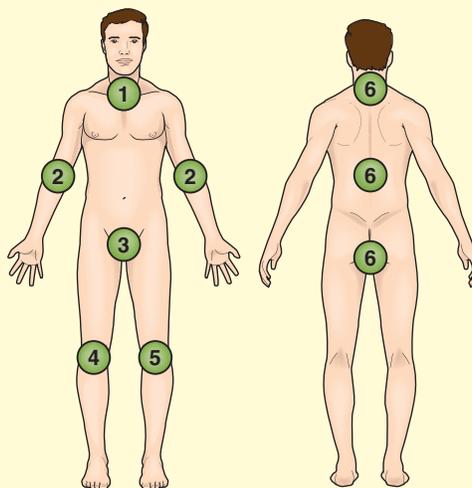
Promotes patient relaxation. Make sure that back rub is appropriate for your patient. Back rubs are contraindicated in some cardiac patients.


STEP 1p(3)(c) Retract foreskin.


STEP 1p(3)(d) Use circular motion to cleanse tip of penis.


STEP 1r(5) Cleanse buttocks from front to back.

SKILL 40-1	BATHING AND PERINEAL CARE—cont'd

STEP	RATIONALE
s. Apply additional body lotion or oil to patient's skin as needed.	Moisturizing lotion prevents dry, chapped skin.
t. Remove soiled linen and place in dirty-linen bag. Clean and replace bathing equipment. Wash hands.	Reduces transmission of microorganisms.
u. Help patient dress. Comb patient's hair. Women may want to apply makeup. Help as needed.	Promotes patient's body image.
v. Make patient's bed (see Boxes 40-16 and 40-17).	Provides clean, comfortable environment.
w. Check function and position of external devices (e.g., indwelling urethral catheters, nasogastric tubes, IV lines).	Ensures that systems remain functional after bathing activities.
x. Place bed in lowest position.	Maintains patient's safety by decreasing height of bedframe from floor.
y. Replace call light and personal possessions. Leave room as clean and comfortable as possible.	Prevents transmission of infection. Clean environment promotes patient's comfort. Keeping call light and articles of care within reach promotes patient's safety.
z. Perform hand hygiene.	Reduces transmission of microorganisms.
2. Commercial bag bath or CHG cleansing pack	
a. A cleansing pack contains six to eight premoistened towels for cleaning. Warm package contents in microwave following package directions. If you are bathing patient using warm commercial or CHG cloth, check temperature of cloth before use. Gloves diminish sense of heat.	Provides warm, soothing heat. CHG reduces bacteria for up to 24 hours and prevents infection (AHRQ, 2013). Prevents burn to skin.
b. Use all six CHG cloths in the following order (see illustration): • Cloth 1: Neck, shoulders, and chest • Cloth 2: Both arms, both hands, web spaces, and axilla • Cloth 3: Abdomen and then groin/perineum • Cloth 4: Right leg, right foot, and web spaces • Cloth 5: Left leg, left foot, and web spaces • Cloth 6: Back of neck, back, and buttocks	Reduces transmission of microorganisms.
c. Firmly massage skin when using cloth. Allow skin to air dry for 30 seconds. Do not rinse. It is permissible to lightly cover patient with bath towel to prevent chilling.	Drying skin with towel removes emollient that is left behind after water/cleaner solution evaporates.
d. NOTE: If there is excessive soiling (e.g., in perineal region), use an extra cloth or conventional washcloths, soap, water, and towels.	
3. Tub bath or shower	
a. Consider patient's condition and review orders for precautions concerning his or her movement or positioning.	Prevents accidental injury to patient during bathing.
b. Schedule use of shower or tub.	Prevents unnecessary waiting, which causes fatigue.
c. Check tub or shower for cleanliness. Use cleaning techniques outlined in agency policy. Place rubber mat on tub or shower bottom. Place disposable bath mat or towel on floor in front of tub or shower.	Cleaning prevents transmission of microorganisms. Mats prevent slipping and falling.


STEP 2b Using CHG bathing cloths. (From Universal ICU decolonization: *An enhanced protocol.* Appendix E: *Training and educational materials,* Rockville, MD, September 2013, Agency for Healthcare Research and Quality.)

STEP	RATIONALE
d. Collect all hygienic aids, toiletry items, and linens requested by patient. Place within easy reach of tub or shower.	Placing items close at hand prevents possible falls when patient reaches for equipment.
e. Help patient to bathroom if necessary. Have him or her wear robe and slippers.	Assistance prevents accidental falls. Wearing robe and slippers prevents chilling.
f. Demonstrate how to use call signal for assistance.	Bathrooms are equipped with signaling devices in case patient feels faint or weak or needs immediate assistance. Patients prefer privacy during bath if safety is not jeopardized.
g. Place "occupied" sign on bathroom door.	Maintains patient's privacy.
h. Fill bath tub halfway with warm water. Check temperature of bath water, have patient test water, and adjust temperature if water is too warm. Explain which faucet controls hot water. If patient is taking shower, turn shower on and adjust water temperature before he or she enters shower stall. Use shower seat or tub chair if needed (see illustration).	Adjusting water temperature prevents accidental burns. Older adults and patients with neurological alterations (e.g., diabetes, spinal cord injury) are at high risk for burn as a result of reduced sensation. Use of assistive devices facilitates bathing and minimizes physical exertion.
i. Instruct patient to use safety bars when getting in and out of tub or shower to pull cord to summon assistance (if available). Caution patient against use of bath oil in tub water.	Prevents slipping and falling. Oil causes tub surfaces to become slippery.
j. Instruct patient not to remain in tub longer than 10 or 15 minutes. Check on him or her every 5 minutes.	Prolonged exposure to warm water causes vasodilation and pooling of blood in some patients, leading to light-headedness or dizziness.
k. Return to bathroom when patient signals and knock before entering.	Provides privacy.
l. For patient who is unsteady, drain tub of water before he or she tries to get out. Place bath towel over patient's shoulders. Help patient out of tub as needed and help with drying.	Prevents accidental falls. Patient may become chilled as water drains.

CLINICAL DECISION: *Weak or unstable patients need extra assistance in getting out of a tub. Planning for additional personnel is essential before attempting to help the patient. Lift equipment may be used for transfer. See agency policy.*

STEP	RATIONALE
m. Help patient as needed with getting dressed in clean gown or pajamas, slippers, and robe. (In home setting patient may put on regular clothing.)	Maintains warmth to prevent chilling.
n. Help patient to room and comfortable position in bed or chair.	Maintains relaxation gained from bathing.
o. Clean tub or shower according to agency policy. Remove soiled linen and place in dirty-linen bag. Discard disposable equipment in proper receptacle. Place "unoccupied" sign on bathroom door. Return supplies to storage area.	Prevents transmission of infection through soiled linen and moisture.
p. Perform hand hygiene.	Reduces transfer of microorganisms.

EVALUATION

1. Observe skin, paying particular attention to areas previously soiled, reddened, dry, or showing early signs of breakdown.	Techniques used during bathing leave skin clean and clear. Over time dry skin diminishes. If patient shows areas of redness, use Braden scale to measure risk for pressure ulcers (see Chapter 48).
2. Observe ROM during bath.	Measures joint mobility.

STEP 3h Shower seat for patient safety.

SKILL 40-1	BATHING AND PERINEAL CARE—cont'd

STEP	RATIONALE
3. Ask patient to rate level of comfort.	Determines patient's tolerance of bathing activities.
4. Ask patient to rate level of fatigue.	Determines patient's tolerance of bathing activities.
5. Use **Teach Back** to determine patient's and family's understanding of the importance of hygiene care to prevent health care–associated infection (HAI), ask the following, "We talked about why it is important for you to have a daily bath while in the hospital. Can you explain to me why we are using bathing cloths for your bath? Can you explain what you plan to do to be sure the area around your wound is bathed correctly once you get home?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient and family are able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Areas of excessive dryness, rashes, or pressure ulcers appear on skin.
- Complete pressure ulcer assessment (see Chapter 48).
- Apply moisturizing lotions or topical skin applications per agency policy.
- Limit frequency of complete baths. It may become necessary (if patient has a sensitivity to CHG) to switch to plain soap and water.
- Obtain special bed surface if patient is at risk for skin breakdown.

2. Patient becomes excessively tired or unable to cooperate or participate in bathing.
- Reschedule bathing to a time when patient is more rested.
- Provide pillow or elevate head of bed during bath for patient with breathing difficulties.
- Notify health care provider if this is a change in patient's fatigue level.
- Perform hygiene measures in stages between scheduled rest periods.

3. The rectum, perineum, or genital area is inflamed or swollen or has foul-smelling odor.
- Bathe perineal area frequently enough to keep clean and dry.
- Obtain an order for a sitz bath.
- Apply protective barrier ointment or antiinflammatory cream.
- Report findings to health care provider.

RECORDING AND REPORTING

- Report any skin irritations, breaks in skin, or ulcerations to nurse in charge or health care provider. These are serious in patients with altered circulation to the lower extremities.
- Report intolerance of activity to patient's nurse.
- Record procedure, amount of assistance provided, patient's participation in care, condition of skin, and any significant findings (e.g., reddened areas, breaks in skin, inflammation, ulcerations).
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- Assess patient's tub and shower area for need for safety devices (e.g., grab bars, shower chair, handheld shower).
- Assess patient for the need for assistive bathing devices (e.g., long-handle sponge, mirrors, or lift equipment).

SKILL 40-2	PERFORMING NAIL AND FOOT CARE

DELEGATION CONSIDERATIONS

The skill of nail and foot care of patients *without* circulatory problems or diabetes can be delegated to nursing assistive personnel (NAP). Instruct the NAP to:
- Not clip patient's toenails.
- Use warm, not hot, water for soaking nails.
- Not soak feet of patients who have diabetes or peripheral vascular disease.
- Report any changes that may indicate inflammation or injury to tissue.

EQUIPMENT

- Washbasin
- Emesis basin
- Washcloth
- Bath or face towel
- Nail clippers
- Soft cuticle or nail brush
- Plastic orange stick
- Emery board or nail file
- Body lotion
- Disposable bath mat (optional)
- Paper towels
- Clean gloves (if drainage is present)
- Linen bag or hamper

STEP	RATIONALE
ASSESSMENT	
1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
2. Perform hand hygiene. Apply clean gloves if drainage present. Inspect all surfaces of fingers, toes, feet, and nails. Pay particular attention to areas of dryness, inflammation, or cracking. Also inspect areas between toes, heels, and soles of feet.	Integrity of feet and nails determines frequency and level of hygiene required. Heels, soles, and sides of feet are prone to irritation from ill-fitting shoes.

CLINICAL DECISION: *Patients with peripheral vascular diseases or diabetes mellitus, older adults, and patients whose immune system is suppressed often require nail care from a specialist to reduce the risk of tissue injury and infection. Defer care other than washing the feet in these cases until patient has been evaluated.*

STEP	RATIONALE
3. Assess color and temperature of toes, feet, and fingers. Assess capillary refill of nails. Palpate radial and ulnar pulse of each hand and dorsalis pedis pulse of foot; note character of pulses (see Chapter 31).	Assesses adequacy of blood flow to extremities. Circulatory alterations often change integrity of nails and increase patient's chance of localized infection when break in skin integrity occurs.
4. Ask female patients whether they use nail polish and polish remover frequently.	Chemicals in these products cause excessive dryness.
5. Assess type of footwear worn by patient: Does patient wear socks? Are shoes tight or ill fitting? Does patient wear garters or knee-high nylons? Is footwear clean?	Types of shoes and footwear predispose patient to foot and nail problems (e.g., infection, areas of friction, ulcerations). These conditions decrease mobility and increase risk for amputation in patient with diabetes.
6. Identify patient's risk for foot or nail problems:	Certain conditions increase likelihood of foot or nail problems.
a. Older adult	Normal physiological changes such as poor vision, lack of coordination, or inability to bend over contribute to difficulty in performing foot and nail care (Touhy and Jett, 2014).
b. Diabetes mellitus, peripheral vascular disease	Vascular changes associated with diabetes mellitus reduce blood flow to peripheral tissues. Break in skin integrity places patient with diabetes at high risk for skin infection.
c. Heart failure, renal disease	Both conditions increase tissue edema, particularly in dependent areas (e.g., feet). Edema reduces blood flow to neighboring tissues.
d. Cerebrovascular accident (stroke)	Presence of residual foot or leg weakness or paralysis results in altered walking patterns. Altered gait pattern causes increased friction and pressure on feet.
7. Assess type of home remedies that patient uses for existing foot problems:	Certain preparations or applications cause more injury to soft tissue than initial foot problem.
a. Over-the-counter liquid preparations to remove corns	Liquid preparations cause burns and ulcerations.
b. Cutting corns or calluses with razor blade or scissors	Cutting corns or calluses sometimes results in infection caused by a break in skin integrity. The patient with diabetes or any patient with decreased peripheral circulation has an increased risk for infection secondary to a break in skin integrity.
c. Use of oval corn pads	Oval pads exert pressure on toes, thereby decreasing circulation to surrounding tissues.
d. Application of adhesive tape	Skin of older adult is thin and delicate and prone to tearing when adhesive tape is removed.
8. Assess patient's ability to care for nails or feet: visual alterations, fatigue, and musculoskeletal weakness.	Determines patient's ability to perform self-care and degree of assistance required from nurse.
9. Assess patient's knowledge of foot and nail care practices.	Determines patient's need for health teaching.
PLANNING	
1. Obtain health care provider's order for cutting nails if agency policy requires it.	Patients with reduced circulation are more at risk for infection. Accidental cutting of skin increases risk for infection for them.
2. Explain procedure, including need to soak feet, which requires several minutes.	Patient needs to be able to place fingers and feet in basin for 10 to 20 minutes. Some patients may become tired.
3. Collect appropriate equipment.	
IMPLEMENTATION	
1. Perform hand hygiene. Apply gloves if lesions or drainage present or anticipated.	Reduces transmission of microorganisms.
2. Arrange equipment on over-bed table.	Easy access to equipment prevents delays.
3. Provide privacy by closing curtains around bed or closing door.	Maintaining privacy reduces embarrassment and anxiety.

SKILL 40-2	PERFORMING NAIL AND FOOT CARE—cont'd

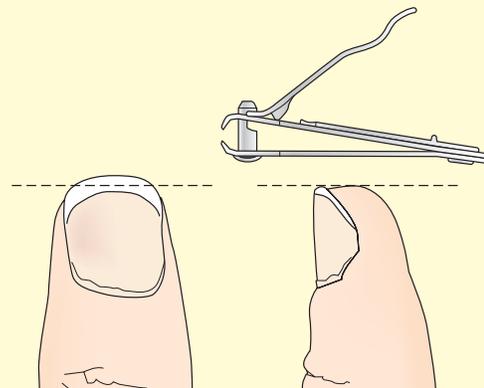
STEP	RATIONALE
4. Help ambulatory patient sit in bedside chair. Help bed-bound patient to supine position with head of bed elevated. Place disposable bath mat or towel on floor under patient's feet or place towel on bed.	Sitting in chair facilitates immersing feet in basin. Bath mat or towel protects feet from exposure to soil or microorganisms on floor; towel lessens chance of splashing water on floor or bed.
5. Fill wash basin with warm water. Test water temperature.	Warm water softens nails and thickened epidermal cells, reduces inflammation of skin, and promotes local circulation. Proper water temperature prevents burns.
6. Place basin on bath mat or towel and help patient place feet in basin. Place call light within patient's reach.	Patients with muscular weakness or tremors often have difficulty positioning feet. Maintains patient's safety.

CLINICAL DECISION: *Soaking the feet of patients with diabetes mellitus or peripheral vascular disease is not recommended. Soaking may lead to maceration (excessive softening of the skin) and drying of the skin (ADA, 2014), leading to tissue breakdown and infection.*

STEP	RATIONALE
7. Adjust over-bed table to low position and place it over patient's lap. (Patient sits in chair or lies in bed.)	Easy access prevents accidental spills.
8. Fill emesis basin with warm water and place basin on paper towels on over-bed table.	Warm water softens nails and thickened epidermal cells.
9. Instruct patient to place fingers in emesis basin and arms in comfortable position.	Prolonged positioning causes discomfort unless normal anatomical alignment is maintained.
10. Allow patient's feet and fingernails to soak for 10 to 20 minutes. Rewarm water after 10 minutes.	Softening corns, calluses, and cuticles ensures easy removal of dead cells and easy manipulation of cuticle. *Do not soak if patient has diabetes.*
11. Clean gently under fingernails with plastic stick while fingers are immersed with water in basin; then dry fingers thoroughly (see illustration).	Plastic stick removes debris under nails that harbors microorganisms. Do not use wood, which could cause splintering. Thorough drying impedes fungal growth and prevents maceration of tissues.
12. Using nail clippers, clip fingernails straight across and even with tops of fingers; check agency policy regarding clipping of nails (see illustration). Using a file, shape nails straight across. If patient has circulatory problems, do not cut nail; file nail only.	Cutting straight across prevents splitting of nail margins and formation of sharp nail spikes that irritate lateral nail margins. Filing prevents cutting nail too close to nail bed.
13. Use soft cuticle brush or nail brush around cuticles. Do not push cuticles back roughly or cut them.	Reduces incidence of inflamed cuticles.
14. Move over-bed table away from patient.	Provides easier access to feet.
15. Put on clean gloves and scrub callused areas of feet with washcloth.	Gloves prevent transmission of fungal infection. Friction removes dead skin layers.
16. Clean gently under nails with plastic orange stick. Remove feet from basin and dry thoroughly.	Nails harbor debris and dirt and are a source of potential infection from poor care habits (Ball et al., 2015).
17. Clean and trim toenails using procedures in Steps 11 and 12. Do not file corners of toenails. Check agency policy for trimming patient's nails.	Shaping corners of toenails damages tissues.
18. Apply lotion to feet and hands and help patient back to bed and into comfortable position.	Lotion lubricates dry skin by helping to retain moisture.
19. Remove clean gloves and place in receptacle. Clean and return equipment and supplies to proper place. Dispose of soiled linen in hamper. Perform hand hygiene.	Reduces transmission of infection.

EVALUATION

1. Inspect nails and surrounding skin surfaces after soaking and nail trimming.	Evaluates condition of skin and nails. Allows nurse to note any remaining rough nail edges.

STEP 11 Clean under fingernails.


STEP 12 Use nail clippers to clip nails straight across.

STEP	RATIONALE
2. Ask patient to explain or demonstrate nail care.	Evaluates patient's level of learning foot and nail care techniques.
3. Observe patient's walk after toenail care.	Evaluates level of comfort and mobility achieved.
4. Use **Teach Back** to determine patient's and family's understanding of risks involved in nail care. State, "I want to be sure you know what problems you can have if you do not take care of nails correctly. Can you tell me how you might get an infection?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient and family are able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Cuticles and surrounding tissues are inflamed and tender to touch.
  - Repeated soakings are necessary to relieve inflammation and loosen layers of skin cells.
  - Patients with peripheral vascular disease or diabetes often require referral to a podiatrist.
  - Evaluate need for antifungal cream.
2. Localized areas of tenderness occur on feet with calluses or corns at point of friction.
  - Recommend a change in footwear is necessary.
  - Refer to a podiatrist or nurse in charge.
3. Ulcer appears between toes or other pressure areas in foot.
  - Notify physician or nurse in charge.
  - Implement appropriate pressure ulcer interventions (see Chapter 48).
  - Refer to a podiatrist or nurse certified in foot care.
  - Increase frequency of foot assessment and hygiene.

RECORDING AND REPORTING

- Record procedure and observations (e.g., breaks in skin, inflammation, ulcerations).
- Report any breaks in skin or ulcerations to nurse in charge or physician. These are serious in patients with peripheral vascular disease and illnesses in which patient's circulation is impaired. Special foot-care treatments are often necessary.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- If patient has diabetes or decreased peripheral circulation, perform procedure only after consulting with a health care provider.
- Alternative therapies: moleskin applied to areas of feet that are under friction is less likely to cause pressure than corn pads; spot adhesive bandages guard against friction, but they do not have padding to protect against pressure; wrapping small pieces of lamb's wool around toes reduces irritation of soft corns between toes.
- If patient is ambulatory, instruct to soak feet in bathtub. When patient's mobility is limited, use large basin or pan.

SKILL 40-3	PERFORMING MOUTH CARE FOR AN UNCONSCIOUS OR DEBILITATED PATIENT

DELEGATION CONSIDERATIONS

The skill of providing oral hygiene for an unconscious or debilitated patient can be delegated to nursing assistive personnel (NAP). The nurse must assess the patient's risk for aspiration by determining presence of the gag reflex. Instruct the NAP about:
- Proper positioning of patient to lessen chance of aspiration.
- Safe use of oral suction catheter for clearing oral secretions (see Skill 41-1).
- Signs of impaired integrity of oral mucosa to report to nurse.
- Reporting any bleeding of mucosa or gums, painful reaction by patient, or excessive coughing or choking to the nurse.

EQUIPMENT

- Antibacterial solution (e.g., 0.12% chlorhexidine rinse and paste) (requires health care provider's order) (Sedwick et al., 2012)
- Small pediatric soft-bristle toothbrush or toothette sponges for patients for whom brushing is contraindicated
- Tongue blade
- Pen light
- Bath towel
- Small oral airway
- Paper towels
- Emesis basin
- Water glass with cool water
- Water-soluble lip lubricant
- Small-bulb syringe or suction machine equipment (required for patients with poor or absent gag reflex)
- Clean gloves

SKILL 40-3	PERFORMING MOUTH CARE FOR AN UNCONSCIOUS OR DEBILITATED PATIENT—cont'd

STEP	RATIONALE

ASSESSMENT

STEP	RATIONALE
1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
2. Perform hand hygiene. Apply clean gloves.	Reduces transmission of microorganisms. Gloves prevent contact with microorganisms in blood or saliva.
3. Assess patient's risk for oral hygiene problems (see Table 40-3).	Impaired level of consciousness increases likelihood of alterations in integrity of oral cavity structures and requires more frequent care. Proper oral care reduces risk of pneumonia (Nicolosi et al., 2014).
4. Test for presence of gag reflex by placing tongue blade on back half of patient's tongue. Do not place fingers in patient's mouth.	Reveals whether patient is at risk for aspiration. Helps determine need for and type of suction apparatus to have available.
5. Use tongue blade and pen light to inspect condition of oral cavity (see Chapter 31).	Determines integrity of gums, teeth, mucosa, and tongue and need for hygiene.
6. Assess patient's respirations	Baseline to determine change. Change in respirations can be early sign of aspiration.
7. Remove gloves. Perform hand hygiene.	Prevents spread of infection.

PLANNING

STEP	RATIONALE
1. Explain procedure to patient even if patient is unconscious.	Allows debilitated patient to anticipate procedure without anxiety. Unconscious patient may retain ability to hear.
2. Collect appropriate equipment.	Prevents interruptions during procedure.
3. Place paper towels on over-bed table and arrange equipment. If needed, turn on suction machine and connect tubing to suction catheter.	Prevents soiling of table top. Equipment prepared in advance ensures smooth, safe procedure.
4. Pull curtain around bed or close room door.	Provides privacy.

IMPLEMENTATION

STEP	RATIONALE
1. Unless contraindicated (e.g., head injury, neck trauma), raise bed, lower side rail, and position patient close to side of bed with head of bed raised up to 30 degrees; turn patient's head toward mattress. Patient can also be placed on side (Sims' position). (Raise side rail if necessary to leave beside.)	Turning patient's head to side allows secretions to drain from mouth instead of collecting in back of pharynx. Prevents aspiration, which could cause lower respiratory tract infection (pneumonia). Moving patient close to side of bed and raising bed facilitate proper body mechanics during skill and reduce risk for injury to nurse. Proper use of side rail protects caregiver from straining and provides for patient safety.
2. Lower side rail (if needed). Apply clean gloves.	Reduces transfer of microorganism.
3. Place towel under patient's head and emesis basin under chin.	Prevents soiling of bed linen.
4. Remove partial plate or dentures if present (see Box 40-10).	Allows for thorough cleaning of prosthetics later. Provides clearer access to oral cavity.
5. If patient is uncooperative or having difficulty keeping mouth open, insert oral airway. Insert upside down and turn airway sideways and then over tongue to keep teeth apart. Do not use force.	Prevents patient from biting down on your fingers and provides access to oral cavity.

CLINICAL DECISION: *Never place fingers into the mouth of an unconscious or debilitated patient. The normal response of the patient is to bite down.*

STEP	RATIONALE
6. Clean mouth using brush or toothette moistened with water or cleaning agent such as chlorhexidine paste (if prescribed). Clean chewing and inner tooth surfaces first. Clean outer tooth surfaces. Moisten brush with chlorhexidine rinse to rinse. Use toothette to clean roof of mouth, gums, and inside cheeks (see illustration). Gently brush tongue but avoid stimulating gag reflex. Moisten clean brush or toothette with chlorhexidine to rinse. Use bulb syringe or suction as needed to remove excess rinse.	Brushing action removes food particles between teeth and along chewing surfaces. Chlorhexidine 0.12% is an antimicrobial agent effective against dental plaque biofilms (Sedwick et al., 2012). Swabbing helps remove secretions and crusts from mucosa and moistens mucosa. Repeated rinsing removes peroxide, which is irritating to mucosa, and debris.
7. For patients without teeth, use toothette moistened in chlorhexidine rinse to clean oral cavity.	This is less traumatic to mucosa of gums.
8. Suction oral secretions as they accumulate if needed.	Suction removes secretions and fluid that collect in posterior pharynx, which if aspirated could lead to pneumonia.

CLINICAL DECISION: *Do not use a catheter to suction orally and then reuse to suction tracheally. Use separate catheters.*

STEP	RATIONALE
9. Use toothette sponge to apply thin layer of water-soluble jelly to lips (see illustration).	Water-soluble jelly lubricates lips to prevent drying and cracking.

STEP	RATIONALE
10. Inform patient that procedure is completed.	Provides meaningful stimulation to patient.
11. Remove gloves and dispose in proper receptacle. Raise side rail. Perform hand hygiene.	Prevents transmission of microorganisms to environmental surfaces (e.g., side rails, patient's linens). Reduces risk for patient injury.
12. Reposition patient comfortably, raise side rail, and return bed to original position.	Maintains patient's comfort and safety.
13. Apply clean gloves to clean equipment. Return supplies to proper place. Place soiled linen in proper receptacle.	Proper disposal of soiled equipment and handling of soiled linens prevent spread of infection.
14. Remove and discard soiled gloves. Perform hand hygiene.	Reduces transmission of microorganisms.

EVALUATION

1. Apply clean gloves and inspect oral cavity.	Determines efficacy of cleaning. Removing thick secretions reveals any underlying inflammation or lesions.
Remove gloves and dispose in proper receptacle. Perform hand hygiene.	Reduces transmission of microorganisms.
2. Ask patient if mouth feels clean.	Evaluates level of comfort.
3. Assess patient's respirations and auscultate lung sounds on an ongoing basis.	Ensures early recognition of aspiration.
4. Use **Teach Back** to determine family caregiver's ability to recognize early signs of aspiration. State, "Your husband is at risk for aspirating fluids down his breathing tube. I want to be sure you know the signs of aspiration. Can you identify them for me?" Revise your instruction now or develop plan for revised teaching if family member is not able to teach back correctly.	Evaluates what family caregiver is able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Secretions or crusts remain on oral mucosa, tongue, or gums.
- Increase frequency of oral hygiene.
- Use a pediatric-size toothbrush to provide better hygiene.

2. Localized inflammation of gums or mucosa is present, or lips are cracked and inflamed.
- Increase frequency of oral hygiene with a soft-bristle toothbrush.
- Apply water-soluble moisturizing gel on oral mucosa and massage.
- Apply water-soluble moisturizing gel or lubricant to lips.

3. Patient aspirates secretions.
- Turn patient onto side immediately.
- Suction oral airway as secretions accumulate to maintain patent airway.
- Perform tracheal bronchial suctioning as needed.
- Notify health care provider immediately.
- Elevate patient's head of bed once secretions are clear to facilitate breathing.
- Be prepared to have chest x-ray film examination ordered by health care provider.

RECORDING AND REPORTING

- Record procedure, including pertinent observations (e.g., presence of bleeding gums, dry mucosa, ulcerations, crusts on tongue) on checklist or nurses' notes.
- Report any unusual findings to nurse in charge or health care provider.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- Irrigate oral cavity with bulb syringe; patient can use a gravy baster to remove secretions.
- Give mouth care at least twice a day.
- Have caregivers demonstrate positioning patient to prevent aspiration.

STEP 6 Using moistened toothette to rinse teeth.

STEP 9 Application of water-soluble moisturizer to lips.

KEY POINTS

- Assess a patient's physical and cognitive ability to perform basic hygiene measures.
- Provide hygiene care according to a patient's needs and preference.
- During hygiene integrate other activities such as physical assessment, wound care, and ROM exercises.
- While providing daily hygiene needs, use teaching and communication skills to develop a caring relationship with the patient.
- Various personal, sociocultural, economic, and developmental factors influence patients' hygiene practices.
- Patients' health beliefs predict the likelihood of assuming health promotion behavior such as maintaining good hygiene.
- Reduced sensation, vascular insufficiency, and immobility place a patient at greater risk for impaired skin integrity.
- Administering symptom-relief therapies before hygiene to patients suffering symptoms such as pain or nausea better prepares them for any procedure.
- When administering oral care to unconscious patients, take measures to prevent aspiration.
- A patient's room needs to be comfortable, safe, and large enough to allow the patient and visitors to move about freely.
- Evaluation of hygiene care is made on the basis of a patient's sense of comfort, relaxation, well-being, and understanding of hygiene techniques.

CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

1. During Mrs. White's stay in the hospital, a student nurse prepares to provide perineal care. Mrs. White has a urinary catheter in place. The patient asks the student nurse why chlorhexidine gluconate (CHG) wipes are being used instead of soap and water. What is the response the student nurse should give Mrs. White?
2. Because the student nurse plans to use chlorhexidine gluconate (CHG) to bathe Mrs. White, list two assessments the student should conduct that are pertinent to using the antiseptic.
3. Given Mrs. White's current condition and medical history, which of the following hygiene activities pose the greatest risk for the patient? Why?
   1. Shampoo
   2. Eye care
   3. Mouth care
   4. Foot care

ⓔ *Answers to Clinical Application Questions can be found on the Evolve website.*

REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. What is the proper position to use for an unresponsive patient during oral care to prevent aspiration? (Select all that apply.)
   1. Prone position
   2. Sims' position
   3. Semi-Fowler's position with head to side
   4. Trendelenburg position
   5. Supine position
2. The student nurse is teaching a family member the importance of foot care for his or her mother, who has diabetes. Which safety precautions are important for the family member to know to prevent infection? (Select all that apply.)

   1. Cut nails frequently.
   2. Assess skin for redness, abrasions, and open areas daily.
   3. Soak feet in water at least 10 minutes before nail care.
   4. Apply lotion to feet daily.
   5. Clean between toes after bathing.
3. A nurse uses long firm, strokes distal to proximal while bathing a patient's legs because:
   1. It promotes venous circulation.
   2. It covers a larger area of the leg.
   3. It completes care in a timely fashion.
   4. It prevents blood clots in legs.
4. Integrity of the oral mucosa depends on salivary secretion. Which of the following factors impairs salivary secretion? (Select all that apply.)
   1. Use of cough drops
   2. Immunosuppression
   3. Radiation therapy
   4. Dehydration
   5. Presence of oral airway
5. A nurse is assigned to care for the following patients. Which of the patients is most at risk for developing skin problems and thus requiring thorough bathing and skin care?
   1. A 44-year-old female who has had removal of a breast lesion and is having her menstrual period
   2. A 56-year-old male patient who is homeless and admitted to the emergency department with malnutrition and dehydration and who has an intravenous line
   3. A 60-year-old female who experienced a stroke with right-sided paralysis and has an orthopedic brace applied to the left leg.
   4. A 70-year-old patient who has diabetes and dementia and has been incontinent of stool
6. When you are assigned to a patient who has a reduced level of consciousness and requires mouth care, which physical assessment techniques should you perform before the procedure? (Select all that apply.)
   1. Oxygen saturation
   2. Heart rate
   3. Respirations
   4. Gag reflex
   5. Response to painful stimulus
7. A nurse is listening to a student provide instruction to a patient who is having difficulty with activities needed to care for soft contact lenses. Which of the following statements by the nursing student might require some correction by the nurse?
   1. Use tap water to clean soft lenses.
   2. Follow recommendations of lens manufacturer when inserting the lenses.
   3. Keep lenses moist or wet when not worn.
   4. Use fresh solution daily when storing and disinfecting lenses.
8. The American Dental Association suggests that patients who are at risk for poor hygiene use the following interventions for oral care: (Select all that apply.)
   1. Use antimicrobial toothpaste.
   2. Brush teeth 4 times a day.
   3. Use 0.12% chlorhexidine gluconate (CHG) oral rinses.
   4. Use a soft toothbrush for oral care.
   5. Avoid cleaning the gums and tongue.
9. While planning morning care, which of the following patients would have the highest priority to receive his or her bath first?
   1. A patient who just returned to the nursing unit from a diagnostic test

2. A patient who prefers a bath in the evening when his wife visits and can help him
3. A patient who is experiencing frequent incontinent diarrheal stools and urine
4. A patient who has been awake all night because of pain 8/10

10. An 88-year-old patient comes to the medical clinic regularly. During a recent visit the nurse noticed that the patient had lost 10 lbs in 6 weeks without being on a special diet. The patient tells the nurse that he has had trouble chewing his food. Which of the following factors are normal aging changes that can affect an older adult's oral health? (Select all that apply.)
   1. Dentures do not always fit properly.
   2. Most older adults have an increase in saliva secretions.
   3. With aging the periodontal membrane becomes tighter and painful.
   4. Many older adults are edentulous, and remaining teeth are often decayed.
   5. The teeth of elderly patients are more sensitive to hot and cold.

11. A patient with a malignant brain tumor requires oral care. The patient's level of consciousness has declined, with the patient only being able to respond to voice commands. Place the following steps in the correct order for administration of oral care.
   1. If patient is uncooperative or having difficulty keeping mouth open, insert an oral airway.
   2. Raise bed, lower side rail, and position patient close to side of bed with head of bed raised up to 30 degrees.
   3. Using a brush moistened with chlorhexidine paste, clean chewing and inner tooth surfaces first.
   4. For patients without teeth, use a toothette moistened in chlorhexidine rinse to clean oral cavity.
   5. Remove partial plate or dentures if present.
   6. Gently brush tongue but avoid stimulating gag reflex.

12. The nurse delegates needed hygiene care for an elderly stroke patient. Which intervention would be appropriate for the nursing assistive personnel to accomplish during the bath?
   1. Checking distal pulses
   2. Providing range-of-motion (ROM) exercises to extremities
   3. Determining type of treatment for stage 1 pressure ulcer
   4. Changing the dressing over an intravenous site

13. The nurse observes an adult Middle Eastern patient attempting to bathe himself with only his left hand. The nurse recognizes that this behavior likely relates to:
   1. Obsessive compulsive behavior.
   2. Personal preferences.
   3. The patient's cultural norm.
   4. Controlling behaviors.

14. When a nurse delegates hygiene care for a male patient to a nursing assistive personnel, the NAP must use an electric razor to shave the patient with the following diagnosis:
   1. Congestive heart failure
   2. Pneumonia
   3. Arthritis
   4. Thrombocytopenia

15. A patient receiving chemotherapy experiences stomatitis. The nurse advises the patient to use:
   1. Community mouthwash.
   2. Alcohol-based mouth rinse.
   3. Normal saline rinses.
   4. Firm toothbrush.

Answers: 1. 2, 3; **2.** 2, 4, 5; **3.** 1; **4.** 3, 4; **5.** 4; **6.** 3, 4; **7.** 1; **8.** 1, 3, 4; **9.** 3; **10.** 1, 4; **11.** 2, 5, 1, 3, 6, 4; **12.** 2; **13.** 3; **14.** 4; **15.** 3.

Oxygenation

OBJECTIVES

- Describe the structure and function of the cardiopulmonary system.
- Describe the physiological processes of ventilation, perfusion, and exchange of respiratory gases.
- State the process of the neural and chemical regulation of respiration.
- Differentiate among the physiological processes of cardiac output, myocardial blood flow, and coronary artery circulation.
- Describe the relationship of cardiac output, preload, afterload, contractility, and heart rate to the process of oxygenation.
- Identify the clinical outcomes occurring as a result of hyperventilation, hypoventilation, and hypoxemia.
- Identify the clinical outcomes occurring as a result of disturbances in conduction, altered cardiac output, impaired valvular function, myocardial ischemia, and impaired tissue perfusion.
- Discuss the effect of a patient's level of health, age, lifestyle, and environment on oxygenation.
- Assess for the risk factors affecting a patient's oxygenation.
- Assess for the physical manifestations that occur with alterations in oxygenation.
- Develop a plan of care for a patient with altered need for oxygenation.
- Describe nursing care interventions used to promote oxygenation in the primary care, acute care, and restorative and continuing care settings.
- Evaluate a patient's responses to oxygenation therapies.

SCIENTIFIC KNOWLEDGE BASE

Oxygen is necessary to sustain life. The cardiac and respiratory systems supply the oxygen demands of the body. Blood is oxygenated through the mechanisms of ventilation, perfusion, and transport of respiratory gases. Neural and chemical regulators control the rate and depth of respiration in response to changing tissue oxygen demands. The cardiovascular system provides the transport mechanisms to distribute oxygen to cells and tissues of the body.

Respiratory Physiology

The exchange of respiratory gases occurs between the environment and the blood. Respiration is the exchange of oxygen and carbon dioxide during cellular metabolism. The airways of the lung transfer oxygen from the atmosphere to the alveoli, where the oxygen is exchanged for carbon dioxide. Through the alveolar capillary membrane, oxygen transfers to the blood, and carbon dioxide transfers from the blood to the alveoli. There are three steps in the process of oxygenation: ventilation, perfusion, and diffusion.

Structure and Function.   Conditions or diseases that change the structure and function of the pulmonary system alter respiration. The respiratory muscles, pleural space, lungs, and alveoli (Figure 41-1) are essential for ventilation, perfusion, and exchange of respiratory gases. Gases move into and out of the lungs through pressure changes. Intrapleural pressure is negative, or less than atmospheric pressure, which is 760 mm Hg at sea level. For air to flow into the lungs, intrapleural pressure becomes more negative, setting up a pressure gradient between the atmosphere and the alveoli. The diaphragm and external intercostal muscles contract to create a negative pleural pressure and increase the size of the thorax for inspiration. Relaxation of the diaphragm and contraction of the internal intercostal muscles allow air to escape from the lungs.

Ventilation is the process of moving gases into and out of the lungs. It requires coordination of the muscular and elastic properties of the lung and thorax. The major inspiratory muscle of respiration is the diaphragm. It is innervated by the phrenic nerve, which exits the spinal cord at the fourth cervical vertebra. **Perfusion** relates to the ability of the cardiovascular system to pump oxygenated blood to the tissues and return deoxygenated blood to the lungs. Finally, diffusion is responsible for moving the respiratory gases from one area to another by concentration gradients. For the exchange of respiratory gases to occur, the organs, nerves, and muscles of respiration need to be intact; and the central nervous system needs to be able to regulate the respiratory cycle.

Work of Breathing.   Work of breathing (WOB) is the effort required to expand and contract the lungs. In the healthy individual breathing is quiet and accomplished with minimal effort. The amount of energy expended on breathing depends on the rate and depth of breathing, the ease in which the lungs can be expanded (compliance), and airway resistance.

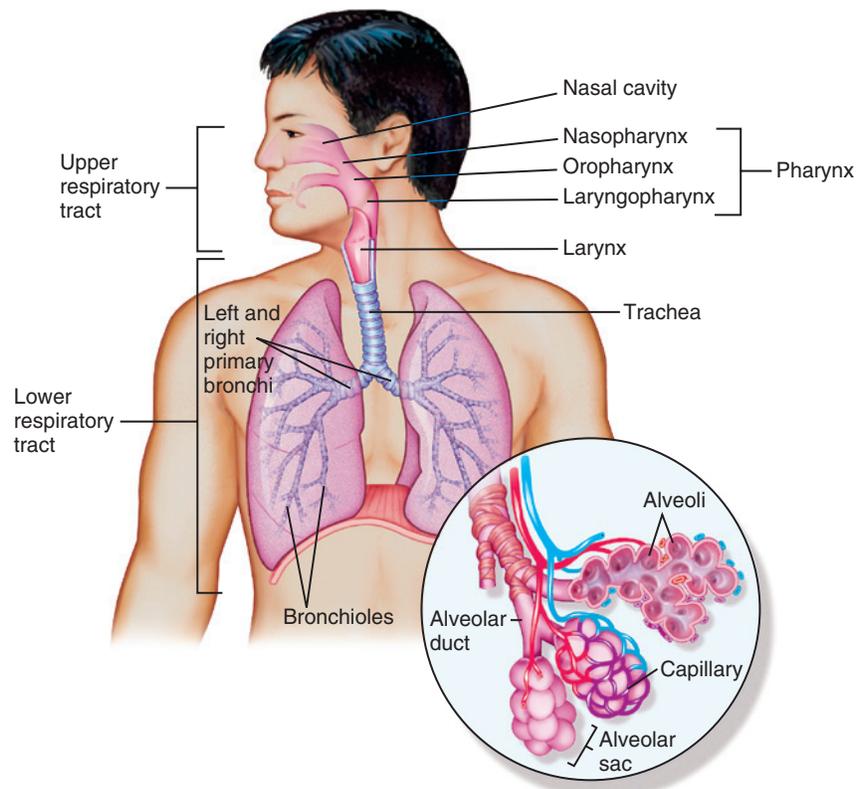
Inspiration is an active process, stimulated by chemical receptors in the aorta. **Expiration** is a passive process that depends on the elastic recoil properties of the lungs, requiring little or no muscle work. **Surfactant** is a chemical produced in the lungs to maintain the surface tension of the alveoli and keep them from collapsing. Patients with advanced chronic obstructive pulmonary disease (COPD) lose the elastic recoil of the lungs and thorax. As a result, the patient's work of breathing increases. In addition, patients with certain pulmonary diseases have decreased surfactant production and sometimes develop atelectasis. **Atelectasis** is a collapse of the alveoli that prevents normal exchange of oxygen and carbon dioxide.


FIGURE 41-1 Structures of pulmonary system. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 9, St Louis, 2016, Mosby.)

Accessory muscles of respiration can increase lung volume during inspiration. Patients with COPD, especially emphysema, frequently use these muscles to increase lung volume. Prolonged use of the accessory muscles does not promote effective ventilation and causes fatigue. During assessment a patient's clavicles may elevate during inspiration, which can indicate ventilatory fatigue, air hunger, or decreased lung expansion.

Compliance is the ability of the lungs to distend or expand in response to increased intraalveolar pressure. Compliance decreases in diseases such as pulmonary edema, interstitial and pleural fibrosis, and congenital or traumatic structural abnormalities such as kyphosis or fractured ribs.

Airway resistance is the increase in pressure that occurs as the diameter of the airways decreases from mouth/nose to alveoli. Any further decrease in airway diameter by bronchoconstriction can increase airway resistance. Diseases causing airway obstruction such as asthma and tracheal edema increase airway resistance. When airway resistance increases, the amount of oxygen delivered to the alveoli decreases.

Decreased lung compliance, increased airway resistance, and the increased use of accessory muscles increase the WOB, resulting in increased energy expenditure. Therefore the body increases its metabolic rate and the need for more oxygen. The need for elimination of carbon dioxide also increases. This sequence is a vicious cycle for a patient with impaired ventilation, causing further deterioration of respiratory status and the ability to oxygenate adequately.

Lung Volumes. The normal lung values are determined by age, gender, and height. Tidal volume is the amount of air exhaled following a normal inspiration. Residual volume is the amount of air left in the alveoli after a full expiration. Forced vital capacity is the maximum amount of air that can be removed from the lungs during forced expiration (McCance and Huether, 2014). Variations in tidal volume and other lung volumes are associated with alterations in patients' health status or activity, such as pregnancy, exercise, obesity, or obstructive and restrictive conditions of the lungs.

Pulmonary Circulation. The primary function of pulmonary circulation is to move blood to and from the alveolar capillary membrane for gas exchange. Pulmonary circulation begins at the pulmonary artery, which receives poorly oxygenated mixed venous blood from the right ventricle. Blood flow through this system depends on the pumping ability of the right ventricle. The flow continues from the pulmonary artery through the pulmonary arterioles to the pulmonary capillaries, where blood comes in contact with the alveolar capillary membrane and the exchange of respiratory gases occurs. The oxygen-rich blood then circulates through the pulmonary venules and pulmonary veins, returning to the left atrium.

Respiratory Gas Exchange. Diffusion is the process for the exchange of respiratory gases in the alveoli of the lungs and the capillaries of the body tissues. Diffusion of respiratory gases occurs at the alveolar capillary membrane (Figure 41-2). The thickness of the membrane affects the rate of diffusion. Increased thickness of the membrane impedes diffusion because gases take longer to transfer across the membrane. Patients with pulmonary edema, pulmonary infiltrates, or pulmonary effusion have a thickened membrane; resulting in slow diffusion, slow exchange of respiratory gases, and decreased delivery of oxygen to tissues. Chronic diseases (e.g., emphysema), acute diseases (e.g., pneumothorax), and surgical processes (e.g., lobectomy) often alter the amount of alveolar capillary membrane surface area.

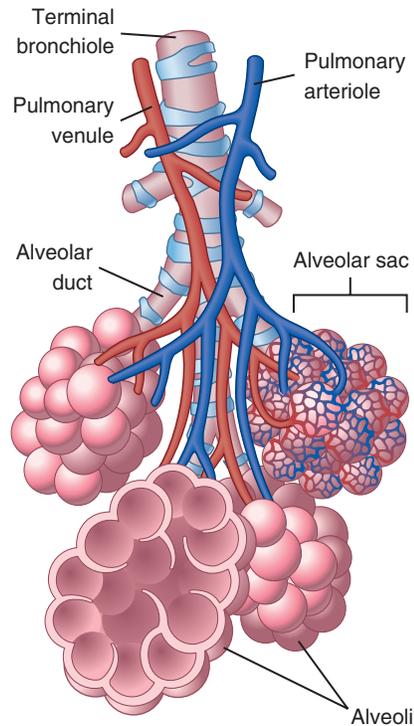
Oxygen Transport. The oxygen-transport system consists of the lungs and cardiovascular system. Delivery depends on the amount of oxygen entering the lungs (ventilation), blood flow to the lungs and


FIGURE 41-2 Alveoli at terminal end of lower airway. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 9, St Louis, 2016, Mosby.)

tissues (perfusion), rate of diffusion, and oxygen-carrying capacity. Three things influence the capacity of the blood to carry oxygen: the amount of dissolved oxygen in the plasma, the amount of hemoglobin, and the ability of hemoglobin to bind with oxygen. Hemoglobin, which is a carrier for oxygen and carbon dioxide, transports most oxygen (approximately 97%). The hemoglobin molecule combines with oxygen to form oxyhemoglobin. The formation of oxyhemoglobin is easily reversible, allowing hemoglobin and oxygen to dissociate (deoxyhemoglobin), which frees oxygen to enter tissues.

Carbon Dioxide Transport. Carbon dioxide, a product of cellular metabolism, diffuses into red blood cells and is rapidly hydrated into carbonic acid (H_2CO_3). The carbonic acid then dissociates into hydrogen (H) and bicarbonate (HCO_3^-) ions. Hemoglobin buffers the hydrogen ion, and the HCO_3^- diffuses into the plasma. Reduced hemoglobin (deoxyhemoglobin) combines with carbon dioxide, and the venous blood transports the majority of carbon dioxide back to the lungs to be exhaled.

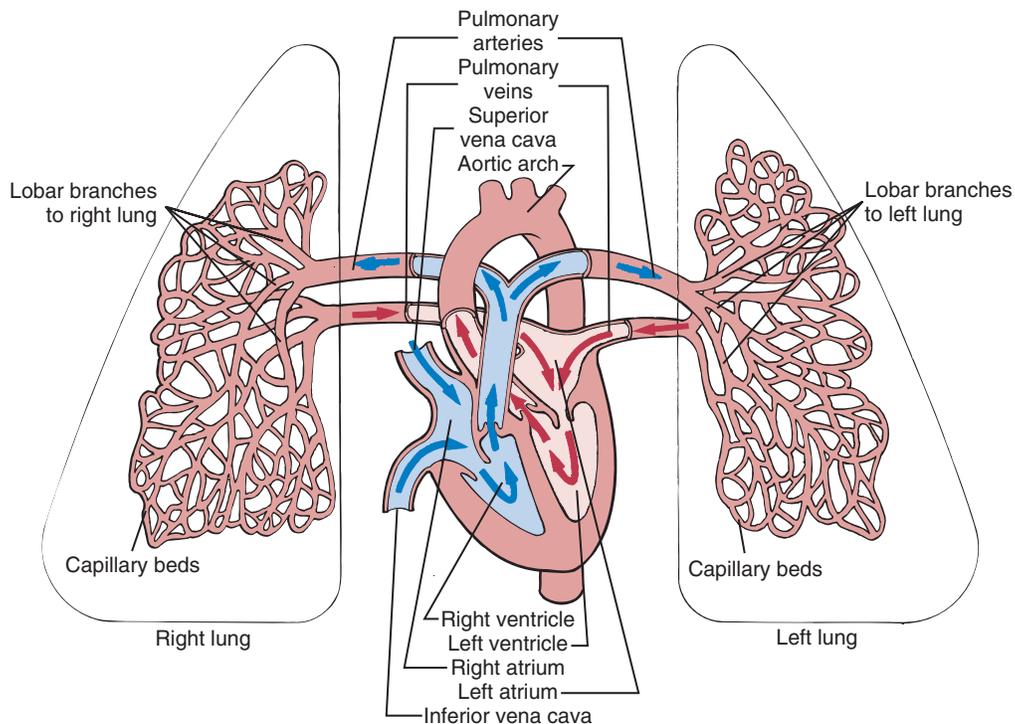
Regulation of Respiration. Regulation of respiration is necessary to ensure sufficient oxygen intake and carbon dioxide elimination to meet the demands of the body (e.g., during exercise, infection, or pregnancy). Neural and chemical regulators control the process of respiration. Neural regulation includes the central nervous system control of respiratory rate, depth, and rhythm. The cerebral cortex regulates the voluntary control of respiration by delivering impulses to the respiratory motor neurons by way of the spinal cord. Chemical regulation maintains the appropriate rate and depth of respirations based on changes in the carbon dioxide (CO_2), oxygen (O_2), and hydrogen ion (H^+) concentration (pH) in the blood. Changes in levels of O_2, CO_2, and H (pH) stimulate the chemoreceptors located in the medulla, aortic body, and carotid body, which in turn stimulate neural regulators to adjust the rate and depth of ventilation to maintain normal arterial blood gas levels.


FIGURE 41-3 Schematic representation of blood flow through the heart. *Arrows* indicate direction of flow and pulmonary circulation. (From McCance KL, Huether SE: *Pathophysiology: the biologic basis for disease in adults and children,* ed 7, St Louis, 2014, Mosby.)

Cardiovascular Physiology

Cardiopulmonary physiology involves delivery of deoxygenated blood (blood high in carbon dioxide and low in oxygen) to the right side of the heart and then to the lungs, where it is oxygenated. Oxygenated blood (blood high in oxygen and low in carbon dioxide) then travels from the lungs to the left side of the heart and the tissues. The cardiac system delivers oxygen, nutrients, and other substances to the tissues and facilitates the removal of cellular metabolism waste products by way of blood flow through other body systems such as respiratory, digestive, and renal (McCance and Huether, 2014).

Structure and Function. The right ventricle pumps deoxygenated blood through the pulmonary circulation (Figure 41-3). The left ventricle pumps oxygenated blood through the systemic circulation. As blood passes through the circulatory system, there is an exchange of respiratory gases, nutrients, and waste products between the blood and the tissues.

Myocardial Pump. The pumping action of the heart is essential to oxygen delivery. There are four cardiac chambers: two atria and two ventricles. The ventricles fill with blood during diastole and empty during systole. The volume of blood ejected from the ventricles during systole is the **stroke volume**. Hemorrhage and dehydration cause a decrease in circulating blood volume and a decrease in stroke volume.

Myocardial fibers have contractile properties that allow them to stretch during filling. In a healthy heart this stretch is proportionally related to the strength of contraction. As the myocardium stretches, the strength of the subsequent contraction increases; this is known as the *Frank-Starling (Starling's) law of the heart.* In the diseased heart (cardiomyopathy or myocardial infarction [MI]) Starling's law does not apply because the increased stretch of the myocardium is beyond the physiological limits of the heart. The subsequent contractile

response results in insufficient stroke volume, and blood begins to "back up" in the pulmonary (left heart failure) or systemic (right heart failure) circulation.

Myocardial Blood Flow. To maintain adequate blood flow to the pulmonary and systemic circulation, myocardial blood flow must supply sufficient oxygen and nutrients to the myocardium itself. Blood flow through the heart is unidirectional. The four heart valves ensure this forward blood flow (see Figure 41-3). During ventricular diastole the atrioventricular (mitral and tricuspid) valves open, and blood flows from the higher-pressure atria into the relaxed ventricles. As systole begins, ventricular pressure rises and the mitral and tricuspid valves close. Valve closure causes the first heart sound (S_1).

During the systolic phase the semilunar (aortic and pulmonic) valves open, and blood flows from the ventricles into the aorta and pulmonary artery. The mitral and tricuspid valves stay closed during systole so all of the blood is moved forward into the pulmonary artery and aorta. As the ventricles empty, the ventricular pressures decrease, allowing closure of the aortic and pulmonic valves. Valve closure causes the second heart sound (S_2). Some patients with valvular disease have backflow or regurgitation of blood through the incompetent valve, causing a murmur that you can hear on auscultation (see Chapter 31).

Coronary Artery Circulation. The coronary circulation is the branch of the systemic circulation that supplies the myocardium with oxygen and nutrients and removes waste. The coronary arteries fill during ventricular diastole (McCance and Huether, 2014). The left coronary artery has the most abundant blood supply and feeds the more muscular left ventricular myocardium, which does most of the work of the heart.

Systemic Circulation. The arteries of the systemic circulation deliver nutrients and oxygen to tissues, and the veins remove waste from tissues. Oxygenated blood flows from the left ventricle through

the aorta and into large systemic arteries. These arteries branch into smaller arteries; then arterioles; and finally the smallest vessels, the capillaries. The exchange of respiratory gases occurs at the capillary level, where the tissues are oxygenated. The waste products exit the capillary network through venules that join to form veins. These veins become larger and form the vena cava, which carry deoxygenated blood back to the right side of the heart, where it then returns to the pulmonary circulation.

Blood Flow Regulation. The amount of blood ejected from the left ventricle each minute is the **cardiac output**. The normal cardiac output is 4 to 6 L/min in the healthy adult at rest. The circulating volume of blood changes according to the oxygen and metabolic needs of the body. For example, cardiac output increases during exercise, pregnancy, and fever but decreases during sleep. The following formula represents cardiac output:

$$\text{Cardiac output (CO)} = \text{Stroke volume (SV)} \times \text{Heart rate (HR)}$$

Preload, afterload, and myocardial contractility all affect stroke volume.

Preload is the amount of blood in the left ventricle at the end of diastole, often referred to as end-diastolic volume. The ventricles stretch when filling with blood. The more stretch on the ventricular muscle, the greater the contraction and the greater the stroke volume (Starling's law). In certain clinical situations, medical treatment alters preload and subsequent stroke volumes by changing the amount of circulating blood volume. For example, when treating a patient who is hemorrhaging, increased fluid therapy and replacement of blood increase circulating volume, thus increasing the preload and stroke volume, which in turn increases cardiac output. If volume is not replaced, preload, stroke volume and the subsequent cardiac output decrease.

Afterload is the resistance to left ventricular ejection. The heart works harder to overcome the resistance so blood can be fully ejected from the left ventricle. The diastolic aortic pressure is a good clinical measure of afterload. In hypertension the afterload increases, making cardiac workload also increase.

Myocardial **contractility** also affects stroke volume and cardiac output. Poor ventricular contraction decreases the amount of blood ejected. Injury to the myocardial muscle such as an acute MI causes a decrease in myocardial contractility. The myocardium of the older adult is stiffer with a slower ventricular filling rate and prolonged contraction time (Touhy and Jett, 2014).

Heart rate affects blood flow because of the relationship between rate and diastolic filling time. With a sustained heart rate greater than 160 beats/min, diastolic filling time decreases, decreasing stroke volume and cardiac output. The heart rate of the older adult is slow to increase under stress, but studies have found that this may be caused more by lack of conditioning than age. Exercise is beneficial in maintaining function at any age (Touhy and Jett, 2014).

Conduction System. The rhythmic relaxation and contraction of the atria and ventricles depend on continuous, organized transmission of electrical impulses. The cardiac conduction system generates and transmits these impulses (Figure 41-4).

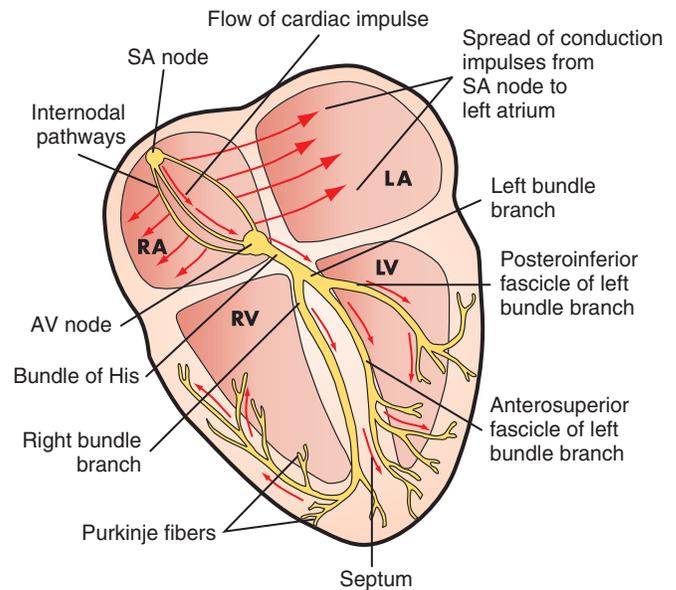
The conduction system of the heart generates the impulses needed to initiate the electrical chain of events for a normal heartbeat. The autonomic nervous system influences the rate of impulse generation and the speed of transmission through the conductive pathway and the strength of atrial and ventricular contractions. Sympathetic and parasympathetic nerve fibers innervate all parts of the atria and ventricles and the sinoatrial (SA) and atrioventricular (AV) nodes. Sympathetic fibers increase the rate of impulse generation and speed


FIGURE 41-4 Conduction system of the heart. *AV,* Atrioventricular; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle; *SA,* sinoatrial. (From Lewis SL et al: *Medical-surgical nursing: assessment and management of clinical problems,* ed 7, St Louis, 2007, Mosby.)
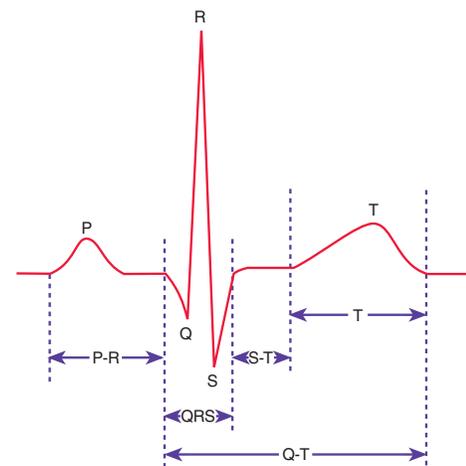

FIGURE 41-5 Normal electrocardiogram waveform.

of transmission. The parasympathetic fibers originating from the vagus nerve decrease the rate.

The conduction system originates with the SA node, the "pacemaker" of the heart. The SA node is in the right atrium next to the entrance of the superior vena cava. Impulses are initiated at the SA node at an intrinsic rate of 60 to 100 cardiac action potentials per minute in an adult at rest (McCance and Huether, 2014).

The electrical impulses are transmitted through the atria along intraatrial pathways to the AV node. The AV node mediates impulses between the atria and the ventricles. It assists atrial emptying by delaying the impulse before transmitting it through the Bundle of His and the ventricular Purkinje network.

An **electrocardiogram (ECG)** reflects the electrical activity of the conduction system. An ECG monitors the regularity and path of the electrical impulse through the conduction system; however, it does not reflect the muscular work of the heart. The normal sequence on the ECG is called the **normal sinus rhythm (NSR)** (Figure 41-5).

NSR implies that the impulse originates at the SA node and follows the normal sequence through the conduction system. The P wave represents the electrical conduction through both atria. Atrial contraction follows the P wave. The PR interval represents the impulse travel time from the SA node through the AV node, through the Bundle of His, and to the Purkinje fibers. The normal length for the PR interval is 0.12 to 0.2 second. An increase in the time greater than 0.2 second indicates a block in the impulse transmission through the AV node; whereas a decrease, less than 0.12 second, indicates the initiation of the electrical impulse from a source other than the SA node.

The QRS complex indicates that the electrical impulse traveled through the ventricles. Normal QRS duration is 0.06 to 0.1 second. An increase in QRS duration indicates a delay in conduction time through the ventricles. Ventricular contraction usually follows the QRS complex.

The QT interval represents the time needed for ventricular depolarization and repolarization. The normal QT interval is 0.12 to 0.42 second. This interval varies inversely with changes in heart rate (McCance and Huether, 2014). Changes in electrolyte values such as hypocalcemia or therapy with drugs such as disopyramide (Norpace) or amiodarone (Cordarone) increase the QT interval. Shortening of the QT interval occurs with digitalis therapy, hyperkalemia, and hypercalcemia.

Factors Affecting Oxygenation

Four factors influence adequacy of circulation, ventilation, perfusion, and transport of respiratory gases to the tissues: (1) physiological, (2) developmental, (3) lifestyle, and (4) environmental. The physiological factors are discussed here, and the others are discussed in the Nursing Knowledge Base section that follows.

Physiological Factors. Any condition affecting cardiopulmonary functioning directly affects the ability of the body to meet oxygen demands. Respiratory disorders include hyperventilation, hypoventilation, and hypoxia. Cardiac disorders include disturbances in conduction, impaired valvular function, myocardial hypoxia, cardiomyopathy conditions, and peripheral tissue hypoxia. Other physiological processes affecting a patient's oxygenation include alterations affecting the oxygen-carrying capacity of blood, decreased inspired oxygen concentration, increases in the metabolic demand of the body, and alterations affecting chest wall movement caused by musculoskeletal abnormalities or neuromuscular alterations.

Decreased Oxygen-Carrying Capacity. Hemoglobin carries the majority of oxygen to tissues. Anemia and inhalation of toxic substances decrease the oxygen-carrying capacity of blood by reducing the amount of available hemoglobin to transport oxygen. Anemia (e.g., a lower-than-normal hemoglobin level) is a result of decreased hemoglobin production, increased red blood cell destruction, and/or blood loss. Patients have fatigue, decreased activity tolerance, increased breathlessness, increased heart rate, and pallor (especially seen in the conjunctiva of the eye). Oxygenation decreases as a secondary effect with anemia. The physiological response to chronic hypoxemia is the development of increased red blood cells (polycythemia). This is the adaptive response of the body to increase the amount of hemoglobin and the available oxygen-binding sites.

Carbon monoxide (CO) is the most common toxic inhalant decreasing the oxygen-carrying capacity of blood. In CO toxicity hemoglobin strongly binds with CO, creating a functional anemia. Because of the strength of the bond, CO does not easily dissociate from hemoglobin, making hemoglobin unavailable for oxygen transport.

Hypovolemia. Conditions such as shock and severe dehydration cause extracellular fluid loss and reduced circulating blood volume, or **hypovolemia**. Decreased circulating blood volume results in hypoxia to body tissues. With significant fluid loss, the body tries to adapt by peripheral vasoconstriction and increasing the heart rate to increase the volume of blood returned to the heart, thus increasing the cardiac output.

Decreased Inspired Oxygen Concentration. With the decline of the concentration of inspired oxygen, the oxygen-carrying capacity of the blood decreases. Decreases in the fraction of inspired oxygen concentration (FiO_2) are caused by upper or lower airway obstruction, which limits delivery of inspired oxygen to alveoli; decreased environmental oxygen (at high altitudes); or hypoventilation (occurs in drug overdoses).

Increased Metabolic Rate. Increased metabolic activity increases oxygen demand. The level of oxygenation declines when body systems are unable to meet this demand. An increased metabolic rate is normal in pregnancy, wound healing, and exercise because the body is using energy or building tissue. Most people are able to meet the increased oxygen demand and do not display signs of oxygen deprivation. Fever increases the need of tissues for oxygen; as a result carbon dioxide production increases. When fever persists, the metabolic rate remains high, and the body begins to break down protein stores. This causes muscle wasting and decreased muscle mass, including respiratory muscles such as the diaphragm and intercostal muscles.

The body attempts to adapt to the increased carbon dioxide levels by increasing the rate and depth of respiration. The patient's WOB increases, and the patient eventually displays signs and symptoms of hypoxemia. Patients with pulmonary diseases are at greater risk for hypoxemia.

Conditions Affecting Chest Wall Movement. Any condition reducing chest wall movement results in decreased ventilation. If the diaphragm does not fully descend with breathing, the volume of inspired air decreases, delivering less oxygen to the alveoli and tissues.

Pregnancy. As the fetus grows during pregnancy, the enlarging uterus pushes abdominal contents upward against the diaphragm. In the last trimester of pregnancy, the inspiratory capacity declines, resulting in dyspnea on exertion and increased fatigue.

Obesity. Patients who are morbidly obese have reduced lung volumes from the heavy lower thorax and abdomen, particularly when in the recumbent and supine positions. Many morbidly obese patients suffer from obstructive sleep apnea. Morbidly obese patients have a reduction in lung and chest wall compliance as a result of encroachment of the abdomen into the chest, increased WOB, and decreased lung volumes. In some patients an obesity-hypoventilation syndrome develops in which oxygenation is decreased and carbon dioxide is retained. The obese patient is also susceptible to atelectasis or pneumonia after surgery because the lungs do not expand fully and the lower lobes retain pulmonary secretions.

Musculoskeletal Abnormalities. Musculoskeletal impairments in the thoracic region reduce oxygenation. Such impairments result from abnormal structural configurations, trauma, muscular diseases, and diseases of the central nervous system. Abnormal structural configurations impairing oxygenation include those affecting the rib cage such as pectus excavatum and the vertebral column such as kyphosis, lordosis, or scoliosis.

Trauma. Flail chest is a condition in which multiple rib fractures cause instability in part of the chest wall. The unstable chest wall allows the lung under the injured area to contract on inspiration and bulge on expiration, resulting in hypoxia. Patients with thoracic or upper

abdominal surgical incisions use shallow respirations to avoid pain, which also decreases chest wall movement. Opioids used to treat pain depress the respiratory center, further decreasing respiratory rate and chest wall expansion.

Neuromuscular Diseases. Neuromuscular diseases affect tissue oxygenation by decreasing a patient's ability to expand and contract the chest wall. Ventilation is impaired, resulting in atelectasis, hypercapnia, and hypoxemia. Examples of conditions causing hypoventilation include myasthenia gravis, Guillain-Barré syndrome, and poliomyelitis.

Central Nervous System Alterations. Diseases or trauma of the medulla oblongata and/or spinal cord result in impaired respiration. When the medulla oblongata is affected, neural regulation of respiration is impaired, and abnormal breathing patterns develop. Cervical trauma at C3 to C5 usually results in paralysis of the phrenic nerve. When the phrenic nerve is damaged, the diaphragm does not descend properly, thus reducing inspiratory lung volumes and causing hypoxemia. Spinal cord trauma below the C5 vertebra usually leaves the phrenic nerve intact but damages nerves that innervate the intercostal muscles, preventing anteroposterior chest expansion.

Influences of Chronic Disease. Oxygenation decreases as a direct consequence of chronic lung disease. Changes in the anteroposterior diameter of the chest wall (barrel chest) occur because of overuse of accessory muscles and air trapping in emphysema. The diaphragm is flattened, and the lung fields are overdistended, resulting in varying degrees of hypoxemia and/or hypercapnia (McCance and Huether, 2014).

Alterations in Respiratory Functioning

Illnesses and conditions affecting ventilation or oxygen transport cause alterations in respiratory functioning. The three primary alterations are hypoventilation, hyperventilation, and hypoxia.

The goal of ventilation is to produce a normal arterial carbon dioxide tension ($PaCO_2$) between 35 and 45 mm Hg and a normal arterial oxygen tension (PaO_2) between 80 and 100 mm Hg. Hypoventilation and hyperventilation are often determined by arterial blood gas analysis (McCance and Huether, 2014). Hypoxemia refers to a decrease in the amount of arterial oxygen. Nurses monitor arterial oxygen saturation (SpO_2) using a noninvasive oxygen saturation monitor pulse oximeter. Normally SpO_2 is greater than or equal to 95% (see Chapter 30).

Hypoventilation. **Hypoventilation** occurs when alveolar ventilation is inadequate to meet the oxygen demand of the body or eliminate sufficient carbon dioxide. As alveolar ventilation decreases, the body retains carbon dioxide. For example, atelectasis, a collapse of the alveoli, prevents normal exchange of oxygen and carbon dioxide. As more alveoli collapse, less of the lung is ventilated, and hypoventilation occurs.

In patients with COPD, the administration of excessive oxygen results in hypoventilation. These patients have adapted to a high carbon dioxide level so their carbon dioxide–sensitive chemoreceptors are not functioning normally. Their peripheral chemoreceptors of the aortic arch and carotid bodies are primarily sensitive to lower oxygen levels, causing increased ventilation. Because the stimulus to breathe is a decreased arterial oxygen (PaO_2) level, administration of oxygen greater than 24% to 28% (1 to 3 L/min) prevents the PaO_2 from falling to a level (60 mm Hg) that stimulates the peripheral receptors, thus destroying the stimulus to breathe (McCance and Huether, 2014). The resulting hypoventilation causes excessive retention of carbon dioxide, which can lead to respiratory acidosis and respiratory arrest.

Signs and symptoms of hypoventilation include mental status changes, dysrhythmias, and potential cardiac arrest. If untreated, the patient's status rapidly declines, leading to convulsions, unconsciousness, and death.

Hyperventilation. **Hyperventilation** is a state of ventilation in which the lungs remove carbon dioxide faster than it is produced by cellular metabolism. Severe anxiety, infection, drugs, or an acid-base imbalance induces hyperventilation (see Chapter 42). Acute anxiety leads to hyperventilation and exhalation of excessive amounts of carbon dioxide. Increased body temperature (fever) increases the metabolic rate, thereby increasing carbon dioxide production. The increased carbon dioxide level stimulates an increase in the patient's rate and depth of respiration, causing hyperventilation.

Hyperventilation is sometimes chemically induced. Salicylate (aspirin) poisoning and amphetamine use result in excess carbon dioxide production, stimulating the respiratory center to compensate by increasing the rate and depth of respiration. It also occurs as the body tries to compensate for metabolic acidosis. For example, the patient with diabetes in ketoacidosis produces large amounts of metabolic acids. The respiratory system tries to correct the acid-base balance by overbreathing. Ventilation increases to reduce the amount of carbon dioxide available to form carbonic acid (see Chapter 42). This can also result in the patient developing respiratory alkalosis. Signs and symptoms of hyperventilation include rapid respirations, sighing breaths, numbness and tingling of hands/feet, light-headedness, and loss of consciousness.

Hypoxia. **Hypoxia** is inadequate tissue oxygenation at the cellular level. It results from a deficiency in oxygen delivery or oxygen use at the cellular level. It is a life-threatening condition. Untreated it produces possibly fatal cardiac dysrhythmias.

Causes of hypoxia include (1) a decreased hemoglobin level and lowered oxygen-carrying capacity of the blood; (2) a diminished concentration of inspired oxygen, which occurs at high altitudes; (3) the inability of the tissues to extract oxygen from the blood, as with cyanide poisoning; (4) decreased diffusion of oxygen from the alveoli to the blood, as in pneumonia; (5) poor tissue perfusion with oxygenated blood, as with shock; and (6) impaired ventilation, as with multiple rib fractures or chest trauma.

The clinical signs and symptoms of hypoxia include apprehension, restlessness, inability to concentrate, decreased level of consciousness, dizziness, and behavioral changes. The patient with hypoxia is unable to lie flat and appears both fatigued and agitated. Vital sign changes include an increased pulse rate and increased rate and depth of respiration. During early stages of hypoxia the blood pressure is elevated unless the condition is caused by shock. As the hypoxia worsens, the respiratory rate declines as a result of respiratory muscle fatigue.

Cyanosis, blue discoloration of the skin and mucous membranes caused by the presence of desaturated hemoglobin in capillaries, is a late sign of hypoxia. The presence or absence of cyanosis is not a reliable measure of oxygen status. Central cyanosis, observed in the tongue, soft palate, and conjunctiva of the eye where blood flow is high, indicates hypoxemia. Peripheral cyanosis, seen in the extremities, nail beds, and earlobes, is often a result of vasoconstriction and stagnant blood flow.

Alterations in Cardiac Functioning

Illnesses and conditions affecting cardiac rhythm, strength of contraction, blood flow through the heart or to the heart muscle, and decreased peripheral circulation cause alterations in cardiac functioning. Older adults experience alterations in cardiac function as a result

of calcification of the conduction pathways, thicker and stiffer heart valves caused by lipid accumulation and fibrosis, and a decrease in the number of pacemaker cells in the SA node (Touhy and Jett, 2014; Meiner, 2011).

Disturbances in Conduction. Electrical impulses that do not originate from the SA node cause conduction disturbances. These rhythm disturbances are called **dysrhythmias,** meaning a deviation from the normal sinus heart rhythm. Dysrhythmias occur as a primary conduction disturbance such as in response to ischemia; valvular abnormality; anxiety; drug toxicity; caffeine, alcohol, or tobacco use; or a complication of acid-base or electrolyte imbalance (see Chapter 42).

Dysrhythmias are classified by cardiac response and site of impulse origin. Cardiac response is tachycardia (greater than 100 beats/min), bradycardia (less than 60 beats/min), a premature (early) beat, or a blocked (delayed or absent) beat. Tachydysrhythmias and brady-dysrhythmias lower cardiac output and blood pressure. Tachydys-rhythmias reduce cardiac output by decreasing diastolic filling time. Bradydysrhythmias lower cardiac output because of the decreased heart rate.

Atrial fibrillation is a common dysrhythmia in older adults. The electrical impulse in the atria is chaotic and originates from multiple sites. The rhythm is irregular because of the multiple pacemaker sites and the unpredictable conduction to the ventricles. The QRS complex is normal; however, it occurs at irregular intervals. Atrial fibrillation is often described as an irregularly irregular rhythm.

Abnormal impulses originating above the ventricles are supraventricular dysrhythmias. The abnormality on the waveform is the configuration and placement of the P wave. Ventricular conduction usually remains normal, and there is a normal QRS complex.

Paroxysmal supraventricular tachycardia is a sudden, rapid onset of tachycardia originating above the AV node. It often begins and ends spontaneously. Sometimes excitement, fatigue, caffeine, smoking, or alcohol use precipitates paroxysmal supraventricular tachycardia.

Ventricular dysrhythmias represent an ectopic site of impulse formation within the ventricles. It is ectopic in that the impulse originates in the ventricle, not the SA node. The configuration of the QRS complex is usually widened and bizarre. P waves are not always present; often they are buried in the QRS complex. **Ventricular tachycardia** and **ventricular fibrillation** are life-threatening rhythms that require immediate intervention. Ventricular tachycardia is a life-threatening dysrhythmia because of the decreased cardiac output and the potential to deteriorate into ventricular fibrillation or sudden cardiac death (AHA, 2010b).

Altered Cardiac Output. Failure of the myocardium to eject sufficient volume to the systemic and pulmonary circulations occurs in heart failure. Primary coronary artery disease, cardiomyopathy, valvular disorders, and pulmonary disease lead to myocardial pump failure.

Left-Sided Heart Failure. Left-sided heart failure is an abnormal condition characterized by decreased functioning of the left ventricle. If left ventricular failure is significant, the amount of blood ejected from the left ventricle drops greatly, resulting in decreased cardiac output. Signs and symptoms include fatigue, breathlessness, dizziness, and confusion as a result of tissue hypoxia from the diminished cardiac output. As the left ventricle continues to fail, blood begins to pool in the pulmonary circulation, causing pulmonary congestion. Clinical findings include crackles in the bases of the lungs on auscultation, hypoxia, shortness of breath on exertion, cough, and paroxysmal nocturnal dyspnea.

Right-Sided Heart Failure. Right-sided heart failure results from impaired functioning of the right ventricle. It more commonly results from pulmonary disease or as a result of long-term left-sided failure. The primary pathological factor in right-sided failure is elevated pulmonary vascular resistance (PVR). As the PVR continues to rise, the right ventricle works harder, and the oxygen demand of the heart increases. As the failure continues, the amount of blood ejected from the right ventricle declines, and blood begins to "back up" in the systemic circulation. Clinically the patient has weight gain, distended neck veins, hepatomegaly and splenomegaly, and dependent peripheral edema.

Impaired Valvular Function. Valvular heart disease is an acquired or congenital disorder of a cardiac valve that causes either hardening (stenosis) or impaired closure (regurgitation) of the valves. When stenosis occurs, the flow of blood through the valves is obstructed. For example, when stenosis occurs in the semilunar valves (aortic and pulmonic valves), the adjacent ventricles have to work harder to move the ventricular blood volume beyond the stenotic valve. Over time the stenosis causes the ventricle to hypertrophy (enlarge); and, if the condition is untreated, left- or right-sided heart failure occurs. When regurgitation occurs, there is a backflow of blood into an adjacent chamber. For example, in mitral regurgitation the mitral leaflets do not close completely. When the ventricles contract, blood escapes back into the atria, causing a murmur, or "whooshing" sound (see Chapter 31).

Myocardial Ischemia. **Myocardial ischemia** results when the supply of blood to the myocardium from the coronary arteries is insufficient to meet myocardial oxygen demands. Two common outcomes of this ischemia are angina pectoris and MI.

Angina. **Angina pectoris** is a transient imbalance between myocardial oxygen supply and demand. The condition results in chest pain that is aching, sharp, tingling, or burning or that feels like pressure. Typically chest pain is left sided or substernal and often radiates to the left or both arms, the jaw, neck, and back. In some patients angina pain does not radiate. It usually lasts from 3 to 5 minutes (McCance and Huether, 2014). Patients report that it is often precipitated by activities that increase myocardial oxygen demand (e.g., eating heavy meals, exercise, or stress). It is usually relieved with rest and coronary vasodilators, the most common being a nitroglycerin preparation.

Myocardial Infarction. **Myocardial infarction (MI)** or **acute coronary syndrome (ACS)** results from sudden decreases in coronary blood flow or an increase in myocardial oxygen demand without adequate coronary perfusion. Infarction occurs because ischemia is not reversed. Cellular death occurs after 20 minutes of myocardial ischemia (McCance and Huether, 2014).

Chest pain associated with MI in men is usually described as crushing, squeezing, or stabbing. The pain is often in the left chest and sternal area; may be felt in the back; and radiates down the left arm to the neck, jaws, teeth, epigastric area, and back. It occurs at rest or exertion and lasts more than 20 minutes. Rest, position change, or sublingual nitroglycerin administration does not relieve the pain.

There is a significant difference between men and women in relation to coronary artery disease. As women get older, their risk of heart disease begins to rise (AHA, 2015). Women on average have greater blood cholesterol and triglyceride levels than men. Obesity in women is more prevalent, which also increases risk for diabetes and cardiac disease (Najafi et al., 2013). Women's symptoms differ from those of men. The most common initial symptom in women is angina, but they also present with atypical symptoms such as fatigue, indigestion,

shortness of breath, and back or jaw pain. Women have twice the risk of dying within the first year after a heart attack than men (Najafi et al., 2013).

NURSING KNOWLEDGE BASE

Factors Influencing Oxygenation

In addition to physiological factors, multiple developmental, lifestyle, and environmental factors affect patients' oxygenation status. It is important to recognize these as possible risks or factors that impact their health care goals.

Developmental Factors. The developmental stage of a patient and the normal aging process affect tissue oxygenation.

Infants and Toddlers. Infants and toddlers are at risk for upper respiratory tract infections as a result of frequent exposure to other children, an immature immune system, and exposure to secondhand smoke. In addition, during the teething process some infants develop nasal congestion, which encourages bacterial growth and increases the potential for respiratory tract infection. Upper respiratory tract infections are usually not dangerous, and infants or toddlers recover with little difficulty.

School-Age Children and Adolescents. School-age children and adolescents are exposed to respiratory infections and respiratory risk factors such as cigarette smoking or secondhand smoke. A healthy child usually does not have adverse pulmonary effects from respiratory infections. The CDC (2013b) reported that 6.7% of middle school–age children and 23.3% of high school–age children currently used tobacco products, which include cigarettes, cigars, hookahs, snus, smokeless tobacco pipes, bidis, keteks, dissolvable tobacco, and electronic cigarettes (CDC, 2013b). Current cigarette smoking among middle school– and high school–age children has declined. Nine out of ten smokers started smoking by the age of 18, and 99% started by the age of 26 (CDC, 2014c). A person who starts smoking in adolescence and continues to smoke into middle age has an increased risk for cardiopulmonary disease and lung cancer.

Young and Middle-Age Adults. Young and middle-age adults are exposed to multiple cardiopulmonary risk factors: an unhealthy diet, lack of exercise, stress, over-the-counter and prescription drugs not used as intended, illegal substances, and smoking. Reducing these modifiable factors decreases a patient's risk for cardiac or pulmonary diseases. This is also the time when individuals establish lifelong habits and lifestyles. It is important to help your patients make good choices and informed decisions about their health care practices. The increased cost of cigarettes plus the state smoke-free air policies and laws that reduce smoking in public places have proven to be helpful in smoking cessation (CDC, 2012).

Older Adults. The cardiac and respiratory systems undergo changes throughout the aging process (Box 41-1). The changes are associated with calcification of the heart valves, SA node, and costal cartilages. The arterial system develops atherosclerotic plaques.

Osteoporosis leads to changes in the size and shape of the thorax. The trachea and large bronchi become enlarged from calcification of the airways. The alveoli enlarge, decreasing the surface area available for gas exchange. The number of functional cilia is reduced, causing a decrease in the effectiveness of the cough mechanism, putting the older adult at increased risk for respiratory infections (Touhy and Jett, 2014).

Lifestyle Factors. Lifestyle modifications are difficult for patients because they often have to change an enjoyable habit such as cigarette

---

smoking or eating certain foods. Risk-factor modification is important and includes smoking cessation, weight reduction, a low-cholesterol and low-sodium diet, management of hypertension, and moderate exercise (see Chapter 6). Although it is difficult to change long-term behavior, helping patients acquire healthy behaviors reduces the risk for or slows or halts the progression of cardiopulmonary diseases.

Nutrition. Nutrition affects cardiopulmonary function in several ways. Severe obesity decreases lung expansion, and increased body weight increases tissue oxygen demands. The malnourished patient experiences respiratory muscle wasting, resulting in decreased muscle strength and respiratory excursion. Cough efficiency is reduced secondary to respiratory muscle weakness, putting a patient at risk for retention of pulmonary secretions.

Patients who are morbidly obese and/or malnourished are at risk for anemia. Diets high in carbohydrates play a role in increasing the carbon dioxide load for patients with carbon dioxide retention. As carbohydrates are metabolized, an increased load of carbon dioxide is created and excreted via the lungs.

Dietary practices also influence the prevalence of cardiovascular diseases. Cardioprotective nutrition includes diets rich in fiber; whole grains; fresh fruits and vegetables; nuts; antioxidants; lean meats, fish, and chicken; and omega-3 fatty acids. Restriction of sodium, controlling arterial pressure, and weight loss independently facilitate the regression of left ventricular hypertrophy (Katholi and Couri, 2011). Diets high in potassium prevent hypertension and help improve control in patients with hypertension. A 2000-calorie diet of fruits; vegetables; and low-fat dairy foods that are high in fiber, potassium,

calcium, and magnesium and low in saturated and total fat helps prevent and reduce the effects of hypertension.

Exercise. Exercise increases the metabolic activity and oxygen demand of the body. The rate and depth of respiration increase, enabling the person to inhale more oxygen and exhale excess carbon dioxide. A physical exercise program has many benefits (see Chapter 39). People who exercise for 30 to 60 minutes daily have a lower pulse rate and blood pressure, decreased cholesterol level, increased blood flow, and greater oxygen extraction by working muscles. Fully conditioned people increase oxygen consumption by 10% to 20% because of increased cardiac output and increased efficiency of the myocardial muscle (James et al, 2014).

Smoking. Cigarette smoking and secondhand smoke are associated with a number of diseases, including heart disease, COPD, and lung cancer. Cigarette smoking worsens peripheral vascular and coronary artery diseases (McCance and Huether, 2014). Inhaled nicotine causes vasoconstriction of peripheral and coronary blood vessels, increasing blood pressure and decreasing blood flow to peripheral vessels.

Women who take birth control pills and smoke cigarettes have an increased risk for thrombophlebitis and pulmonary emboli. Smoking during pregnancy can result in low-birth-weight babies, preterm delivery, and babies with reduced lung function (CDC, 2014f). Even exposure to secondhand smoke can be a risk for low-birth-weight babies, preterm delivery, and miscarriages (CDC, 2014f).

The risk of lung cancer is 10 times greater for a person who smokes than for a nonsmoker. In the United States the use of tobacco accounts for 30% of all cancer deaths. This includes 87% of the deaths from lung cancer and cancer of the larynx, mouth, pharynx, esophagus, and bladder. Smoking has been linked to the development of other cancers, including kidney, cervix, and leukemia (ACS, 2014a). Nicotine patches, gum, and lozenges are available over the counter, and nicotine nasal spray and inhalers can be obtained by prescription. Prescription drugs such as bupropion (Zyban) and varenicline (Chantix) are also available to help people quit smoking (ACS, 2014b).

Exposure to environmental tobacco smoke (secondhand smoke) increases the risk of lung cancer and cardiovascular disease in the nonsmoker. Children with parents who smoke have a higher incidence of asthma, pneumonia, and ear infections. Babies exposed to secondhand smoke are at higher risk for sudden infant death syndrome (ACS, 2014a).

Substance Abuse. Excessive use of alcohol and other drugs impairs tissue oxygenation in two ways. First, the person who chronically abuses substances often has a poor nutritional intake. With the resultant decrease in intake of iron-rich foods, hemoglobin production declines. Second, excessive use of alcohol and certain other drugs depresses the respiratory center, reducing the rate and depth of respiration and the amount of inhaled oxygen. Substance abuse by either smoking or inhaling substances such as crack cocaine or fumes from paint or glue cans causes direct injury to lung tissue that leads to permanent lung damage (Stoppler, 2013). The report on inhalant abuse (huffing) by teenagers to get a euphoric effect includes use of a wide variety of substances such as paint thinner, nail polish remover, glue, spray paint, nitrous oxide, and other common household products. Sudden death can occur from cardiac arrhythmias; or chronic abuse can cause damage to heart, lungs, and kidneys (Stoppler, 2013).

Stress. A continuous state of stress or severe anxiety increases the metabolic rate and oxygen demands of the body. The body responds to anxiety and other stresses with an increased rate and depth of respiration. Most people adapt; but some, particularly those with chronic illnesses or acute life-threatening illnesses such as an MI, cannot tolerate the oxygen demands associated with anxiety (see Chapter 38).

Environmental Factors. The environment influences oxygenation. The incidence of pulmonary disease is higher in smoggy, urban areas than in rural areas. In addition, a patient's workplace sometimes increases the risk for pulmonary disease. Occupational pollutants include asbestos, talcum powder, dust, and airborne fibers. For example, farm workers in dry regions of the southwestern United States are at risk for coccidioidomycosis, a fungal disease caused by inhalation of spores of the airborne bacterium *Coccidioides immitis*. Asbestosis is an occupational lung disease that develops after exposure to asbestos. The lung with asbestosis often has diffuse interstitial fibrosis, creating a restrictive lung disease. Patients exposed to asbestos are at risk for developing lung cancer, and this risk increases with exposure to tobacco smoke.

CRITICAL THINKING

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require you to anticipate information, analyze the data, and make decisions regarding your patient's care. During assessment consider all elements that build toward making an appropriate nursing diagnosis (Figure 41-6).

To understand how alterations in oxygenation affect patients and your selection of appropriate interventions, you need to integrate knowledge from nursing and other disciplines and information gathered from patients. Critical thinking attitudes ensure that you approach patient care in a methodical and logical way. The use of professional standards such as those developed by the Centers for Disease Control and Prevention (CDC), the American Cancer Society (ACS), the American Heart Association (AHA), the American Lung Association (ALA), the American Thoracic Society (ATS), and the American Nurses Association (ANA) provide valuable guidelines for care and management of patients.

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care.

◆ Assessment

During the assessment process, thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care. Nursing assessment of cardiopulmonary functioning includes an in-depth history of a patient's normal and present cardiopulmonary function, past impairments in circulatory or respiratory functioning, and methods that a patient uses to optimize oxygenation. The nursing history includes a review of drug, food, and other allergies. Physical examination of a patient's cardiopulmonary status reveals the extent of existing signs and symptoms. Utilizing assessment values of pulse oximetry and capnography aids in the assessment of patients with spontaneous breathing, intubated patients, and patients requiring oxygen therapy or mechanical ventilation. Pulse oximetry provides an instant feedback about the patient's level of oxygenation. **Capnography**, also known as *end-tidal CO₂ monitoring,* provides instant information about the patient's ventilation (how effectively CO_2 is being eliminated by the pulmonary system), perfusion (how effectively CO_2 is being transported through the vascular system), and how effectively CO_2 is produced by cellular metabolism (Urden et al., 2014). Capnography is

Knowledge

- Cardiopulmonary anatomy and physiology
- Cardiopulmonary pathophysiology
- Clinical signs and symptoms of altered oxygenation
- Physiological factors affecting oxygenation
- Developmental factors affecting oxygenation
- Impact of lifestyle and environment on oxygenation

Experience

- Caring for patients with alterations in respiratory and cardiac function
- Personal experience with how a change in altitude or physical conditioning affects respiratory patterns
- Experience observing patient's response to oxygenation therapies
- Personal experience with respiratory infections or cardiopulmonary alterations

ASSESSMENT

- Identify recurring and present signs and symptoms associated with impaired oxygenation
- Determine the presence of risk factors for alterations
- Ask the patient about use of medications
- Determine the patient's normal and current activity status
- Determine the patient's tolerance to activity

Standards

- Apply intellectual standards of clarity, precision, specificity, and accuracy when obtaining a health history for the patient with cardiopulmonary alterations
- Apply relevant standards from American Cancer Society, American Heart Association, American Thoracic Society, and Centers for Disease Control and Prevention

Attitudes

- Carry out the responsibility of obtaining correct information about the patient
- Display confidence while assessing extent of patient's respiratory alterations
- Be creative in assessing cultural factors influencing patient's risk factors

FIGURE 41-6 Critical thinking model for oxygenation assessment.

measured near the end of exhalation. Finally, a review of laboratory and diagnostic test results provides valuable assessment data.

Through the Patient's Eyes. Ask patients about their priorities and what they expect from their health care visit. Identifying their expectations involves patients in the decision-making process and helps them participate in their care. For example, planning a smoking cessation program for a patient who is not ready for the change is frustrating for both the patient and the nurse. Establish realistic, short-term outcomes that build to a larger goal. For example, tobacco cessation treatments are effective, but a patient needs to be willing to participate in the program and may need to use several strategies to be successful. Educating the patient on the opportunities for individual, group, or telephone counseling and identifying a social support system give more individual choices when developing the cessation plan. After this is determined, the various nicotine and nonnicotine medications for treatment of tobacco dependence can be discussed to find one that may fit the patient's lifestyle. A combination of counseling and medication is more effective than either one alone (CDC, 2014c).

Remember that your goals and expectations do not always coincide with those of your patient. By addressing a patient's concerns and expectations, you establish a relationship that addresses other health care goals and expected outcomes. Knowing your patients' mindsets and respecting their wishes goes a long way in helping them make significant beneficial lifestyle changes.

Nursing History. The nursing history focuses on the patient's ability to meet oxygen needs. The nursing history for respiratory function includes the presence of a cough, shortness of breath, dyspnea, wheezing, pain, environmental exposures, frequency of respiratory tract infections, pulmonary risk factors, past respiratory problems, current medication use, and smoking history or secondhand smoke exposure. The nursing history for cardiac function includes pain and characteristics of pain, fatigue, peripheral circulation, cardiac risk factors, and the presence of past or concurrent cardiac conditions. Ask specific questions related to cardiopulmonary disease (Box 41-2).

Pain. The presence of chest pain requires an immediate thorough assessment, including location, duration, radiation, and frequency. In addition, it is important to note any other symptoms associated with chest pain, such as nausea, diaphoresis, extreme fatigue, or weakness. Cardiac pain does not occur with respiratory variations. Chest pain in men is most often on the left side of the chest and radiates to the left arm. Chest pain in women is much less definitive and is often a sensation of breathlessness, jaw or back pain, nausea, and fatigue (AHA, 2015). Pericardial pain results from inflammation of the pericardial sac, occurs on inspiration, and does not usually radiate.

Pleuritic chest pain results from inflammation of the pleural space of the lungs; the pain is peripheral and radiates to the scapular regions. Inspiratory maneuvers such as coughing, yawning, and sighing worsen pleuritic chest pain. Patients usually describe it as knifelike, lasting from a minute to hours and always in association with inspiration.

Musculoskeletal pain is often present following exercise, rib trauma, and prolonged coughing episodes. Inspiration worsens this pain, and patients often confuse it with pleuritic chest pain.

Fatigue. Fatigue is a subjective sensation in which a patient reports a loss of endurance. Fatigue in the patient with cardiopulmonary alterations is often an early sign of a worsening of the chronic underlying process. To provide an objective measure of fatigue, ask the patient to rate it on a scale of 0 to 10, with 10 being the worst level and 0 representing no fatigue.

Dyspnea. Dyspnea is associated with hypoxia. It is the subjective sensation of difficult or uncomfortable breathing. Dyspnea is shortness of breath usually associated with exercise or excitement, but in some patients it is present without any relation to activity or exercise. It is associated with many conditions such as pulmonary diseases, cardiovascular diseases, neuromuscular conditions, and anemia. In addition, it occurs in the pregnant woman in the final months of pregnancy. Finally, environmental factors such as pollution, cold air, and smoking also cause or worsen dyspnea.

Dyspnea is associated with exaggerated respiratory effort, use of the accessory muscles of respiration, nasal flaring, and marked increases in the rate and depth of respirations. The use of a visual analogue scale (VAS) helps patients objectively assess their dyspnea. The VAS is a 100-mm vertical line. Have patients rate their dyspnea on a scale of

---

BOX 41-2 Nursing Assessment Questions

Nature of the Cardiopulmonary Problem
- What types of breathing problems are you having?
- Describe the problem that you're having with your heart.
- Does the problem (e.g., chest pain, rapid heart rate) occur at a specific time of the day, during or after exercise, or all the time?
- If you have chest pain, what relieves or makes the pain worse?

Signs and Symptoms
- How has your breathing pattern changed?
- Do you have sputum with coughing? Is this different in color, volume or thickness?
- If you have chest pain, does the pain occur with breathing?

Onset and Duration
- If you are having chest pain, what causes the pain and how long does it last? Is this a different type of pain?
- When did you notice your sputum change in color and amount?
- When did your coughing increase? How does this differ from your usual pattern of coughing?

Severity
- On a scale of 0 to 10, with 10 being the most severe, rate your shortness of breath.
- What helps relieve your shortness of breath?
- On a scale of 0 to 10, with 0 being no pain and 10 the most severe pain, rate your chest pain. Is the severity of your pain different today?
- What do you do for this pain?

Predisposing Factors
- Have you been exposed to a cold or flu?
- Are you taking your prescribed medications?
- Do you smoke? Have you been exposed to secondhand smoke?
- Have you been doing any unusual exercises?

Effect of Symptoms
- Do any of your symptoms affect your daily activities? If so, how?
- How do your symptoms affect your appetite, sleeping habits, and activity status?

---

0 to 10, with 0 equated with no dyspnea and 10 equated with the worst breathlessness a patient has experienced. The use of the VAS to assess the level of a patient's dyspnea is helpful in later evaluating interventions designed to reduce dyspnea (Pang et al., 2014).

When gathering information about a patient's sensation of dyspnea, ask the patient when the dyspnea occurs (such as with exertion, stress, or respiratory tract infection) and what improves the dyspnea (e.g., rest, inhaled medication, or position change). Determine whether the patient's dyspnea affects the ability to lie flat. **Orthopnea** is an abnormal condition in which a patient uses multiple pillows when reclining to breathe easier or sits leaning forward with arms elevated. The number of pillows used usually helps to quantify the orthopnea (e.g., two- or three-pillow orthopnea). Also ask if the patient must sleep in a recliner chair to breathe easier.

Cough. Cough is a sudden, audible expulsion of air from the lungs. The person breathes in, the glottis is partially closed, and the accessory muscles of expiration contract to expel the air forcibly. Coughing is a protective reflex to clear the trachea, bronchi, and lungs of irritants and secretions. Patients with a chronic cough tend to deny, underestimate, or minimize their coughing, often because they are so accustomed to it that they are unaware of its frequency.

Patients with chronic sinusitis usually cough only in the early morning or immediately after rising from sleep. This clears the airway of mucus resulting from sinus drainage. Patients with chronic bronchitis generally cough and produce sputum all day, although greater amounts are produced after rising from a semi-recumbent or flat position. This is a result of the dependent accumulation of sputum in the airways and is associated with reduced mobility (see Chapter 39).

If a patient has a cough, determine how frequently it occurs and whether it is productive or nonproductive. A productive cough results in sputum production (e.g., material coughed up from the lungs that a patient swallows or expectorates). Sputum contains mucus, cellular debris, microorganisms, and sometimes pus or blood. Collect data about the type and quantity of sputum. Instruct patients to try to cough up some sputum and not to simply clear the throat, which produces only saliva. Have the patient cough into a specimen cup. Inspect the sputum for color such as green or blood tinged, consistency such as thin or thick, odor such as none or foul, and amount in tablespoons or milliliters.

If **hemoptysis** (bloody sputum) is present, determine if it is associated with coughing and bleeding from the upper respiratory tract, sinus drainage, or the gastrointestinal tract (**hematemesis**). Hemoptysis has an alkaline pH, and hematemesis has an acidic pH; thus pH testing of the specimen may help to determine the source (McCance and Huether, 2014). Describe hemoptysis according to amount and color and whether it is mixed with sputum. When there is bloody or blood-tinged sputum, health care providers frequently perform diagnostic tests such as examination of sputum specimens, chest x-ray examinations, **bronchoscopy**, and other x-ray film studies.

Wheezing. **Wheezing** is a high-pitched musical sound caused by high-velocity movement of air through a narrowed airway. It is associated with asthma, acute bronchitis, or pneumonia. It occurs during inspiration, expiration, or both. Determine if there are any precipitating factors such as respiratory infection, allergens, exercise, or stress.

Environmental Exposures. Environmental exposure to inhaled substances is closely linked with respiratory disease. Investigate exposures in the patient's home, workplace, and recent travel. The most common environmental exposures in the home are cigarette smoke, CO, and radon (EPA, 2014). In addition, determine whether a patient who is a nonsmoker is exposed to secondhand smoke.

CO poisoning often results from a blocked furnace flue or fireplace. The patient will have vague complaints of general malaise, flulike symptoms, and excessive sleepiness. Patients are particularly at risk in the late fall when they turn the furnace on or begin to use the fireplace again.

Radon gas is a radioactive substance from the breakdown of uranium in soil, rock, and water that enters homes through the ground or well water. When homes are poorly ventilated, this gas is unable to escape and becomes trapped. If a patient who smokes also lives in a home with a high radon level, the risk for lung cancer is very high (EPA, 2014). Ask if there are any CO or radon detectors in the home.

Smoking. It is important to determine patients' direct and secondary exposure to tobacco. Ask about any history of smoking; include the number of years smoked and the number of packages smoked per day. This is recorded as pack-year history (packages per day × years smoked). For example, if a patient smoked two packs a day for 20 years, the patient has a 40 pack-year history. Determine exposure to second-hand smoke, because any form of tobacco exposure increases a patient's risk for cardiopulmonary diseases.

Respiratory Infections. Obtain information about a patient's frequency and duration of respiratory tract infections. Although everyone occasionally has a cold, for some people it results in bronchitis or pneumonia. On average patients have four colds per year. Determine

if and when a patient has had a pneumococcal or influenza (flu) vaccine. This is especially important when assessing older adults because of their increased risk for respiratory disease (Touhy and Jett, 2014). Ask about any known exposure to tuberculosis (TB) and the date and results of the last tuberculin skin test.

Determine a patient's risk for human immunodeficiency virus (HIV) infection. Patients with a history of intravenous (IV) drug use and multiple unprotected sex partners are at risk of developing HIV infection. Patients do not always display symptoms of HIV infection until they present with *Pneumocystis carinii* pneumonia (PCP) or *Mycoplasma* pneumonia.

Allergies. Inquire about your patient's exposure to airborne allergens (e.g., pet dander or mold). The allergic response is often watery eyes, sneezing, runny nose, or respiratory symptoms such as cough or wheezing. When obtaining information, ask specific questions about the type of allergens, response to these allergens, and successful and unsuccessful relief measures. In addition, determine the effect of environmental air quality and secondhand smoke exposure on the patient's allergy and symptoms.

Safe nursing practice also includes obtaining information about food, drug, or insect sting allergies on the initial history and physical. However, always double-check this information with the patient on any subsequent assessment, especially concerning respiratory allergens.

Health Risks. Determine familial risk factors such as a family history of lung cancer or cardiovascular disease. Documentation includes blood relatives who had cardiopulmonary disease and their present level of health or age at time of death. Other family risk factors include the presence of infectious diseases, particularly TB.

Medications. Another component of the nursing history describes all medications that a patient is using. These include prescribed medications, over-the-counter medications, folk medicine, herbal medicines, alternative therapies, and illicit drugs and substances. Some of these preparations have adverse effects by themselves or because of interactions with other drugs. For example, a person using a prescribed bronchodilator drug decides to use an over-the-counter inhalant as well. Many of these contain ephedrine or *ma huang,* a natural ephedrine, which acts like epinephrine. This product reacts with the prescribed medication by potentiating or decreasing the effect of the prescribed medication. Patients taking warfarin (Coumadin) for blood thinning prolong the prothrombin time (PT)/international normalized ratio (INR) results if they are taking gingko biloba, garlic, or ginseng with the anticoagulant. The drug interaction can precipitate a life-threatening bleed.

It is important to determine if a patient uses illicit drugs. Illicit drugs, particularly inhaled opioids, which are often diluted with talcum powder, cause pulmonary disorders resulting from the irritant effect of the powder on lung tissues. Marijuana is usually smoked in the form of a joint or pipe. Marijuana smoke contains carcinogens and is an irritant to the lungs, putting users at higher risk for lung cancer and respiratory illnesses (NIDA, 2014). Cocaine is snorted through the nose, smoked, or injected. Cocaine abusers can have acute cardiovascular changes such as constricted blood vessels and increased heart rate and blood pressure, which increases the risk for heart attack or stroke. Cocaine deaths are caused by cardiac arrest and respiratory failure (NIDA, 2013).

As with all medications, assess the patient's knowledge and ability to self-administer medications correctly (see Chapter 32). Of particular importance is the assessment that the patient understands the potential side effects of medications. Patients need to recognize adverse reactions and be aware of the dangers in combining prescribed medications with over-the-counter drugs.

TABLE 41-1 Effects of Aging on Assessment Findings of the Cardiopulmonary System

Function	Pathophysiological Change	Key Clinical Findings
Heart		
Muscle contraction	Thickening of the ventricular wall, increased collagen and decreased elastin in the heart muscle	Decreased cardiac output Diminished cardiac reserve
Blood flow	Heart valves become thicker and stiffer, more often in the mitral and aortic valves	Systolic murmur
Conduction system	SA node becomes fibrotic from calcification; decrease of number of pacemaker cells in SA node	Increased PR, QRS, and Q-T intervals, decreased amplitude of QRS complex Irregular heart rhythm
Arterial vessel compliance	Calcified vessels, loss of arterial distensibility, decreased elastin in vessel walls, more tortuous vessels	Hypertension with an increase in systolic blood pressure.
Lungs		
Breathing mechanics	Decreased chest wall compliance, loss of elastic recoil Decreased respiratory muscle mass/strength	Prolonged exhalation phase Decreased vital capacity
Oxygenation	Increased ventilation/perfusion mismatch Decreased alveolar surface area Decreased carbon dioxide diffusion capacity	Decreased PaO_2 Decreased cardiac output Slightly increased $PaCO_2$
Breathing control/breathing pattern	Decreased responsiveness of central and peripheral chemoreceptors to hypoxemia and hypercapnia	Increased respiratory rate Decreased tidal volume
Lung defense mechanisms	Decreased number of cilia Decreased IgA production and humoral and cellular immunity	Decreased airway clearance Diminished cough reflex Increased risk for infection
Sleep and breathing	Decreased respiratory drive Decreased tone of upper airway muscles	Increased risk of aspiration and respiratory infection Decreased PaO_2 Snoring, obstructive sleep apnea

IgA, Immunoglobulin A; *PaCO₂,* arterial carbon dioxide tension; *PaO₂,* arterial oxygen tension; SA, sinoatrial.

Physical Examination. The physical examination includes assessment of the cardiopulmonary system (see Chapter 31). Give special consideration when assessing an older adult patient for changes that occur with the aging process (Table 41-1). These changes affect the patient's activity tolerance and level of fatigue or cause transient

TABLE 41-2　Inspection of Cardiopulmonary Status

Abnormality	Cause
Eyes	
Xanthelasma (yellow lipid lesions on eyelids)	Hyperlipidemia
Corneal arcus (whitish opaque ring around junction of cornea and sclera)	Abnormal finding in young to middle-age adults with hyperlipidemia (normal finding in older adults with arcus senilis)
Pale conjunctivae	Anemia
Cyanotic conjunctivae	Hypoxemia
Petechiae on conjunctivae	Fat embolus or bacterial endocarditis
Mouth and Lips	
Cyanotic mucous membranes	Decreased oxygenation (hypoxia)
Pursed-lip breathing	Associated with chronic lung disease
Neck Veins	
Distention	Associated with right-sided heart failure
Nose	
Flaring nares	Air hunger, dyspnea
Chest	
Retractions	Increased work of breathing, dyspnea
Asymmetry	Chest wall injury
Skin	
Peripheral cyanosis	Vasoconstriction and diminished blood flow
Central cyanosis	Hypoxemia
Decreased skin turgor	Dehydration (normal finding in older adults as a result of decreased skin elasticity)
Dependent edema	Associated with right- and left-sided heart failure
Periorbital edema	Associated with kidney disease
Fingertips and Nail Beds	
Cyanosis	Decreased cardiac output or hypoxia
Splinter hemorrhages	Bacterial endocarditis
Clubbing	Chronic hypoxemia

From Ball JW et al: *Seidel's Physical examination handbook,* ed 8, St Louis, 2015, Elsevier.

changes in vital signs and are not always associated with a specific cardiopulmonary disease.

Inspection. Using inspection techniques, perform a head-to-toe observation of the patient for skin and mucous membrane color, general appearance, level of consciousness, adequacy of systemic circulation, breathing patterns, and chest wall movement (Table 41-2). Investigate any abnormalities further during palpation, percussion, and auscultation.

Inspection includes observations of the nails for clubbing (see Chapter 31). Clubbed nails often occur in patients with prolonged oxygen deficiency, endocarditis, and congenital heart defects.

Observe chest wall movement for retraction (e.g., sinking in of soft tissues of the chest between the intercostal spaces) and use of accessory muscles. Elevation of a patient's clavicles reveals increased work of breathing. Also observe the patient's breathing pattern and assess for paradoxical breathing (the chest wall contracts during inspiration and expands during exhalation) or asynchronous breathing. At rest the normal adult rate is 12 to 20 regular breaths/min. Bradypnea is less than 12 breaths/min, and tachypnea is greater than 20 breaths/min (see Chapter 30). In some conditions, such as metabolic acidosis, the acidic pH stimulates an increase in rate, usually greater than 35 breaths/min, and depth of respirations (**Kussmaul respiration**) to compensate by decreasing carbon dioxide levels. **Apnea** is the absence of respirations lasting for 15 seconds or longer. **Cheyne-Stokes respiration** occurs when there is decreased blood flow or injury to the brainstem. This is an abnormal respiratory pattern with periods of apnea followed by periods of deep breathing and then shallow breathing followed by more apnea (McCance and Huether, 2014). Also note the shape of the chest wall. Conditions such as emphysema, advancing age, and COPD cause the chest to assume a rounded "barrel" shape.

Palpation. Palpation of the chest provides assessment data in several areas. It documents the type and amount of thoracic excursion; elicits any areas of tenderness; and helps to identify tactile fremitus, thrills, heaves, and the cardiac point of maximal impulse (PMI). Palpation of the extremities provides data about the peripheral circulation (e.g., the presence and quality of peripheral pulses, skin temperature, color, and capillary refill) (see Chapter 31).

Palpation of the feet and legs determines the presence or absence of peripheral edema. Patients with alterations in cardiac function such as those with heart failure or hypertension often have pedal or lower-extremity edema. Edema is graded from 1+ to 4+ depending on the depth of visible indentation after firm finger pressure (see Chapter 31).

Palpate the pulses in the neck and extremities to assess arterial blood flow (see Chapter 31). Use a scale of 0 (absent pulse) to 4 (full, bounding pulse) to describe what you feel. The normal pulse is 2; and a weak, thready pulse is 1.

Percussion. Percussion detects the presence of abnormal fluid or air in the lungs. It also determines diaphragmatic excursion.

Auscultation. Auscultation helps identify normal and abnormal heart and lung sounds (see Chapter 31). Auscultation of the cardiovascular system includes assessment for normal S_1 and S_2 sounds and the presence of abnormal S_3 and S_4 sounds (gallops), murmurs, or rubs. Identify the location, intensity, pitch, and quality of a murmur. Auscultation also identifies any bruit over the carotid, abdominal aorta, and femoral arteries.

Auscultation of lung sounds involves listening for movement of air throughout all lung fields: anterior, posterior, and lateral. Adventitious, or abnormal, breath sounds occur with collapse of a lung segment, fluid in a lung segment, or narrowing or obstruction of an airway.

Diagnostic Tests. A variety of diagnostic tests monitor cardiopulmonary functioning. Some of these screening tests involve simple blood specimens, x-ray films, or other noninvasive means. One screening mechanism is TB skin testing (Box 41-3). This is a simple test and is required for health care workers; restaurant employees; students on entry to school, teachers, and other school employees; prisoners and correctional facility employees; and residents of long-term care facilities (CDC, 2014a, 2014b).

Diagnostic testing used in the assessment and evaluation of the patient with cardiopulmonary alterations is summarized in Tables 41-3 through 41-5. When reviewing results of pulmonary function studies, be aware of expected variations in patients from different cultures.

BOX 41-3 Tuberculosis Skin Testing

- Skin testing determines whether a person is infected with *Mycobacterium tuberculosis*.
- Tuberculosis (TB) skin testing (TST) is performed by an intradermal injection of 0.1 mL of tuberculin purified protein derivative (PPD) on the inner surface of the forearm (see Chapter 32). The injection produces a pale elevation of the skin (a wheal) 6 to 10 mm in diameter. Afterward the injection site is circled, and the patient is instructed not to wash the circle off.
- Read tuberculin skin tests between 48 to 72 hours after the test. If the site is not read within 72 hours, a patient must have another skin test.
- *Positive results:* A palpable, elevated, hardened area around the injection site, caused by edema and inflammation from the antigen-antibody reaction, measured in millimeters. (See Chapter 32 for evaluation of positive results by millimeters.) People born outside the United States may have had bacille Calmette-Guérin (BCG) vaccine for TB disease, which results in a positive reaction to the TST and may complicate the treatment plan. The positive skin reaction does not indicate that the BCG vaccine provided protection against the disease (CDC, 2014e).
- Reddened flat areas are *not* positive reactions and are not measured.
- TST is less reliable in older adults (see Box 41-1) and those with an altered immune function such as a human immunodeficiency virus (HIV)–positive patient or someone receiving chemotherapy.

TABLE 41-3 Cardiopulmonary Diagnostic Blood Studies

Test and Normal Values	Interpretation
Complete Blood Count Normal values for a complete blood count (CBC) vary with age and gender	A CBC determines the number and type of red and white blood cells per cubic millimeter of blood.
Cardiac Enzymes *Creatine kinase (CK):* A serial CK with 50% increase between two samples 3-6 hours apart, peaking 12-24 hours after chest pain or a single CK elevation twofold is diagnostic for an acute myocardial infarction. Male normal: 55-170 units/L; female normal: 30-135 units/L	Providers use cardiac enzymes to diagnose acute myocardial infarcts.
Cardiac Troponins Plasma cardiac troponin I <0.03 ng/mL	Value elevates as early as 3 hours after myocardial injury. Value often remains elevated for 7-10 days.
Plasma cardiac troponin T <0.1 ng/mL	Value often remains elevated for 10-14 days.
Serum Electrolytes Potassium (K^+) 3.5-5 mEq/L or 3.5-5 mmol/L	Patients on diuretic therapy are at risk for hypokalemia (low potassium). Patients receiving angiotensin-converting enzyme (ACE) inhibitors are at risk for hyperkalemia (elevated potassium).
Cholesterol Fasting cholesterol less than 200 mg/dL or less than 5.2 mmol/L (SI units)	Contributing factors include sedentary lifestyle with intake of saturated fatty acids, familial hypercholesterolemia.
Low-density lipoproteins (LDLs) (bad cholesterol) <130 mg/dL Very low–density lipoproteins (VLDLs) 7-32 mg/dl	High LDL cholesterol (hypercholesterolemia) is caused by excessive intake of saturated fatty acids, dietary cholesterol intake, and obesity. Familial hypercholesterolemia and hyperlipidemia, hypothyroidism, nephrotic syndrome, and diabetes mellitus are also contributing factors. VLDLs are predominant carriers of triglycerides and can be converted to LDL by lipoprotein lipase. Levels in excess of 25%-50% indicate increased risk of cardiac disease.
High-density lipoproteins (HDLs) (good cholesterol) Male: >45 mg/dL; female: >55 mg/dL	Factors such as cigarette smoking, obesity, lack of regular exercise, beta-adrenergic blocking agents, genetic disorders of HDL metabolism, hypertriglyceridemia, and type 2 diabetes cause low HDL cholesterol.
Triglycerides Male: 40-160 mg/dL; female: 35-135 mg/dL	Obesity, excessive alcohol intake, diabetes mellitus, beta-adrenergic blocking agents, and familial hypertriglyceridemia cause hypertriglyceridemia.
Additional Tests Brain natriuretic peptide <100 pg/mL	Increased levels may be used to help determine severity of congestive heart failure.
C-reactive protein <0.1/dL or <10 mg/L	Test used by clinicians to detect inflammation if there is a high suspicion of tissue injury or infection somewhere in the body. It can also be used to evaluate a patient's risk of developing coronary artery disease and stroke.

Data from Pagana KD et al: *Mosby's diagnostic and laboratory test reference,* ed 12, St Louis, 2015, Mosby.

TABLE 41-4	Cardiac Function Diagnostic Tests
Test	**Significance**
Holter monitor	Portable ECG worn by a patient. The test produces a continuous ECG tracing over a period of time. Patients keep a diary of activity, noting when they experience rapid heartbeats or dizziness. Evaluation of the ECG recording along with the diary provides information about the electrical activity of the heart during activities of daily living.
ECG exercise stress test	ECG is monitored while a patient walks on a treadmill at a specified speed and duration of time. Test evaluates the cardiac response to physical stress. It is not a valuable tool for evaluation of cardiac response in women because of an increased false-positive finding.
Thallium stress test	ECG stress test with the addition of thallium-201 injected intravenously. It determines coronary blood flow changes with increased activity.
Electrophysiological study (EPS)	EPS is an invasive measure of intracardiac electrical pathways. It provides more specific information about difficult-to-treat dysrhythmias and assesses adequacy of antidysrhythmic medication.
Echocardiography	This is a noninvasive measure of heart structure and heart wall motion. It graphically demonstrates overall cardiac performance.
Scintigraphy	Scintigraphy is radionuclide angiography; used to evaluate cardiac structure, myocardial perfusion, and contractility.
Cardiac catheterization and angiography	These are used to visualize cardiac chambers, valves, the great vessels, and coronary arteries. Pressures and volumes within the four chambers of the heart are also measured.

Data from Pagana KD et al: *Mosby's diagnostic and laboratory test reference,* ed 12, St Louis, 2015, Mosby.
ECG, Electrocardiogram.

These changes are caused by structural variations in chest wall size (Box 41-4).

Invasive diagnostic tests such as a thoracentesis are painful. How painful a diagnostic procedure is depends on the patient's tolerance for pain (see Chapter 44). Reduce the patient's anxiety by explaining the thoracentesis procedure and telling him or her what to expect. Be sure that he or she understands the importance of following instructions such as taking a deep breath and holding it when requested and not coughing during the procedure. Provide appropriate pain management 30 to 60 minutes before the procedure to reduce the perception of pain. After any procedure monitor the patient for signs of changes in cardiopulmonary functioning such as sudden shortness of breath, pain, oxygen desaturation, and anxiety.

◆ **Nursing Diagnosis**

Based upon your assessment, you develop nursing diagnoses for patients with oxygenation alterations by clustering specific defining characteristics and identifying the related etiology (Box 41-5). The defining characteristics for diagnoses related to oxygenation can be similar. For example, both *Impaired Gas Exchange* and *Ineffective Breathing Pattern* have the defining characteristics of dyspnea and nasal flaring. A closer review of assessment findings as well as an analysis of the patient's history will help you clarify and select the correct diagnosis. For example, a patient who is a victim of trauma and has rib pain and is showing an increased respiratory rate is more likely to be suffering *Ineffective Breathing Pattern*. The clustered defining characteristics and related factor will support a problem nursing diagnosis. The clustering of risk factors will support a risk nursing diagnosis.

These nursing diagnosis examples are appropriate for the patient with alterations in oxygenation:

- *Activity Intolerance*
- *Decreased Cardiac Output*
- *Fatigue*
- *Impaired Gas Exchange*
- *Impaired Verbal Communication*
- *Ineffective Airway Clearance*
- *Ineffective Breathing Pattern*
- *Risk for Aspiration*

⊕ BOX 41-4   CULTURAL ASPECTS OF CARE

Cultural Impact on Pulmonary Diseases

The impact of pulmonary diseases on patients and their families varies among cultures. It is important to understand these variations in terms of assessing for and providing care in patients with lung diseases. In 2010, 84% of all TB reported cases occurred in racial and ethnic minorities (CDC, 2013a). Major countries of origin for foreign-born TB cases are the Philippines, Vietnam, India, and China (American Lung Association, 2010).

The cigarette smoking prevalence rate in America's youth is highest in Alaskan Natives (23.1%), followed by Caucasians (14.9%), Hispanics (9.3%), African-Americans (6.5%), and Asian Americans (4.3%). This puts them at risk for lung cancer, chronic obstructive pulmonary disease (COPD), and heart disease. African-Americans have higher mortality rates from lung cancer despite the lower smoking prevalence (American Lung Association, 2010).

Immigrant families are more likely to live in urban areas, which have high level of toxins and heavy vehicle traffic. Air pollution has been linked to cancer, asthma, and heart disease. African-American women have the highest mortality rates from asthma among all ethnic/gender groups (American Lung Association, 2010). A recent report on health care disparities found that Asian Americans over the age of 65 had the highest rates of never having received a pneumococcal vaccine, which explains why influenza and pneumonia are the fourth leading cause of death in this group (American Lung Association, 2010). Community Health Departments need to target these groups during education programs for their flu and pneumonia vaccine clinics.

Implications for Patient-Centered Care

- If your patients are foreign born, ask if they have had the bacille Calmette-Guérin (BCG) vaccine, which can cause a positive reaction to the TB skin test.
- Immunization clinics should concentrate on the underserved urban communities, especially those with large numbers of older adults. Provide TB skin testing, flu vaccines, pneumonia vaccines as needed.
- Community Health Departments need to target at risk population for flu and pneumonia vaccine clinics.
- Public health programs for those at highest risk for pulmonary diseases should focus on pollution prevention, immunizations, and smoking cessation programs.

TABLE 41-5   Ventilation and Oxygenation Diagnostic Studies

Measurement and Normal Values	Interpretation/Purpose
Arterial Blood Gases pH 7.35-7.45 PCO_2 35-45 mm Hg HCO_3 21-28 mEq/L PO_2 80-100 mm Hg SaO_2 saturation 95%-100% Older adult: 95% Base excess 0 ± 2 mEq/L	Provides important information for assessment of patient's respiratory and metabolic acid/base balance and adequacy of oxygenation (see Chapter 42)
Pulmonary Function Tests Basic ventilation studies (Pulmonary functions vary by ethnic group.)	Determines ability of the lungs to efficiently exchange oxygen and carbon dioxide Used to differentiate pulmonary obstructive from restrictive disease
Peak Expiratory Flow Rate (PEFR) The point of highest flow during maximal expiration (Normal in adults is based on age and body weight.)	Reflects changes in large airway sizes; an excellent predictor of overall airway resistance in a patient with asthma Daily measurement for early detection of asthma exacerbations
Bronchoscopy Normal airways without masses, pus, or foreign bodies	Visual examination of the tracheobronchial tree through a narrow, flexible fiberoptic bronchoscope Performed to obtain fluid, sputum, or biopsy samples; remove mucus plugs or foreign bodies
Lung Scan Normal lung structure without masses	Nuclear scanning test used to identify abnormal masses by size and location Identification of masses used in planning therapy and treatments Also used to find a blood clot preventing normal perfusion or ventilation ($\dot{V}/\dot{Q}$ scan)
Thoracentesis Surgical perforation of chest wall and pleural space with a needle to aspirate fluid for diagnostic or therapeutic purposes or to remove a specimen for biopsy; performed using aseptic technique and local anesthetic (Patient usually sits upright with the anterior thorax supported by pillows or an over-bed table.)	Specimen of plural fluid obtained for cytological examination Results may indicate an infection or neoplastic disease Identification of infection or a type of cancer important in determining a plan of care
Sputum Specimens Normal: negative	Nasal aspirate/swabs for respiratory syncytial virus, influenza
Sputum culture and sensitivity	Obtained to identify a specific microorganism or organism growing in sputum Identifies drug resistance and sensitivities to determine appropriate antibiotic therapy
Sputum for acid-fast bacillus (AFB)	Screens for presence of AFB for detection of tuberculosis by early-morning specimens on 3 consecutive days
Sputum for cytology	Obtained to identify lung cancer Differentiates type of cancer cells (small cell, oat cell, large cell)

Data from Pagana KD et al: *Mosby's diagnostic and laboratory test reference,* ed 12, St Louis, 2015, Mosby.

◆ **Planning**

During planning, use critical thinking skills to synthesize information from multiple sources (Figure 41-7). Critical thinking ensures that your plan of care integrates individualized patient needs. Professional standards are especially important to consider when developing a plan of care. These standards often establish scientifically proven guidelines for selecting effective nursing interventions.

Goals and Outcomes.   Develop an individualized plan of care for each nursing diagnosis (see the Nursing Care Plan). Together with your patient set realistic expectations, goals, and measurable outcomes of care.

Patients with impaired oxygenation require a nursing care plan directed toward meeting actual or potential oxygenation needs. Allow patients to collaborate in setting relevant goals of care. Develop individual outcomes based on patient-centered goals. For example, for the goal of maintaining a patent airway, select specific expected outcomes for the patient, such as the following:
- Patient's lungs are clear to auscultation.
- Patient achieves bilateral lung expansion.

BOX 41-5   Nursing Diagnostic Process

Impaired Gas Exchange Related to Decreased Lung Expansion

Assessment Activities	Defining Characteristics
Ask patient or family about patient's mood, attentiveness, memory, and activity level.	Confusion Decreased activity Fatigue Irritability Restlessness Sleepiness
Observe patient's respirations for rate, rhythm, depth.	Dyspnea Nasal flaring Tachypnea Use of accessory muscles
Inspect skin and mucous membranes.	Diaphoresis Pallor Cyanosis
Auscultate chest.	Decreased respiratory excursion Abnormal, distant lung sounds

• Patient coughs productively.
• Pulse oximetry (SpO_2) is maintained or improved.

Often a patient with cardiopulmonary disease has multiple nursing diagnoses (Figure 41-8). In this case identify when goals or outcomes apply to more than one diagnosis. The presence of multiple diagnoses also makes priority setting a critical activity.

Setting Priorities. A patient's level of health, age, lifestyle, and environmental risks affect the level of tissue oxygenation. Patients with severe impairments in oxygenation frequently require nursing interventions in multiple areas. Consider which goal is the most important to achieve while the patient is in the hospital or primary care setting. For example, in an acute care setting maintaining a patent airway has a higher priority than improving the patient's exercise tolerance. The need for a patent airway is immediate; and, as the patient's level of oxygen improves, activity tolerance increases. In a second example, when caring for a patient who has an abdominal incision, pain control is a priority. In this situation controlling the patient's pain facilitates coughing and deep breathing and activity.

However, in a community-based or primary care setting, priorities often focus on smoking cessation, exercise, and/or diet modifications. Both you and the patient need to focus on the same goal and expected outcomes. In addition to individualizing each goal, be sure that the goals are realistic, have a reasonable time frame, and are attainable for the patient. In addition, be sure to respect the patient's preferences for his or her degree of active engagement in the care process. Some will choose to be very active and desire to make day-to-day decisions. Others may choose to assume a more passive role, preferring you to choose a course of action while keeping them informed.

Teamwork and Collaboration. The time spent with a patient in any setting is limited. Therefore collaborate with family members, colleagues, and other health care specialists to achieve the established goals and expected outcomes. Some patients need to improve their exercise and activity tolerance; for other patients continuing care involves participating in a community-based cardiopulmonary rehabilitation program. Finally, some patients need home physical therapy.

Knowledge
• Role of other health care professionals in caring for the patient with impaired oxygenation
• Role of community support groups in assisting the patient to manage cardiopulmonary disease
• Knowledge of effects of pulmonary interventions
• Patient-centered care principles for involving patient in plan of care

Experience
• Previous patient responses to planned nursing therapies for impaired oxygenation

PLANNING
• Select nursing interventions that promote optimal oxygenation in the primary care, acute care, or restorative and continuing care setting
• Consult with other health care professionals as needed
• Involve the patient and family in making decisions for developing a plan of care

Standards
• Individualize therapies to patient's needs
• Apply established pulmonary and cardiac rehabilitation guidelines
• Apply established nursing care guidelines for care of the patient with cardiopulmonary disease (e.g., protocols, care paths)

Attitudes
• Display confidence when selecting interventions
• Use creativity when developing home care strategies for the patient's disease management
• Demonstrate responsibility and accountability when delegating care for patient

FIGURE 41-7 Critical thinking model for oxygenation planning.

Collaboration with physical therapists, nutritionists, and community-based nurses is valuable for patients with heart failure or chronic lung conditions. These professionals work with patients and use resources in the community to assist them in attaining and maintaining the highest possible level of wellness. In addition, professionals identify community resources and support systems for both the patient and family in preventing and managing symptoms related to cardiopulmonary diseases. Communicating among everyone on the patient's health care team and recognizing everyone's contributions in achieving the health care goals for the patient are imperative.

◆ Implementation

There are interventions for promoting and maintaining adequate oxygenation across the continuum of care. As a nurse, you will be responsible for independent interventions such as positioning, coughing techniques, and health education for disease prevention. In addition, you will provide physician-initiated interventions such as oxygen therapy, lung inflation techniques, and chest physiotherapy.

Health Promotion. Maintaining a patient's optimal level of health is important in reducing the number and/or severity of

◎ NURSING CARE PLAN

Ineffective Airway Clearance

ASSESSMENT

Mr. Edwards is a 75-year-old currently lying in a semi-Fowler's position in bed talking with his wife. Kathy Allen is a nursing student completing a respiratory assessment. Mr. Edwards has a history of chronic obstructive pulmonary disease for 2 years. He continues to smoke ½ pack of cigarettes a day and does not participate in any exercise. He does not "see any reason" to increase his fluid intake. His SpO_2 ranges from 78% to 84%. On ambulation is SpO_2 falls to 78%-80%. He must do his self-care activities slowly because of fatigue. Presently he is admitted for right upper lobe pneumonia. He reports having an intermittent productive cough that occasionally produces thick, yellow sputum. He has more episodes of coughing when lying flat. His vital signs are temperature, 101.4° F (38.5° C); pulse, 102 beats/min; respirations, 30 breaths/min; blood pressure, 130/90 mm Hg; and SpO_2, 84%. He has episodes of chilling and diaphoresis. His health care provider has told him that, if he gradually increases his exercise, drinks more fluids, and stops smoking, his respiratory status will improve.

Assessment Activities	Findings/Defining Characteristics*
Ask Mr. Edwards how long he has had this cough.	He replies, "I have a morning **cough** every day, but this cough is different. It started about a week ago. It is **worse when I lie flat**."
Ask Mr. Edwards what is different about this cough.	He replies, "My ribs are getting sore. It is difficult to cough up anything, my **mouth** is **dry**, and I have become more **fatigued**."
Observe Mr. Edwards' skin and mucous membranes.	**Skin and mucous membranes** are **dry.**
Auscultate lung fields.	**Abnormal lung sounds** (crackles) are heard in the right upper lobe and left and right lower lobes.
Ask Mr. Edwards to produce a sputum sample.	Sputum is **thick** and **discolored** yellow to yellow-green and difficult to cough up and expectorate.

***Defining characteristics** are shown in bold type.

NURSING DIAGNOSIS: Ineffective airway clearance related to retained thick pulmonary secretions

PLANNING

Goals	Expected Outcomes (NOC)†
	Respiratory Status: Airway Patency
Mr. Edwards will be able to effectively clear secretions by discharge.	Lung sounds will improve in 48 hours.
	Mr. Edwards will notice increased ease in coughing within 48 hours.
	Sputum will be thin and white within 3 days.
	Respiratory rate will be within 12 to 20 breaths/min in 48 hours.
Mr. Edwards will increase oral hydration within 48 hours.	Mr. Edwards will drink 2500 mL of water or preferred liquids every 24 hours starting today.
	Mr. Edwards will verbalize that his mouth is not dry in 48 hours.

†Outcome classification labels from Moorhead S et al.: *Nursing outcomes classification (NOC),* ed 5, St Louis, 2013, Elsevier.

INTERVENTIONS (NIC)‡	RATIONALE
Airway Management	
Position Mr. Edwards with head elevated at least 45 degrees.	Maintaining a semi-Fowler's position allows for thoracic expansion. This position prevents the abdominal organs from pushing up against the diaphragm, compromising inspiration. This position improves respiratory gas exchange.
Ambulate in room or hall as tolerated at least 2 times a day. If unable to ambulate, reposition from side to side every 2 hours or more.	Body movement helps patients take bigger breaths, increasing their tidal volume and preventing atelectasis (Atkins and Kautz, 2014).
Have Mr. Edwards deep breathe and cough every hour. Teach him to take a deep breath, hold it for several seconds, open his mouth, tighten his abdominal muscles, and cough 2 to 3 times with his mouth open.	Retained secretions predispose patient to atelectasis and pneumonia. Controlled coughing improves effectiveness of cough and removal of airway secretions (AARC, 1993, 2011, Borge et al., 2014).
Increase fluids to 2500 mL in 24 hours if not contraindicated by cardiac or renal status. Offer fluids Mr. Edwards prefers.	Fluids help may help promote secretion removal and relieve oral mucosa and skin dryness (Hong et al., 2013).

‡Intervention classification labels from Bulechek GM et al: *Nursing interventions classification (NIC),* ed 6, St Louis, 2013, Elsevier.

EVALUATION

Nursing Actions	Patient Response/Finding	Achievement of Outcome
Auscultate the chest.	Lung sounds are clear in left lung, crackles present in right lower lobe.	Improving lung sounds
Ask Mr. Edwards if he can deep breathe and cough. Measure SpO_2.	Mr. Edwards reports that it is easier to cough up his secretions. SpO_2 is 95%.	Airway clears with coughing. SpO_2 is within normal levels.
Observe sputum.	"Sputum is thinner and white."	Sputum is thin and white.
Monitor respiratory rate.	Rate is between 12 and 20 breaths/min.	Mr. Edwards verifies it is easier to breathe.
Assess Mr. Edwards' level of hydration: Assess skin turgor and observe oral mucosa and calculate 20 hour fluid intake.	Skin turgor is normal. Mucous membranes are moist. Fluid intake in previous 24 hours was 2600 mL.	Oral membranes are pink and moist. Minimum fluid intake of 2500 mL was achieved.

CONCEPT MAP

Nursing diagnosis: Risk for imbalanced body temperature
- Elevated body temperature >101° F (38.3° C)
- Chills
- Diaphoresis

Interventions
- Administer ordered antipyretic
- Reduce excessive bedding
- Provide oral fluids
- Administer ordered IV antibiotics

Nursing diagnosis: Impaired gas exchange related to pulmonary secretions
- Dyspnea, respiratory rate >30 breaths/min
- Decreased SpO_2 74%—84%
- Tachycardia
- Abnormal lung sounds in right upper and both lower lobes
- Decreased diaphragmatic excursion

Interventions
- Administer 2 L/min of O_2 via nasal cannula
- Encourage patient to cough and deep breathe every hour
- Position in high Fowler's position

Primary health problem: Chronic obstructive pulmonary disease and pneumonia
Priority assessments: Respiratory rate and depth, breath sounds, oxygen saturation level, arterial blood gases, color, accessory muscle use, activity tolerance

Nursing diagnosis: Fatigue related to decreased oxygenation
- Unable to complete hygiene activities
- Decreased activity tolerance on ambulation
- SpO_2 <80% with ambulation/activity

Interventions
- Pace hygiene activities
- Provide frequent rest periods
- Encourage progressive ambulation

Nursing diagnosis: Ineffective airway clearance related to retained thick pulmonary secretions
- Abnormal lung sounds in both lobes
- Dyspnea
- Thick, yellow sputum
- Coughs with difficulty

Interventions
- Teach cascade cough
- Increase fluids
- Encourage patient to cough and deep breathe every hour
- Nasotracheal suction

——— Link between medical diagnosis and nursing diagnosis   - - - - - Link between nursing diagnoses

FIGURE 41-8 Concept map for Mr. Edwards.

respiratory symptoms. Prevention of respiratory infections is foremost in maintaining optimal health. Providing cardiopulmonary-related health information (Box 41-6) is an important nursing responsibility.

The health information that your patients and their families bring to the situation varies. Some patients have a lot of exposure to health care information and understand their treatment plans. Other families might have a lot of exposure to health care information but are unable to understand and follow treatment plans. Last, you might encounter families who are experiencing their first exposure to health care information and are very unsure of their interpretation of the information. When providing health information, be sure that the patient's health literacy levels are assessed and addressed through individualized patient education sessions (see Chapter 25).

Vaccinations. Annual flu vaccines are recommended for all people 6 months and older (CDC, 2014e). Patients with chronic illnesses (heart, lung, kidney, or immunocompromised), infants, older adults, and pregnant women can get very sick; thus they should be immunized (CDC, 2014g). Close contacts of infants under 6 months should also be immunized. Seasonal flu vaccine protects against influenza viruses that research indicates will be the most common during that year. The vaccine is also recommended for people in close or frequent contact with anyone in the high-risk groups. It is effective in reducing the severity of illness and the risk of serious complications and death. Researchers do not fully understand the value of vaccination in immune-compromised patients. HIV-positive patients receive the flu vaccine; however, they often require a second vaccine to gain protection. It is important to assess patient's allergies and any allergic response

BOX 41-6 PATIENT TEACHING

Prevention of Recurrent Respiratory Infections

Objective
- The patient will be able to verbalize the methods to reduce the risk factors for recurring respiratory infections.

Teaching Strategies
- Assess the patient's health literacy, educational background, reading level, and cultural preferences to determine appropriate educational approaches.
- Communicate with patient and family to identify collaborative goals for reducing risk factors.
- Explain the link between smoking and increase risk for respiratory infections (CDC, 2014c).
- Refer to smoking cessation programs and discuss appropriate medication to support smoking cessation from the primary health provider (ACS, 2014b).
- If a patient does not smoke, teach the importance of avoiding secondhand smoke and areas of high air pollution.
- Instruct patient and family about appropriate hand hygiene techniques to reduce transmission of microorganisms.
- Explain to patient and family why annual influenza vaccines and appropriate pneumonia vaccines are needed (CDC, 2014c, e, g).
- Instruct patient and family about signs and symptoms of respiratory infection that should be reported to health care provider such as increased coughing, shortness of breath, change of color of sputum, fever, and fatigue.

Evaluation
- Ask patient to state benefits of smoking cessation and the risks for secondhand smoke.
- Ask patient about plans for flu and pneumonia vaccines.
- Ask patient to describe in simple terms the symptoms of respiratory infection and when to call the health care provider.

to vaccines or any components. People with a known hypersensitivity to eggs or other components of the vaccine should consult their physician before being vaccinated. There is a flu vaccine made without egg proteins that is approved for adults 18 years of age and older (Li, 2013). Adults with an acute febrile illness should schedule the vaccination after they have recovered. The vaccines are formulated annually based on worldwide surveillance data. The live, attenuated nasal spray vaccine is given to people from 2 through 49 years of age if they are not pregnant or do not have certain long-term health problems such as asthma; heart, lung or kidney disease; diabetes; or anemia. The inactivated flu vaccine should be given to these individuals and those 50 and older (CDC, 2014e).

Pneumococcal vaccine (PCV13) is routinely given to infants in a series of four doses and is recommended for patients at increased risk of developing pneumonia. This includes all adults over 65 years of age, those with chronic illnesses or who are immunocompromised (such as HIV/AIDS), any adult who smokes or has asthma, and those living in special environments such as nursing homes or long-term care facilities (CDC, 2013c).

Healthy Lifestyle. Identification and elimination of risk factors for cardiopulmonary disease are important parts of primary care. Encourage patients to eat a healthy low-fat, high-fiber diet; monitor their cholesterol, triglyceride, high-density lipoprotein (HDL), and low-density lipoprotein (LDL) levels; reduce stress; exercise; and maintain a body weight in proportion to their height. Eliminating cigarettes

and other tobacco, reducing exposure to pollutants, monitoring air quality, and adequately hydrating are additional healthy behaviors. Encourage patients to examine their habits and make appropriate changes. Patients with cardiopulmonary alterations need to minimize their risk for infection, especially during the winter months (see Box 41-6).

Exercise is a key factor in promoting and maintaining a healthy heart and lungs. Encourage patients to exercise at least 3 to 4 times a week for 30 to 60 minutes. Aerobic exercise is necessary to improve lung and heart function and strengthen muscles. Walking is an efficient way to achieve a good aerobic workout. Many shopping malls have programs allowing people to walk in the enclosed mall before the shops open. During the hot summer months teach patients to limit activities to early in the day or late in the evening, when temperatures are lower. Teach them how to maintain adequate hydration and sodium intake, especially if they are taking diuretics. Patients with known cardiac disease and those with multiple risk factors are cautioned to avoid exertion in cold weather. Shoveling snow is especially risky and often precipitates a cardiac event. Other activities such as hanging holiday lights and decorations in the extreme cold can precipitate chest pain and bronchospasm.

Environmental Pollutants. Avoiding exposure to secondhand smoke is essential to maintaining optimal cardiopulmonary function. Most businesses and restaurants now ban smoking or have separate areas designated as smoking areas. If patients are exposed to secondhand smoke in their home environments, counseling and support for all family members are necessary. Family members need to support the smoker in successful smoking cessation.

Consider if a patient is exposed to chemicals and pollutants in the work environment. Farmers, painters, carpenters, and others benefit from the use of particulate filter masks to reduce the inhalation of particles.

Acute Care. Patients with acute pulmonary illnesses require nursing interventions directed toward halting the pathological process (e.g., respiratory tract infection); shortening the duration and severity of an illness (e.g., hospitalization with pneumonia); and preventing complications from the illness or treatments (e.g., hospital-acquired infection resulting from invasive procedures).

Dyspnea Management. Dyspnea is difficult to treat. Health care providers individualize treatments for each patient and usually implement more than one therapy. Treatment of the underlying process causing dyspnea is then followed with other therapies (e.g., pharmacological measures, oxygen therapy, physical techniques, and psychosocial techniques). Pharmacological agents include bronchodilators, inhaled steroids, mucolytics, and low-dose antianxiety medications. Oxygen therapy reduces dyspnea associated with exercise and hypoxemia. Physical techniques such as cardiopulmonary reconditioning (e.g., exercise, breathing techniques, and cough control), relaxation techniques, biofeedback, and meditation are also beneficial.

Airway Maintenance. The airway is patent when the trachea, bronchi, and large airways are free from obstructions. Airway maintenance requires adequate hydration to prevent thick, tenacious secretions. Proper coughing techniques remove secretions and keep the airway open. A variety of interventions such as suctioning, chest physiotherapy, and nebulizer therapy assist patients in managing alterations in airway clearance.

Mobilization of Pulmonary Secretions. The ability of a patient to mobilize pulmonary secretions makes the difference between a short-term illness and a long recovery involving complications. Nursing interventions promoting removal of pulmonary secretions assist in

achieving and maintaining a clear airway and help to promote lung expansion and gas exchange.

Hydration. Maintenance of adequate systemic hydration keeps mucociliary clearance normal. In patients with adequate hydration, pulmonary secretions are thin, white, watery, and easily removable with minimal coughing. Excessive coughing to clear thick, tenacious secretions is fatiguing and energy depleting. The best way to maintain thin secretions is to provide a fluid intake of 1500 to 2500 mL/day unless contraindicated by cardiac or renal status. The color, consistency, and ease of mucus expectoration determine adequacy of hydration.

Humidification. **Humidification** is the process of adding water to gas. Temperature is the most important factor affecting the amount of water vapor a gas can hold. Relative humidity is the percentage of water in the gas. Air or oxygen with a high relative humidity keeps the airways moist and loosens and mobilizes pulmonary secretions. Humidification is necessary for patients receiving oxygen therapy at greater than 4 L/min (check agency protocol). It might be necessary to add humidification at lower oxygen concentrations if the environment is dry and arid. Bubbling oxygen through water adds humidity to the oxygen delivered to the upper airways (see Skill 41-4).

An oxygen hood is used for infants, and a humidity tent is used for children with illnesses such as croup and tracheitis to liquefy secretions and help reduce fever (Hockenberry and Wilson, 2015). The nebulizer at the top of the humidity tent remains filled with water to prevent nonhumidified air or oxygen from entering the tent. Air in the humidity tent sometimes becomes cool and falls below 20° C (68° F), causing the child to become chilled. Children in humidity tents require frequent changes of clothing and bed linen to remain warm and dry.

Nebulization. **Nebulization** adds moisture or medications to inspired air by mixing particles of varying sizes with the air. Aerosolization suspends the maximum number of water drops or particles of the desired size in inspired air. The moisture added through nebulization improves clearance of pulmonary secretions. Nebulization delivers bronchodilators and mucolytic agents.

When the thin layer of fluid supporting the mucous layer over the cilia dries, the cilia are damaged and unable to adequately clear the airway. Humidification through nebulization enhances mucociliary clearance, the natural mechanism of the body for removing mucus and cellular debris from the respiratory tract.

Coughing and Deep-Breathing Techniques. Coughing is effective for maintaining a patent airway. Directed coughing is a deliberate maneuver that is effective when spontaneous coughing is not adequate (AARC, 1993; Borge et al., 2014). Directed coughing permits a patient to remove secretions from both the upper and lower airways. The normal series of events in the cough mechanism are deep inhalation, closure of the glottis, active contraction of the expiratory muscles, and glottis opening. Deep inhalation increases the lung volume and airway diameter, allowing the air to pass through partially obstructing mucus plugs or other foreign matter. Contraction of the expiratory muscles against the closed glottis causes a high intrathoracic pressure to develop. When the glottis opens, a large flow of air is expelled at a high speed, providing momentum for mucus to move to the upper airways where the patient can expectorate or swallow it.

Diaphragmatic breathing/belly breathing is a technique that encourages deep breathing to increase air to the lower lungs. The diaphragm descends (belly moves out) when breathing in and ascends (belly sinks in) when breathing out (CFF, 2012). Deep breathing also opens the pores of Kohn between alveoli to allow sharing of oxygen between alveoli. This is especially important if the airway of the alveoli is plugged with mucus. The neighboring alveoli can share the air distribution through the pores of Kohn.

Evaluate the effectiveness of coughing by sputum expectoration, the patient's report of swallowed sputum, or clearing of adventitious sounds by auscultation. Encourage patients with chronic pulmonary diseases, upper respiratory tract infections, and lower respiratory tract infections to deep breathe and cough at least every 2 hours while awake. Encourage patients with a large amount of sputum to cough every hour while awake and then awaken them at night to cough every 2 to 3 hours. This is necessary until the acute phase of mucus production has ended. After surgery it is recommended that patients perform directed cough every 2 to 4 hours while awake to prevent accumulation of secretions. Offer postoperative patients support devices (folded blanket, pillow, or palmed hands) to splint an abdominal or thoracic incision to minimize pain during directed coughing. Cough is a source of droplet transmission of pulmonary pathogens; thus the health care provider should follow Standard Precautions. Coughing techniques include deep breathing and coughing for the postoperative patient, cascade, huff, and quad coughing (Borge et al., 2014).

With the *cascade cough* the patient takes a slow, deep breath and holds it for 2 seconds while contracting expiratory muscles. Then he or she opens the mouth and performs a series of coughs throughout exhalation, thereby coughing at progressively lowered lung volumes. This technique promotes airway clearance and a patent airway in patients with large volumes of sputum.

The *huff cough* stimulates a natural cough reflex and is generally effective only for clearing central airways. While exhaling, the patient opens the glottis by saying the word *huff*. With practice he or she inhales more air and is able to progress to the cascade cough.

The *quad cough* technique is for patients without abdominal muscle control such as those with spinal cord injuries. While the patient breathes out with a maximal expiratory effort, the patient or nurse pushes inward and upward on the abdominal muscles toward the diaphragm, causing the cough.

Chest Physiotherapy. **Chest physiotherapy (CPT)** is a group of therapies for mobilizing pulmonary secretions. These therapies include postural drainage, chest percussion, and vibration. CPT is followed by productive coughing or suctioning of a patient who has a decreased ability to cough. It is recommended for patients who produce greater than 30 mL of sputum per day or have evidence of atelectasis on chest x-ray examination (AARC, 2012). The procedure is safe for infants and young children; however, at times conditions and diseases unique to children contraindicate it. CPT is for a select group of patients. Box 41-7 describes the guidelines to determine if CPT is indicated.

Postural drainage is a component of pulmonary hygiene; it consists of drainage, positioning, and turning and is sometimes accompanied by chest percussion and vibration (CFF, 2012). It improves secretion clearance and oxygenation. Positioning involves draining affected lung segments (Table 41-6) and helps to drain secretions from those segments of the lungs and bronchi into the trachea. Some patients do not require postural drainage of all lung segments, and clinical assessment is crucial in identifying specific lung segments requiring it. For example, patients with left lower lobe atelectasis require postural drainage of only the affected region, whereas a child with cystic fibrosis often requires postural drainage of all lung segments.

Chest percussion involves rhythmically clapping on the chest wall over the area being drained to force secretions into larger airways for expectoration (AARC, 2012). It is commonly performed by respiratory therapists in larger health care settings. Position your hand so the fingers and thumb touch and the hands are cupped. The cupping makes the hand conform to the chest wall while trapping a cushion of air to soften the intensity of the clapping. The procedure should produce a hollow sound and should not be painful (CFF, 2012). Perform chest percussion by vigorously striking the chest wall

BOX 41-7   Guidelines for Chest Physiotherapy

Nursing and respiratory therapy collaborate with the health care provider to determine if chest physiotherapy (CPT) is best for the patient. The following guidelines help in physical assessment and subsequent decision making:

- Know a patient's normal range of vital signs. The degree of change is related to the level of hypoxia, overall cardiopulmonary status, and tolerance to activity.
- Conditions requiring CPT such as atelectasis and complicated pneumonia affect vital signs. Conduct a respiratory assessment to confirm need for CPT, including sputum production, effectiveness of cough, history of pulmonary problems successfully relieved with CPT, abnormal lung sounds, documented conditions such as atelectasis, complicated pneumonia, and changes in oxygenation status (AARC, 2012).
- Know the patient's medications. Certain medications, particularly diuretics and antihypertensives, cause fluid and hemodynamic changes. These

decrease a patient's tolerance to positional changes and postural drainage. Long-term steroid use increases a patient's risk of pathological rib fractures and often contraindicates vibration.

- Know the patient's medical history. Certain conditions such as increased intracranial pressure, spinal cord injuries, and abdominal aneurysm resection contraindicate the positional changes of postural drainage. Thoracic trauma or surgery contraindicates percussion and vibration.
- Know the patient's level of cognitive function. Participation in controlled coughing techniques requires him or her to follow instructions. Congenital or acquired cognitive limitations alter a patient's ability to learn and participate in these techniques.
- Be aware of the patient's exercise tolerance. CPT maneuvers are fatiguing.

TABLE 41-6   Positions for Postural Drainage

Lung Segment	Position of Patient	Lung Segment	Position of Patient
Adult Bilateral	High-Fowler's	Left lower lobe—lateral segment	Right side-lying in Trendelenburg's position
Apical segments	Sitting on side of bed	Right lower lobe—lateral segment	Left side-lying in Trendelenburg's position
Right upper lobe—anterior segment	Supine with head elevated	Right lower lobe—posterior segment	Prone with right side of chest elevated in Trendelenburg's position
Left upper lobe—anterior segment	Supine with head elevated	Right middle lobe—posterior segment	Prone with thorax and abdomen elevated
Right upper lobe—posterior segment	Side-lying with right side of chest elevated on pillows	Both lower lobes—anterior segments	Supine in Trendelenburg's position

Continued

TABLE 41-6	Positions for Postural Drainage—cont'd		
Lung Segment	**Position of Patient**	**Lung Segment**	**Position of Patient**
Left upper lobe—posterior segment	Side-lying with left side of chest elevated on pillows	Both lower lobes—posterior segments	Prone in Trendelenburg's position
Right middle lobe—anterior segment	Three-fourths supine position with dependent lung in Trendelenburg's position		
Child Bilateral—apical segments	Sitting on nurse's lap, leaning slightly forward flexed over pillow	Bilateral lobes—anterior segments	Lying supine on nurse's lap, back supported with pillow
Bilateral—middle anterior segments	Sitting on nurse's lap, leaning against nurse		

alternately with cupped hands (Figure 41-9). Perform percussion over a single layer of clothing, not over buttons, snaps, or zippers. The single layer of clothing prevents slapping the patient's skin. Thicker or multiple layers of material dampen the vibrations.

Percussion is contraindicated in patients with bleeding disorders, osteoporosis, or fractured ribs. Avoid percussion over burns, open wounds, or skin infections of the thorax. Take caution to percuss the lung fields under the ribs and not over the spine, breastbone, stomach, or lower back or trauma can occur to the spleen, liver, or kidneys (CFF, 2012).

Vibration is a gentle, shaking pressure applied to the chest wall to shake secretions into larger airways. Place a flattened hand or two hands firmly on the chest wall over the appropriate segment and press the top and bottom hand into each other to vibrate. Tense the muscles of the arm to provide a shaking motion. Have the patient exhale as slowly as possible during the vibration. This technique increases the velocity and turbulence of exhaled air, facilitating secretion removal. Vibration increases the exhalation of trapped air, shakes mucus loose, and induces a cough (CFF, 2012).

A patient may also be instructed to use a vest airway clearance system. The vest airway clearance systems use high-frequency chest wall oscillation (HFCWO) or compression to assist removal of secretions from the lungs. This vest is beneficial for patients with neuromuscular diseases and for patients with chronic lung diseases, such as cystic fibrosis. The goals of oscillating vests are (1) to clear the airways of excessive secretions to reduce the work of breathing, and (2) to

FIGURE 41-9 Chest wall percussion, alternating hand clapping against patient's chest wall.

improve a patient's ability to cough up secretions (Morrison and Agnew, 2014). The vest fits over the patient's clothing and makes it possible for patients to continue airway clearance therapies in the home and school environments when necessary.

Suctioning Techniques. Suctioning is necessary when patients are unable to clear respiratory secretions from the airways by coughing or other less invasive procedures. Suctioning techniques include oropharyngeal and nasopharyngeal suctioning, orotracheal and nasotracheal suctioning, and suctioning an artificial airway.

In most cases use sterile technique for suctioning because the oropharynx and trachea are considered sterile. The mouth is considered clean; therefore you suction oral secretions after suctioning the oropharynx and trachea. In the home setting, use a "clean" versus "sterile" technique because the patient is not exposed to pathogens common to health care settings. Teach patients appropriate measures for disinfecting equipment (AARC, 2004, 2010a).

Each type of suctioning requires the use of a round-tipped, flexible catheter with holes on the sides and end of the catheter. When suctioning, you apply negative pressures (100-150 mm Hg for adults) during withdrawal of the catheter, never on insertion (AARC, 2010a). Patient assessment determines the frequency of suctioning. It is indicated when rhonchi, gurgling breath sounds, and diminished breath sounds are audible on auscultation or visible secretions are present after other methods to remove airway secretions have failed. You may also use suctioning to obtain a sputum specimen for culture or cytology if the patient is not able to cough productively. Too-frequent suctioning puts patients at risk for development of hypoxemia, hypotension, arrhythmias, and possible trauma to the mucosa of the lungs (AARC, 2010a; Lynn-McHale, 2011).

Oropharyngeal and Nasopharyngeal Suctioning. Oropharyngeal or nasopharyngeal suctioning is used when a patient is able to cough effectively but unable to clear secretions by expectorating. Apply suction after a patient has coughed (see Skill 41-1 on pp. 907-914). Once the pulmonary secretions decrease and a patient is less fatigued, he or she is then able to expectorate or swallow the mucus, and suctioning is no longer necessary.

Orotracheal and Nasotracheal Suctioning. Orotracheal or nasotracheal suctioning is necessary when a patient with pulmonary secretions is unable to manage secretions by coughing and does not have an artificial airway present (see Skill 41-1). You pass a sterile catheter through the mouth or nose into the trachea. The nose is the preferred route because stimulation of the gag reflex is minimal. The procedure is similar to nasopharyngeal suctioning, but you advance the catheter tip farther into the patient's trachea. The entire procedure from catheter passage to its removal is done quickly, lasting no longer than 10 seconds (AARC, 2010a). Allow the patient to rest between passes of the catheter. If the patient develops respiratory distress, stop suctioning unless the collection of secretions is causing distress. If the patient is using supplemental oxygen, replace the oxygen cannula or mask during rest periods.

Tracheal Suctioning. Perform tracheal suctioning through an artificial airway such as an endotracheal (ET) or tracheostomy tube. The size of a catheter should be as small as possible but large enough to remove secretions. Recommendation is about half the internal diameter of the ET tube (AARC, 2010a). Never apply suction pressure while inserting the catheter to avoid traumatizing the lung mucosa. Once you insert a catheter the necessary distance, maintain suction pressure between 120 and 150 mm Hg (AARC, 2010a) as you withdraw. Apply suction intermittently **only** while withdrawing the catheter. Rotating the catheter enhances removal of secretions that have adhered to the sides of the airway.

The practice of normal saline instillation (NSI) into artificial airways to improve secretion removal may be harmful and is not recommended. Clinical studies comparing the results of suctioning following NSI with standard suctioning have not shown any clinical or significant results (AARC, 2010a).

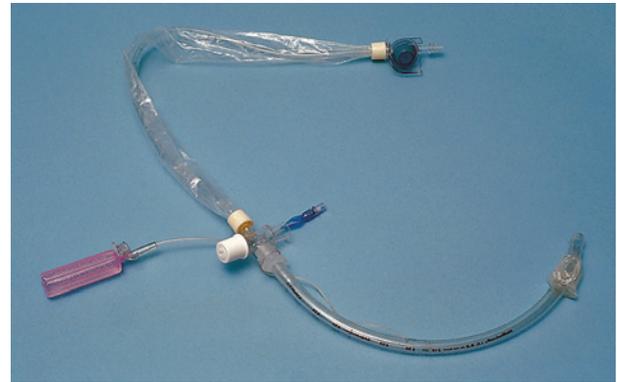
The two current methods of suctioning are the open and closed methods. Open suctioning involves using a new sterile catheter for each suction session (AARC, 2010a). Wear sterile gloves and follow Standard Precautions during the suction procedure. Closed suctioning involves using a reusable sterile suction catheter that is encased in a plastic sheath to protect it between suction sessions (Figure 41-10).


FIGURE 41-10 Ballard tracheal care, closed suction catheter.

FIGURE 41-11 Artificial oral airways.

Closed suctioning is most often used on patients who require invasive mechanical ventilation to support their respiratory efforts because it permits continuous delivery of oxygen while suction is performed and reduces the risk of oxygen desaturation. Although sterile gloves are not used in this procedure, nonsterile gloves are recommended to prevent contact with splashes from body fluids (see Skill 41-1).

Artificial Airways. An artificial airway is for a patient with a decreased level of consciousness or airway obstruction and aids in removal of tracheobronchial secretions. The presence of an artificial airway places a patient at high risk for infection and airway injury. Use clean technique for oral airways, but use sterile technique in caring for and maintaining endotracheal and tracheal airways to prevent health care–associated infections (HAIs). Artificial airways need to stay in the correct position to prevent airway damage (see Skill 41-2 on pp. 915-922).

Oral Airway. The oral airway, the simplest type of artificial airway, prevents obstruction of the trachea by displacement of the tongue into the oropharynx (Figure 41-11). The oral airway extends from the teeth to the oropharynx, maintaining the tongue in the normal position. Use the correct-size airway. Determine the proper oral airway size by measuring the distance from the corner of the mouth to the angle of the jaw just below the ear. The length is equal to the distance from the flange of the airway to the tip. If the airway is too small, the tongue does not stay in the anterior portion of the mouth; if the airway is too large, it forces the tongue toward the epiglottis and obstructs the airway.

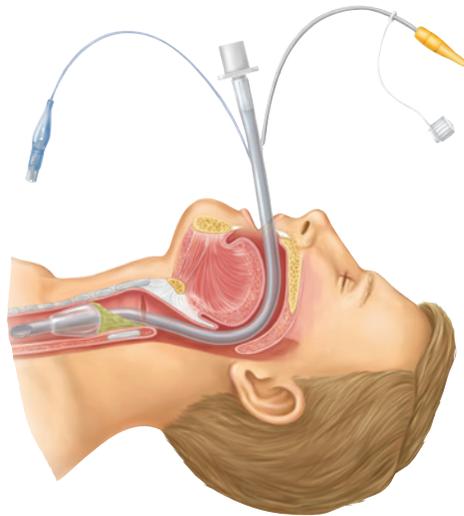
Insert the airway upside down, then turn to the curve of the airway toward the cheek and place it over the tongue. When the airway is in the oropharynx, turn it so the opening points downward. Correctly placed, the airway moves the tongue forward away from the oropharynx, and the flange (e.g., the flat portion of the airway) rests against


FIGURE 41-12 Endotracheal tube inserted into trachea. Cuff inflated to maintain position. (Copyright © 2015 Medtronic. All rights reserved. Used with the permission of Medtronic.)

the patient's teeth. Incorrect insertion merely forces the tongue back into the oropharynx.

Endotracheal and Tracheal Airway. An **endotracheal (ET) tube** is a short-term artificial airway to administer invasive mechanical ventilation, relieve upper airway obstruction, protect against aspiration, or clear secretions. A physician or specially trained clinician inserts the ET tube. The tube is passed through the patient's mouth, past the pharynx, and into the trachea (Figure 41-12). It is generally removed within 14 days; however, it is sometimes used for a longer period of time if the patient is still showing progress toward weaning from invasive mechanical ventilation and extubation.

If a patient requires long-term assistance from an artificial airway, a **tracheostomy** is considered. A surgical incision is made into the inferior border of the cricoid cartilage of the trachea, and a short tracheostomy tube is inserted. Most tracheostomies have a small plastic inner tube that fits inside a larger one (the inner cannula). The most common complication of a tracheostomy tube is partial or total airway obstruction caused by buildup of respiratory secretions. If this occurs, the inner tube can be removed and cleaned or replaced with a temporary spare inner tube that should be kept at the patient's bedside. Keep tracheal dilators at the bedside to have available for emergency tube replacement or reinsertion. Humidification from air humidifiers or humidified oxygen tracheostomy collars can help prevent drying of secretions that cause occlusion. Tracheostomy suctioning should be done as often as necessary to clear secretions. The majority of patients with a tracheostomy tube cannot speak because the tube is inserted below the vocal cords. It is important to use written or nonverbal communication (lip reading) strategies to help patients communicate. Be sure to assess patients for anxiety caused by the inability to speak. Care and cleaning of the tracheostomy tube is discussed in Skill 41-2.

Maintenance and Promotion of Lung Expansion. Nursing interventions to maintain or promote lung expansion include noninvasive techniques such as ambulation, positioning, incentive spirometry, and noninvasive ventilation. Invasive medical interventions such as chest tube insertion and management assist in restoring lung expansion.

Ambulation. Immobility is a major factor in developing atelectasis, ventilator-associated pneumonia (VAP), and functional limitations. The research has shown that, after 1 week of bed rest, muscle strength declines by as much as 20%, which results in an increased oxygen demand, weakened respiratory muscles, and a decline of func-

tional status. Early ambulation studies indicate that the therapeutic benefits of activity include an increase in general strength and lung expansion. Even the patient who requires invasive mechanical ventilation benefits by an early mobility program. Such mobility programs should include input from both respiratory and physical therapists in the treatment plan (Atkins and Kautz, 2014). Progressive mobilization from dangling the legs to standing and then walking is safe for intubated patients (Atkins and Kautz, 2014).

Positioning. The healthy, completely mobile person maintains adequate ventilation and oxygenation by frequent position changes during daily activities. However, when a person's illness or injury restricts mobility, the risk for respiratory impairment is increased. Frequent changes of position are simple and cost-effective methods for reducing stasis of pulmonary secretions and decreased chest wall expansion, both of which increase the risk of pneumonia. Research has shown that turning critically ill patients every 2 hours is not often enough to prevent pneumonia (Rauen et al., 2008).

The 45-degree semi-Fowler's is the most effective position to promote lung expansion and reduce pressure from the abdomen on the diaphragm. When a patient is in this position, be sure that he or she does not slide down in bed, which can reduce lung expansion. Sliding also increases the risk of pressure ulcers. A patient with unilateral lung disease such as pneumothorax, atelectasis, or pneumonia of one lung should be positioned in a manner to promote perfusion of the healthy lung and improve oxygenation. In most cases, position the patient with the good lung down (Rauen et al., 2008). In the presence of pulmonary abscess or hemorrhage, position the patient with the affected lung down to prevent drainage toward the healthy lung. For bilateral lung disease the best position depends on the severity of the disease.

Incentive Spirometry. Incentive spirometry encourages voluntary deep breathing by providing visual feedback to patients about inspiratory volume. It promotes deep breathing and prevents or treats atelectasis in the postoperative patient. There is solid evidence to support the use of lung expansion with incentive spirometry in preventing postoperative pulmonary complications following surgery (AARC, 2011; Cassidy et al., 2013).

Flow-oriented incentive spirometers consist of one or more plastic chambers that contain freely moving colored balls. A patient inhales slowly and with an even flow to elevate the balls and keep them floating as long as possible to ensure a maximally sustained inhalation.

Volume-oriented incentive spirometry devices have a bellows that is raised to a predetermined volume by an inhaled breath (Figure 41-13). An achievement light or counter is used to provide feedback. Some devices are constructed so the light does not turn on unless the bellows is held at a minimum desired volume for a specified period to enhance lung expansion (see Chapter 50).

Incentive spirometry encourages patients to use visual feedback to maximally inflate their lungs and sustain that inflation (AARC, 2011). A postoperative inspiratory capacity one half to three fourths of the preoperative volume is acceptable because of postoperative pain. The AARC guidelines (2011) recommend 5 to 10 breaths per session every hour while awake. Administration of pain medications before incentive spirometry helps a patient achieve deep breathing by reducing pain and splinting.

Invasive Mechanical Ventilation. Invasive mechanical ventilation, also referred to as positive-pressure ventilation**,** is a lifesaving technique used with artificial airways (ET or tracheostomy) for various physiological and clinical indications. Physiological indications for invasive mechanical ventilation include supporting cardiopulmonary gas exchange (alveolar ventilation and arterial oxygenation), increasing lung volume, and reducing the work of breathing (Urden et al., 2014).

FIGURE 41-13 Volume-oriented incentive spirometer.

Clinical indications for invasive mechanical ventilation include reversing hypoxia and acute respiratory acidosis, relieving respiratory distress, preventing or reversing atelectasis and respiratory muscle fatigue, allowing for sedation and/or other neuromuscular blockade, decreasing oxygen consumption, reducing intracranial pressure and stabilizing the chest wall (Urden et al., 2014). It can be used to either fully or partially replace spontaneous breathing depending on the need of the patient. Invasive mechanical ventilation also redistributes blood flow from working respiratory muscles to other vital organs. Following an inspiratory trigger, invasive mechanical ventilation forces a preset mixture of air (oxygen and other gases) into the central airways and then flows into the alveoli, causing the intraalveolar pressure to increase as the lungs inflate. A termination signal triggers the ventilator to cease forcing air into the central airways, causing the central airway pressure to decrease. Expiration then follows passively, the air flowing from the higher alveoli pressure to the lower pressure of the central airways.

There are a variety of ventilator modes; the choice depends on the patient's situation and goals of treatment. Many of the modes are used in conjunction with each other. There are numerous brands of ventilators and they vary in their ability to perform certain functions; not all modes are available on all ventilators. The most commonly used modes include assist-control (AC), synchronized intermittent mandatory ventilation (SIMV) and pressure support ventilation (PSV). Assist control delivers a set tidal volume (VT) with each breath, regardless if the breath was triggered by the patient or the ventilator. Synchronized intermittent mandatory ventilation, like AC, delivers a minimum number of fully assisted breaths per minute that are synchronized with the patient's respiratory effort. Any breaths taken between volume-cycled breaths are not assisted; the volume of these breaths is determined by the patient's strength, effort, and lung mechanics. Pressure Support mode is often combined with SIMV mode, inspiratory pressure is added to spontaneous breaths to overcome the resistance of the endotracheal tube or to help increase the volume of the patient's spontaneous breaths.

Although invasive mechanical ventilation is often lifesaving, it is not without complications. Some complications are preventable and others can be minimized. Physiological complications associated with invasive mechanical ventilation include volutrauma, cardiovascular compromise, gastrointestinal disturbances, and ventilator assisted pneumonia (Urden et al., 2014).

Volutrauma occurs as a result of alveolar overdistention secondary to the mechanical ventilation. Cardiovascular compromise occurs as a result of the increased intrathoracic pressure. It is caused by positive-pressure ventilation that decreases venous return to the right side of the heart, decreasing preload and resulting in a decreased cardiac output. Gastrointestinal (GI) disturbances commonly occur. They are related to gastric distention, vomiting related to pharyngeal stimulation from the artificial airway, constipation, and hypomotility (due to immobility and the administration of analgesics, sedatives and paralytic agents).

Ventilator-associated pneumonia (VAP) is a significant potential complication because the artificial airway tube bypasses many of the lung's normal defense mechanisms. Ventilator associated pneumonia (VAP) is a health care–acquired infection (HAI) that develops in a person requiring invasive mechanical ventilation (via endotracheal intubation or tracheotomy tube) for at least 48 hours (Shi et al., 2013). It is a potentially serious complication in patients who are already critically ill. VAP mortality rates ranges from 20% to 50% among ventilated patients and is estimated to add an additional $40,000 to the cost of a hospital admission (Monaco et al., 2014) (Box 41-8). Hospitals are not reimbursed for costs associated with VAP.

Noninvasive Ventilation. **Noninvasive positive-pressure ventilation (NPPV)** is used to prevent using invasive artificial airways (ET tube or tracheostomy) in patients with acute respiratory failure, cardiogenic pulmonary edema, or exacerbation of COPD. It has also been used following extubation of an ET tube (Luo et al., 2014). The purpose of NPPV is to maintain a positive airway pressure and improve alveolar ventilation. This prevents or treats atelectasis by inflating the alveoli, reducing pulmonary edema by forcing fluid out of the lungs back into circulation, and improving oxygenation in those with sleep apnea. Ventilatory support is achieved using a variety of modes, including **continuous positive airway pressure (CPAP)** and **bilevel positive airway pressure (BiPAP)**.

CPAP treats patients with obstructive sleep apnea, patients with heart failure, and preterm infants with underdeveloped lungs. In obstructive sleep apnea, airways collapse, causing shallow or absent breathing. Any air moving past the obstruction results in loud snoring. An overnight sleep study may be needed to determine the correct settings for a CPAP machine (see Chapter 43). Equipment includes a mask (Figure 41-14) that fits over the nose or both nose and mouth and a CPAP machine that delivers air to the mask (National Heart Lung and Blood Institute, 2011). The smallest mask with the proper fit is the most effective. Because straps hold the mask in place, it is important to assess for excess pressure on the patient's face or nose that could cause skin breakdown or necrosis. The mask should have enough slack to allow one to two fingers between the straps and the face (Soo Hoo et al., 2014). However, it must also be tight enough to form a tight seal on the face so the air does not escape. With higher pressures escape of some air may be avoidable.

The most common mode of support is BiPAP that provides both inspiratory positive airway pressure (IPAP) and expiratory airway pressure (EPAP), also known as *positive end-expiratory pressure (PEEP)*. The difference between these two pressures indicates the amount of pressure support a patient needs (Soo Hoo et al., 2014). During inhalation the positive pressure increases the patient's tidal volume and alveolar ventilation. The pressure support decreases when the patient exhales, allowing for easier exhalation.

Complications of noninvasive ventilation include facial and nasal injury and skin breakdown, dry mucous membranes and thick secretions, and aspiration of gastric contents if vomiting occurs. Complications avoided by noninvasive ventilation are VAP, sinusitis, and effects of large-dose sedative agents. Use of noninvasive ventilation

BOX 41-8   EVIDENCE-BASED PRACTICE

Adherence to a Ventilator Care Bundle on Reducing Ventilator-Associated Pneumonia

PICO Question: In patients requiring invasive mechanical ventilation, does adhering to an evidenced-based ventilator care bundle contribute to a reduction of ventilator-associated pneumonia (VAP)?

Evidence Summary

Ventilator associated pneumonia (VAP) is a health care–acquired infection (HAI) that develops in a person requiring invasive mechanical ventilation (via endotracheal intubation or tracheostomy tube) for at least 48 hours (Shi et al., 2013). *Pseudomonas aeruginosa* and *Staphylococcus aureus* are considered major causes of endotracheal tube–associated VAP, 41.7% and 36.7% respectively. *Streptococcus pneumonia, Acinetobacter baumannii, Enterobacteriacea* and other gram-negative aerobic bacteria are the other microorganisms that contribute to VAP (Loo et al., 2015). Patients with VAP have increased fever, increased secretions, and pulmonary infiltrates seen on chest radiograph. Over time these infiltrates progressively increase, and the patient's lung functions decline. VAP is also highly correlated with sepsis, and interventions to reduce the risk of VAP also assist in reducing the risk for sepsis (O'Leary, 2014). The incidence of VAP increases with the duration of invasive mechanical ventilation.

In 2001, The Institute for Health Care Improvement identified four interventions to prevent complications in high-risk ventilated patients. The Ventilator Bundle (IHCI, 2012) as it came to be known, is a series of evidenced-based interventions related to ventilator care that, when implemented together, achieve significantly better outcomes than when implemented individually (Monaco et al., 2014). In 2010, components of the IHI Ventilator Bundle were revised to add an intervention. The key components of the IHI Ventilator Bundle are (IHCI, 2012):

- Elevation of the head of the bed (HOB) 45 degrees
- Daily "sedation vacations" and assessment of readiness to extubate
- Peptic ulcer disease prophylaxis
- Deep venous thrombosis prophylaxis
- Daily oral care with chlorhexidine

Increased compliance with the IHI's recommended Ventilator Bundle reduces the incidence of VAP in ICU settings (Morris et al., 2011; Monaco et al., 2014).

Application to Nursing Practice

- Follow ICHI bundle.
- Avoid prolonged supine positioning. Pulmonary aspiration is increased by supine positioning and pooling of secretions above the ET tube cuff (Sedwick et al., 2012).
- Compared to supine positioning, studies have shown that with simple positioning with HOB elevation to 30 degrees or higher significantly reduces gastric reflux and VAP. Keep the patient's HOB raised between 30 and 45 degrees unless other medical conditions do not allow this to occur.
- Orotracheal and orogastric tubes are preferred over nasal devices to reduce the risk of VAP (Lacherade et al., 2010).
- Suction frequently to remove oropharyngeal and subglottic secretions to reduce the risk of early-onset VAP.
- Monitor cuff pressure frequently to ensure that there is an adequate seal to prevent aspiration of secretions (Lacherade et al., 2010).
- Provide daily oral care with chlorhexidine (IHCI, 2012; Labeau et al., 2011).
- Always drain ventilator circuit condensation away from patient and into the appropriate receptacle (AARC, 2010a). Drain the tubing hourly to prevent accumulation.

FIGURE 41-14 CPAP mask.

results in shorter intensive care unit (ICU) and hospital stays (Soo Hoo et al., 2014). Perform good oral hygiene every few hours while a patient is on BiPAP to relieve dryness.

Chest Tubes. A **chest tube** (Figure 41-15) is a catheter inserted through the thorax to remove air and fluids from the pleural space, to prevent air or fluid from reentering the pleural space, or to reestablish normal intrapleural and intrapulmonic pressures (Bauman et al., 2011). Chest tubes are common after chest surgery and chest trauma and are used for treatment of pneumothorax or hemothorax to promote lung reexpansion (see Skill 41-3 on pp. 922-926).

A **pneumothorax** is a collection of air in the pleural space. The loss of negative intrapleural pressure causes the lung to collapse. There are a variety of causes for a pneumothorax. A secondary pneumothorax can occur as a result of chest trauma (e.g., stabbing, gunshot wound, or rib fracture from striking the chest against the steering wheel in an automobile accident). Other causes of secondary pneumothorax are the rupture of an emphysematous bleb on the surface of the lung (the destruction caused by emphysema), tearing of the pleura from an invasive procedure such as surgery, insertion of a subclavian IV line, and invasive mechanical ventilation, including PEEP. Spontaneous (primary) pneumothorax is a genetic condition that occurs unexpectedly in healthy individuals who develop blisterlike formations (blebs) on the visceral pleura, usually on the apex of the lungs. The blebs can rupture during sleep or exercise (McCance and Huether, 2014). A patient with a pneumothorax usually feels pain as atmospheric air irritates the parietal pleura. The pain is sharp and pleuritic and worsens on inspiration. Dyspnea is common and worsens as the size of the pneumothorax increases.

A **hemothorax** is an accumulation of blood and fluid in the pleural cavity between the parietal and visceral pleura, usually as a result of trauma. It produces a counter pressure and prevents the lung from full expansion. A rupture of small blood vessels from inflammatory processes such as pneumonia or TB can cause a hemothorax. In addition to pain and dyspnea, signs and symptoms of shock develop if blood loss is severe.

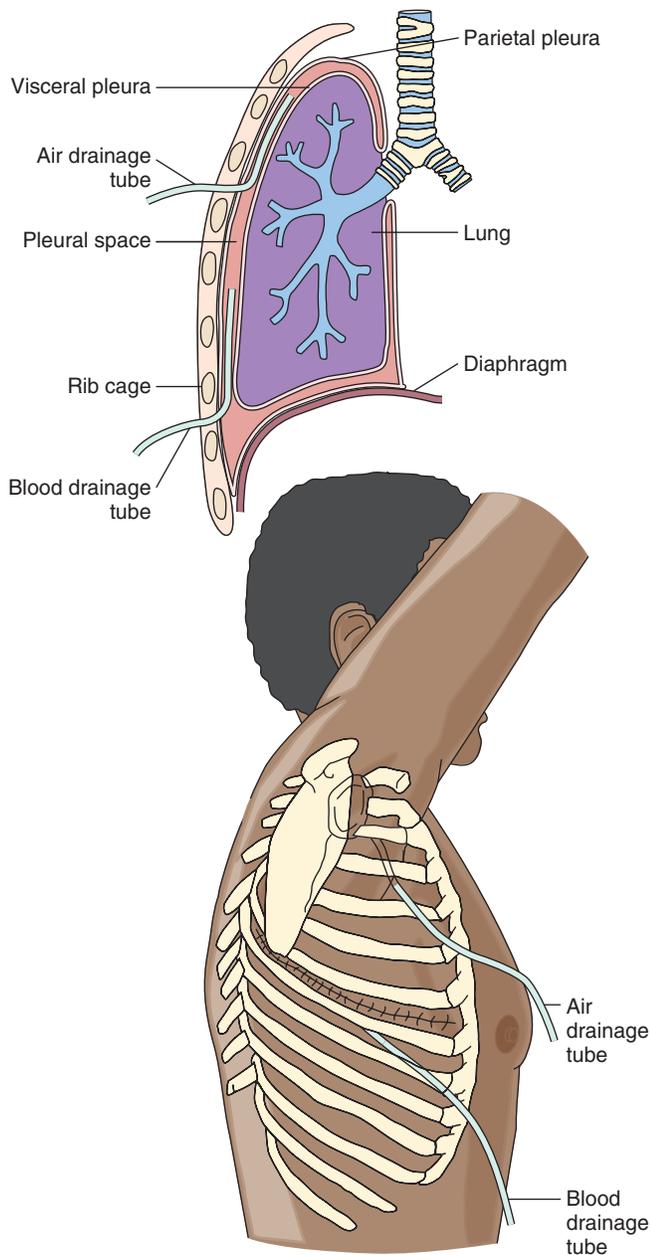
A variety of chest tubes are available to drain air or excess fluid from the pleural space to relieve respiratory distress. A small-bore chest tube (12 to 20 Fr) is used to remove a small amount of air, and a


FIGURE 41-15 Chest tube placement.

larger-bore chest tube is used to remove large amounts of fluid or blood and large amounts of air (Carroll, 2015).

After a chest tube is inserted, it is attached to a drainage system. A traditional chest drainage unit (CDU) has three chambers for collection, water seal, and suction control. This unit can drain a large amount of both fluid and air (Carroll, 2015). Mobile systems rely on gravity, not suction, for drainage. In selected patients these mobile drains reduce the length of time needed for the chest tube, improve ambulation, and decrease the length of time in the hospital (Carroll, 2015). Nonventilated patients and patients who had thoracoscopic lung surgery or minimally invasive cardiac surgery do well with these mobile chest drains. They are lighter and smaller; thus patients are able to move more easily. As a result this reduces the risks of deep vein thrombosis and pulmonary embolism.

The simplest closed drainage system is the single chamber unit. The chamber serves as a fluid collector and a water seal. During normal respiration the fluid in the chamber ascends with inspiration and descends with expiration. A single chamber is used for smaller amounts of drainage such as an empyema (e.g., a collection of infected fluid or pus in the pleural space).

The use of two chambers permits any fluid to flow into the collection chamber as air flows into the water-seal chamber. Fluctuations in the water-seal tube are still anticipated. Two chambers allow for more accurate measurement of chest drainage and are used when larger amounts of drainage are expected.

When a volume of air or fluid needs to be evacuated with controlled suction, all three chambers are used. Mark the suction control with centimeter readings to adjust the amount of suction. Usually 15 to 20 cm of water is used for adults (Carroll, 2015). This means that the chamber is filled with sterile water to the 15- or 20-cm water level.

There is a new dry chest drainage system that does not use water in the suction chamber. An automatic control valve (ACV) is located inside the regulator and continuously balances the force of the suction with the atmospheres. As a result, the ACV responds and adjusts to changes in patient air leaks and fluctuations in suction source vacuum to deliver accurate suction. Set the pressure between -10 cm H_2O and -40 cm H_2O (RTC, 2011). Regardless of the system used, the principles of patient management are the same.

Special Considerations. Keep a chest tube system closed and below the chest (see Skill 41-3). The tube should be secured to the chest wall. Watch for slow, steady bubbling in the suction-control chamber and keep it filled with sterile water at the prescribed level. Make sure that the water-seal chamber is filled to the manufacturer-specified level and watch for fluctuation (tidaling) of the fluid level to ensure that the chest tube and system are working. A constant or intermittent bubbling in the water-seal chamber indicates a leak in the drainage system, and the health care provider must be notified immediately. Mark the level on the outside of the collection chambers every shift. Report any unexpected cloudy or bloody drainage. Do not let the tubing kink or loop, and ideally it should lie horizontally across the bed or chair before dropping vertically into the drainage device. Encourage your patient to cough, deep breath, and use the incentive spirometer. Make sure that he or she is frequently repositioned and ambulated if not contraindicated. Routinely evaluate respiratory rate, breath sounds, SpO_2 levels, and the insertion site for subcutaneous emphysema (RTC, 2011; Carroll, 2015).

Clamping a chest tube is contraindicated when ambulating or transporting a patient. Clamping can result in a tension pneumothorax. Air pressure builds in the pleural space, collapsing the lung and creating a life-threatening event. A chest tube is only clamped when replacing the chest drainage system, assessing for an air leak, or during removal (Bauman et al., 2011).

Chest tubes are not routinely stripped or milked to move clots or increase chest tube drainage (Bauman et al., 2011). Stripping or milking chest tubes is based on nursing assessment (see Skill 41-3).

Handle the chest drainage unit carefully and maintain the drainage device below the patient's chest. If the tubing disconnects from the drainage unit, instruct the patient to exhale as much as possible and to cough. This maneuver rids the pleural space of as much air as possible. Temporarily reestablish a water seal by immersing the open end of the chest tube into a container of sterile water (Bauman et al., 2011).

Removal of chest tubes requires patient preparation. The most frequent sensations reported by patients during chest tube removal include burning, pain, and a pulling sensation. Make sure that the patient is given pain medication at least 30 minutes before removal.

The nurse assists the health care provider in removing the chest tube and monitors the dressing placed over the insertion site and the patient's respiratory status after tube removal.

Maintenance and Promotion of Oxygenation. Promotion of lung expansion, mobilization of secretions, and maintenance of a patent airway assist patients in meeting their oxygenation needs. However, some patients also require oxygen therapy to keep a healthy level of tissue oxygenation.

Oxygen Therapy. Oxygen therapy is widely available and used in a variety of settings to relieve or prevent tissue hypoxia. The goal of oxygen therapy (AARC, 2007) is to prevent or relieve hypoxia by delivering oxygen at concentrations greater than ambient air (21%). Oxygen has dangerous side effects such as oxygen toxicity. The dosage or concentration of oxygen is monitored continuously. Routinely check the health care provider's orders to verify that the patient is receiving the prescribed oxygen concentration. The six rights of medication administration also pertain to oxygen administration (see Chapter 32).

Supplemental oxygen therapy offers many benefits to patients with chronic cardiopulmonary diseases. This therapy reduces mortality, improves self-reported sleep quality and general comfort, increases exercise tolerance, and reduces polycythemia and pulmonary hypertension (Earnest, 2002). Patients may have continuous supplemental oxygen prescription or nocturnal oxygen supplements. In some situations, supplemental oxygen therapy is prescribed to accompany physical therapy. There is evidence that supports the use of oxygen therapy in these situations improves patient participation in physical therapy, improves activity tolerance, reduces the time needed for extended or home care, and returns patient to maximal level of health (Task Force on Supplemental Oxygen Therapy, 2014). It is important to reinforce to your patients why they may have supplemental oxygen during physical therapy but have supplemental oxygen full-time (Box 41-9).

Safety Precautions. Oxygen is a highly combustible gas. Although it does not burn spontaneously or cause an explosion, it can easily cause a fire in a patient's room if it contacts a spark from an open flame or electrical equipment. With increasing use of home oxygen therapy, patients and health care professionals need to be aware of the dangers of combustion (Kassis et al., 2014). Chapter 27 describes steps to take in case of fire.

Promote oxygen safety by the following measures:
- Oxygen is a therapeutic gas and must be prescribed and adjusted only with a health care provider's order. Distribution must

---

BOX 41-9 PROCEDURAL GUIDELINES

Applying a Nasal Cannula or Oxygen Mask

Delegation Considerations

The skill of applying (not adjusting oxygen flow) a nasal cannula or oxygen mask can be delegated to nursing assistive personnel (NAP). You are responsible for assessing patient's respiratory system; response to oxygen therapy; and setup of oxygen therapy, including adjustment of oxygen flow rate. Direct the NAP by:

- Informing how to safely position and adjust the device (e.g., loosening the strap on oxygen mask) and clarifying its correct placement and positioning.
- Instructing to inform the nurse immediately about any vital sign changes; skin irritation from the cannula, mask, or straps; if patient reports pain or breathlessness; or if patient presents with decreased level of consciousness or increased confusion.
- Having personnel provide skin care around patient's ears and nose

Equipment

NOTE: When device is used in the home, the home care equipment vendor provides the equipment. Oxygen-delivery device as ordered by patient's health care provider. Oxygen tubing (consider extension tubing), humidifier if indicated, sterile water for humidifier, oxygen source, oxygen flowmeter, stethoscope, pulse oximeter, appropriate room signs

Steps

1. Identify patient using two identifiers (e.g., name and birth date or name and medical record number) according to agency policy. Compare identifiers with information on patient's MAR or medical record.
2. Assess patient's respiratory status, including symmetry of chest wall expansion, chest wall abnormalities (e.g., kyphosis), temporary conditions (e.g., pregnancy, trauma) affecting ventilation, respiratory rate and depth, sputum production, and lung sounds.
3. Observe for patent airway and remove secretions by having patient cough and expectorate mucus or by suctioning.

   CLINICAL DECISION: Patients with sudden changes in their vital signs, level of consciousness, or behavior are often experiencing profound hypoxia. Patients who demonstrate subtle changes over time have worsening of a chronic or existing condition or a new medical condition.

4. Obtain patient's most recent SpO_2 or arterial blood gas (ABG) values if available. Review patient's medical record for medical order for oxygen, noting delivery method, flow rate, and duration of oxygen therapy.
5. Explain to patient and family what happens during procedure and the purpose of oxygen therapy.
6. Perform hand hygiene.
7. Attach oxygen-delivery device (e.g., nasal cannula or mask) to oxygen tubing and attach to humidified oxygen source adjusted to prescribed flow rate (see illustration).

STEP 7 Adjusting flowmeter to prescribed oxygen flow rate.

BOX 41-9 PROCEDURAL GUIDELINES

Applying a Nasal Cannula or Oxygen Mask—cont'd

8. Position tips of nasal cannula properly in patient's nares and adjust elastic headband or plastic slide on cannula so it is snug and comfortable (see illustration). If using an oxygen face mask, adjust elastic band over ears until mask fits comfortably over patient's face and mouth.

9. Maintain sufficient slack on oxygen tubing and secure to patient's clothes.

10. Observe for proper functioning of oxygen-delivery device.
    a. *Nasal cannula:* Cannula is positioned properly in nares with humidification functioning.
    b. *Reservoir nasal cannula Oxymizer:* Fit as for nasal cannula. Reservoir is positioned under patient's nose or worn as a pendant (see illustration).

    c. *Nonrebreathing mask:* Apply mask over patient's mouth and nose to form tight seal. Valves on mask close so exhaled air does not enter reservoir bag (see illustration).
    d. *Partial rebreathing mask:* Apply mask over patient's mouth and nose to form tight seal. Ensure that bag remains partially inflated.
    e. *Venturi mask:* Apply mask over patient's mouth and nose to form a tight seal. Select appropriate flow rate (see illustration).

BOX 41-9 **PROCEDURAL GUIDELINES**

Applying a Nasal Cannula or Oxygen Mask—cont'd

f. *Face tent:* Apply tent under patient's chin and over mouth and nose. It will be loose, and a mist is always present (see illustration).

11. Verify setting on flowmeter and oxygen source for proper setup and pre-scribed flow rate.

STEP 10f Face tent. (Copyright © Mosby's Clinical Skills: Essentials Collection.)

12. Check cannula/mask every 8 hours. Keep humidification container filled at all times.

13. Monitor patient's response to changes in oxygen flow rate with pulse oximetry. **NOTE:** Monitor ABGs when ordered; however, obtaining ABG measurement is an invasive procedure, and ABGs are not measured frequently.

14. Observe for decreased anxiety, improved level of consciousness and cognitive abilities, decreased fatigue, absence of dizziness, decreased respiratory rate, improved color, improved oxygen saturation, and return to patient's baseline vital signs.

15. Check adequacy of oxygen flow each shift.

16. Observe patient's external ears, bridge of nose, nares, and nasal mucous membranes for evidence of skin breakdown.

17. Use **Teach Back:** State, "I want to be sure that I explained how to regulate your oxygen flow rate. Can you show me how you will set the flow rate? Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.

be in accordance with federal, state, and local regulations (AARC, 2007).

• Place an "Oxygen in Use" sign on the patient's door and in the patient's room. If using oxygen at home, place a sign on the door of the house. No smoking should be allowed on the premises.

• Keep oxygen-delivery systems 10 feet from any open flames.

• Determine that all electrical equipment in the room is functioning correctly and properly grounded (see Chapter 27). An electrical spark in the presence of oxygen can result in a serious fire.

• When using oxygen cylinders, secure them so they do not fall over. Store them upright and either chained or secured in appropriate holders.

• Check the oxygen level of portable tanks before transporting a patient to ensure that there is enough oxygen in the tank.

• Ensure that patients have adequate oxygen tubing to safely move around their home environment. Tubing up to 98 feet (30 m) will deliver the prescribed oxygen flow rate (Aguiar et al., 2015).

Supply of Oxygen. Oxygen is supplied to a patient's bedside either by oxygen tanks or through a permanent wall-piped system. Oxygen tanks are transported on wide-based carriers that allow the tank to be placed upright at the bedside. Regulators control the amount of oxygen delivered. One common type is an upright flowmeter with a flow adjustment valve at the top. A second type is a cylinder indicator with a flow adjustment handle.

In the hospital or home oxygen tanks are delivered with the regulator in place. In the hospital the respiratory care department usually connects the regulator to the oxygen source. Home care vendors are usually responsible for connecting the oxygen tank to the regulator for home use.

Methods of Oxygen Delivery. The nasal cannula and oxygen masks are the most common devices to deliver oxygen to patients. These devices deliver different levels of oxygen to patients (Table 41-7).

Nasal Cannula. A **nasal cannula** is a simple, comfortable device used for precise oxygen delivery. The two nasal prongs are slightly curved and inserted in a patient's nostrils. To keep the nasal prongs in place, fit the attached tubing over the patient's ears and secure it under the chin using the sliding connector. Be alert for skin breakdown over the ears and in the nostrils from too tight an application. Attach the nasal cannula to a humidified oxygen source with a flow rate up 1 to 6 L/min (24% to 44% oxygen). Flow rates equal to or greater than 4 L/min have a drying effect on the mucosa and thus need to be humidified (AARC, 2007). Know which flow rate produces a given percentage of inspired oxygen concentration (FiO_2).

Oxygen Masks. An oxygen mask is a plastic device that fits snugly over the mouth and nose and is secured in place with a strap. It delivers oxygen as the patient breathes through either the mouth or nose by way of a plastic tubing at the base of the mask that is attached to an oxygen source. An adjustable elastic band is attached to either side of the mask that slides over the head to above the ears to hold the mask in place. There are two primary types of oxygen masks: those delivering low concentrations of oxygen and those delivering high concentrations (see Box 41-9).

The simple face mask (Figure 41-16) is used for short-term oxygen therapy. It fits loosely and delivers oxygen concentrations from 6 to 12 L/min (35% to 50% oxygen). The mask is contraindicated for patients with carbon dioxide retention because retention can be worsened. Flow rates should be 5 L or more to avoid rebreathing exhaled carbon dioxide retained in the mask. Be alert to skin breakdown under the mask with long-term use (Downie et al., 2013).

A plastic face mask with a reservoir bag is capable of delivering higher concentrations of oxygen. A partial rebreather or nonrebreather mask is a simple mask with a reservoir bag that should be at least one third to one half full on inspiration and delivers a flow rate of 10 to 15 L/min (60% to 90% oxygen). Frequently inspect the reservoir bag to make sure that it is inflated. If it is deflated, the patient is breathing large amounts of exhaled carbon dioxide. High-flow oxygen systems should be humidified (AARC, 2007).

The Venturi mask delivers higher oxygen concentrations of 24% to 60% and usually requires oxygen flow rates of 4 to 12 L/min, depending on the flow-control meter selected.

Home Oxygen Therapy. Indications for home oxygen therapy include an arterial partial pressure (PaO_2) of 55 mm Hg or less or an arterial oxygen saturation (SaO_2) of 88% or less on room air at rest, on exertion, or with exercise (American Thoracic Society, 2011). Home

TABLE 41-7 Oxygen Delivery Systems

Delivery System	FiO_2 Delivered	Advantages	Disadvantages
Low-Flow Delivery Devices			
Nasal cannula	1-6 L/min: 24%-44%	Safe and simple Easily tolerated Effective for low concentrations Does not impede eating or talking Inexpensive, disposable	Unable to use with nasal obstruction Drying to mucous membranes Can dislodge easily May cause skin irritation or breakdown around ears or nares Patient's breathing pattern (mouth or nasal) affects exact FiO_2
Simple face mask	6-12 L/min: 35%-50%	Useful for short periods such as patient transportation	Contraindicated for patients who retain CO_2 May induce feelings of claustrophobia Therapy interrupted with eating and drinking Increased risk of aspiration
Partial and nonrebreather masks	10-15 L/min: 60%-90%	Useful for short periods Delivers increased FiO_2 Easily humidifies O_2 Does not dry mucous membranes	Hot and confining; may irritate skin; tight seal necessary Interferes with eating and talking Bag may twist or kink; should not totally deflate
Oxygen-conserving cannula *(Oxymizer)*	8 L/min: up to 30%-50%	Indicated for long-term O_2 use in the home Allows increased O_2 concentration and lower flow	Cannula cannot be cleaned More expensive than standard cannula
High-Flow Delivery Devices			
Venturi mask	24%-50%	Provides specific amount of oxygen with humidity added Administers low, constant O_2	Mask and added humidity may irritate skin Therapy interrupted with eating and drinking Specific flow rate must be followed

CO_2, Carbon dioxide; *FiO_2,* fraction of inspired oxygen concentration.

FIGURE 41-16 Simple face mask.

oxygen therapy is administered via nasal cannula or face mask. Patients with permanent tracheostomies use either a T tube or tracheostomy collar (AARC, 2007). Home oxygen therapy has beneficial effects for patients with chronic cardiopulmonary diseases. This therapy improves patients' exercise tolerance and fatigue levels and in some situations assists in the management of dyspnea (see Skill 41-4).

There are three types of oxygen delivery systems: compressed gas cylinders, liquid oxygen, and oxygen concentrators. Before placing a certain delivery system in a home, assess the advantages and disadvantages (Table 41-8) of each type, along with the patient's needs and community resources. In the home the major consideration is the oxygen-delivery source.

Patients and their family caregivers need extensive teaching to be able to manage oxygen therapy efficiently and safely (see Skill 41-4 on pp. 927-929). Teach the patient and family about home oxygen delivery (e.g., oxygen safety, regulation of the amount of oxygen, and how to use the prescribed home oxygen-delivery system) to ensure their ability to maintain the oxygen-delivery system. The home health nurse coordinates the efforts of the patient and family, home respiratory therapist, and home oxygen equipment vendor. The social worker usually assists initially with arranging for the home care nurse and oxygen vendor.

> **QSEN** **QSEN: BUILDING COMPETENCY IN SAFETY** Mr. Jackson, a 68-year-old has a history of chronic obstructive pulmonary disease for 2 years. His SpO_2 ranges from 75% to 82%. Upon reviewing the care plan of your patient Mr. Edwards; you note that the plan is to send him home on oxygen. How do you promote safe oxygen delivery in his home?
>
> (e) *Answers to QSEN Activities can be found on the Evolve website.*

Restoration of Cardiopulmonary Functioning. If a patient's hypoxia is severe and prolonged, cardiac arrest results. A cardiac arrest is a sudden cessation of cardiac output and circulation. When this occurs, oxygen is not delivered to tissues, carbon dioxide is not transported from tissues, tissue metabolism becomes anaerobic, and metabolic and respiratory acidosis occurs. Permanent heart, brain, and other tissue damage occur within 4 to 6 minutes.

Cardiopulmonary Resuscitation. During cardiac arrest there is an absence of pulse and respiration. The American Heart Association continues to research cardiac arrest treatment and outcomes. The 2010 Consensus Conference reviewed the most current and comprehensive resuscitation literature/research to develop the *2010 AHA Guidelines for Cardiopulmonary Resuscitation (CPR) and Emergency Cardiac Care (ECC),* thus simplifying the basic life support (BLS) steps (AHA, 2010b).

TABLE 41-8	Home Oxygen Storage Systems	
Primary Use	**Advantages**	**Disadvantages**
Compressed Gas Cylinders Stationary and portable systems designed for intermittent therapy such as for exercise or sleep or as a back-up system for a concentrator only.	100% oxygen stored in steel or aluminum cylinders; relatively inexpensive, no loss of gas during storage, relatively portable, delivery of up to 15 L/min; does not require electrical source; smaller tanks available for portability.	Bulky and heavy; must be secured safely to prevent them from falling over; frequent refilling necessary with continuous use; patient must know how to read regulator and understand when to call supplier; portable cylinders weigh 15 lbs.
Liquid Oxygen Systems Stationary and portable system of choice for high-volume users and active patients.	100% oxygen; more oxygen occupies a smaller space; patient carries convenient ambulatory units refilled at home as shoulder bag, backpack, or wheeled luggage cart; delivery of up to 6 L/min; they come with a battery pack or electrical connections for cars; patient can safely refill ambulatory units from larger reservoir; quiet and easy operation; minimal maintenance; does not require electricity for operation; requires relatively fewer deliveries of oxygen.	Evaporates, especially in warmer temperatures and when not in use; potential for connections to freeze together or form frost at connections if tight connection not maintained during filling; costly setup and delivery fees. The liquid oxygen is very cold and can harm the skin instantly upon contact.
Oxygen Concentrators Stationary system; cost-effective for patients requiring low-flow continuous oxygen and patients with limited mobility inside or outside the home.	Provide a large source of oxygen, inexpensive, fixed monthly costs; most units with delivery of 1 to 5 L/min; good choice for people who do not leave their homes frequently; no cylinders or tanks to refill; delivery up to 10 L/min with specific makes and models. They must be placed in an open, well-ventilated area away from heat and flames. They work by removing nitrogen from room air to make the air 94% to 98% oxygen. They can be small and can weigh from 22 to 70 pounds.	Oxygen concentration decreases as liter flow increases; power supply needed; increased electric costs; is not an ambulatory unit, therefore requires second system for portability; requires regular maintenance and backup system.
Compressed Gas Small cylinders with compressed gas that allow for portability.	Different models allow from 1 to 5 hours of portable oxygen. Cylinders can be easily wheeled on a cart or a stroller. Smaller tanks can be carried in backpacks, fanny packs, or shoulder bags. Each cylinder is fitted with a regulator used for adjusting the flow rate. At a rate of 2 L/min, they last only a few hours. The most common cylinder used is the E-cylinder; it lasts about 5 hours at a rate of 2 L/min.	They only last a few hours. E-cylinders are not appropriate as a sole source of oxygen for continuous, long-term therapy.

National Heart, Lung, and Blood Institute: What is oxygen therapy? 2012, http://www.nhlbi.nih.gov/health/health-topics/topics/oxt. Accessed May 2015.
The COPD Foundation: *COPD oxygen therapy systems: container/storage and delivery system,* Web MD Medical Reference from the COPD Foundation, 2010, http://www.webmd.com/lung/copd/deciding-which-oxygen-system-meets-your-needs. Accessed May 2015.

The previous ABC (establish an *A*irway, initiate *B*reathing, and maintain *C*irculation) of **cardiopulmonary resuscitation (CPR)** is changed to CAB (*C*hest compression, *A*irway, *B*reathing) for adults and pediatric patients (excluding newborns). In adults (the majority of cardiac arrests) the critical initial elements found to be essential for survival were chest compressions and early defibrillation. Ventilation is done after the first cycle of 30 chest compressions. In addition the AHA (2014) has set a goal for hospitals to deliver the first electrical shock to patients in ventricular fibrillation in less than 2 minutes.

Another issue is that bystander CPR may increase if those not comfortable with doing ventilations would at least perform chest compression. For most adults with out-of-the-hospital arrest, hands-only CPR by bystanders has had similar outcomes to conventional CPR. A lone health care provider who sees an adult in cardiac arrest should activate the emergency response system, get and use an automatic external defibrillator (AED) if available, and give CPR. Defibrillation by AED (Box 41-10) is needed to stop an abnormal heart rhythm, and

AEDs are now available in public places such as schools, airports, and workplaces (AHA, 2006, 2010a, b).

Restorative and Continuing Care. Restorative and continuing care emphasizes cardiopulmonary reconditioning as a structured rehabilitation program. **Cardiopulmonary rehabilitation** helps patients achieve and maintain an optimal level of health through controlled physical exercise, nutrition counseling, relaxation and stress-management techniques, and prescribed medications and oxygen. As physical reconditioning occurs, a patient's complaints of dyspnea, chest pain, fatigue, and activity intolerance decrease. In addition, the patient's anxiety, depression, or somatic concerns often decrease. The patient and the rehabilitation team define the goals of rehabilitation.

Respiratory Muscle Training. Respiratory muscle training improves muscle strength and endurance, resulting in improved activity tolerance. Respiratory muscle training prevents respiratory failure in patients with COPD. One method for respiratory muscle training is the incentive spirometer resistive breathing device (ISRBD). Patients

---

BOX 41-10 **Automated External Defibrillator**

- The automated external defibrillator (AED) is a device used to administer an electrical shock through the chest wall to the heart to stop the abnormal rhythm and restore a normal heart rhythm.
- The AED has built-in computers that assess patient's heart rhythm and determine if defibrillation is necessary. New technology has made them user friendly with audio and visual cues telling users what to do when using them (AHA, 2010b, 2011). The AED analyzes the patient's heart rhythm and determines if a shock is needed. It delivers a shock to the patient after announcing, "Everyone stand clear of patient." A shock is only delivered if the patient needs it.
- Lay rescuer AED programs train lay personnel (security guards, police, and firefighters) on the use of the AED (AHA, 2006, 2010b, 2011).
- The AED is used to strengthen the chain of survival. Every minute of a sudden cardiac arrest without defibrillation decreases the survival rate by 7% to 10% (AHA, 2011).

For witnessed ventricular fibrillation, early cardiopulmonary resuscitation with defibrillation within the first 3 to 5 minutes can result in greater than 50% long-term survival (AHA, 2010a).

Knowledge
- Characteristics of adequate oxygenation status
- Understanding of patient's care expectations

Experience
- Previous patient responses to planned nursing therapies for impaired oxygenation

EVALUATION
- Evaluate signs and symptoms of the patient's oxygenation status after nursing interventions
- Ask for the patients perception of oxygenation status after interventions
- Ask if the patient's expectations are being met

Standards
- Use established expected outcomes to evaluate the patient's response to care (e.g., pulse oximetry remains above 92%, respiratory rate remains between 20 and 24 breaths/min)
- Apply intellectual standards of clarity, precision, specificity, and accuracy when evaluating outcomes of care

Attitudes
- Demonstrate perseverance when an intervention is unsuccessful and must be revised
- Use discipline to reassess and evaluate the patient's signs and symptoms to determine the true success of interventions

FIGURE 41-17 Critical thinking model for oxygenation evaluation.

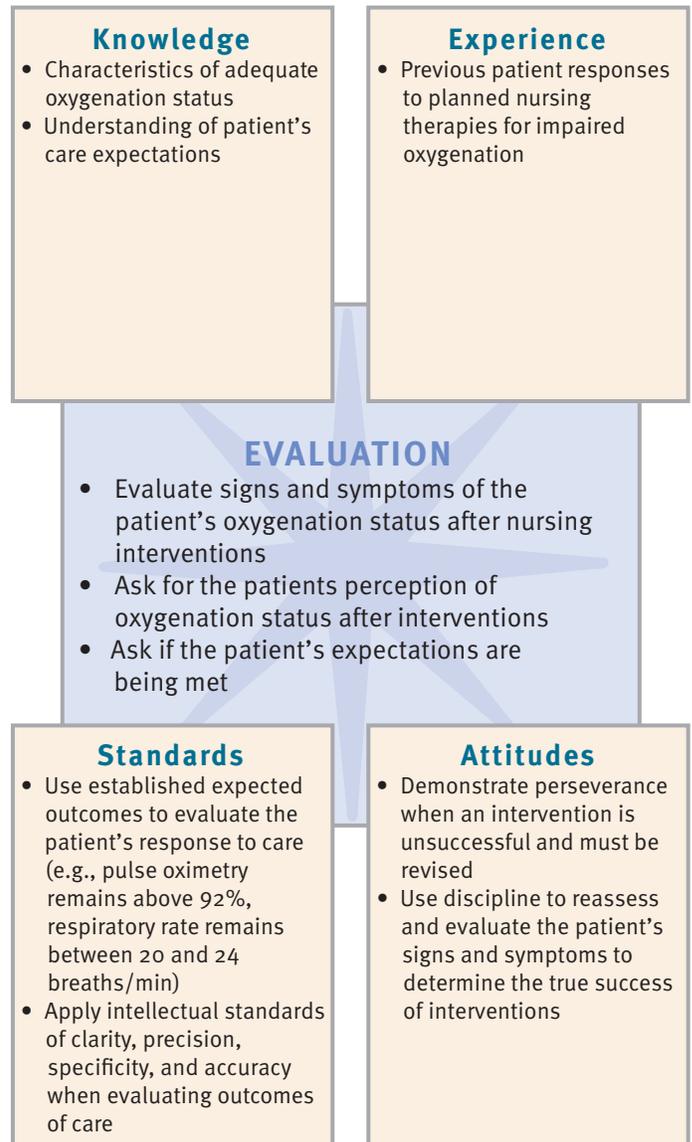
---

achieve resistive breathing by placing a resistive breathing device into a volume-dependent incentive spirometer. Patients achieve muscle training when they use the ISRBD on a scheduled routine (e.g., twice a day for 15 minutes or 4 times a day for 15 minutes).

Breathing Exercises. Breathing exercises include techniques to improve ventilation and oxygenation. The three basic techniques are deep-breathing and coughing exercises, pursed-lip breathing, and diaphragmatic breathing. Deep-breathing and coughing exercises, previously discussed, are routine interventions used by postoperative patients (see Chapter 50).

Pursed-Lip Breathing. **Pursed-lip breathing** involves deep inspiration and prolonged expiration through pursed lips to prevent alveolar collapse. While sitting up, instruct the patient to take a deep breath and exhale slowly through pursed lips as if blowing through a straw. Have him or her blow through a straw into a glass of water to learn the technique. Patients need to gain control of the exhalation phase so it is longer than inhalation. The patient is usually able to perfect this technique by counting the inhalation time and gradually increasing the count during exhalation. In studies using pursed-lip breathing as a method to improve exercise tolerance in patients with COPD, patients were able to demonstrate increases in their exercise tolerance, breathing pattern, and arterial oxygen saturation (Cabral et al., 2014).

Diaphragmatic Breathing. **Diaphragmatic breathing** is useful for patients with pulmonary disease, postoperative patients, and women in labor to promote relaxation and provide pain control. The exercise improves efficiency of breathing by decreasing air trapping and reducing the WOB.

Diaphragmatic breathing is more difficult than other breathing methods because it requires a patient to relax intercostal and accessory respiratory muscles while taking deep inspirations, which takes practice. The patient places one hand flat below the breastbone (upper hand) and the other hand (lower hand) flat on the abdomen. Ask him or her to inhale slowly, making the abdomen push out (as the diaphragm flattens, the abdomen should extend out) and moving the lower hand outward. When the patient exhales, the abdomen goes in (the diaphragm ascends and pushes on lungs to help expel trapped air). The patient practices these exercises initially in the supine position and then while sitting and standing. The exercise is often used with the pursed-lip breathing technique.


◆ **Evaluation**

Evaluate nursing interventions and therapies by evaluating if patient expectations have been met and by comparing the patient's progress with the goals and expected outcomes of the nursing care plan (Figure 41-17).

Through the Patient's Eyes. It is important to determine a patient's perceptions of his or her care. Does the patient feel that interventions have improved the ability to maintain a more normal lifestyle? Focus on evaluating how the disease is affecting day-to-day activities and how the patient believes he or she is responding to treatment. Patients who have chronic lung problems often must be motivated to participate in necessary therapies. Evaluate the patient's motivation and emotional readiness to adhere to treatments provided. Be aware of the need to change a treatment plan to be culturally sensitive to improve adherence. Determine if the patient and family/caregiver feel more in control of their health situation after you have provided instruction. Consider the use of survey tools such as the COPD Self-Efficacy Scale, Chronic Respiratory Disease Questionnaire, and

Pulmonary-Specific Quality of Life for COPD Scale (AARC, 2010b) to evaluate a patient's perception of his or her quality of life.

   Patient Outcomes. Compare the patient's actual progress to the goals and expected outcomes of the nursing care plan to determine his or her health status. If the nursing measures used are not successful in improving oxygenation, modify the care plan and reevaluate. Continuous evaluation helps to determine whether new or revised therapies are required and if new nursing diagnoses have developed and require a new plan of care. Do not hesitate to notify the health care provider about a patient's deteriorating oxygenation status. Prompt notification helps avoid an emergency situation or even the need for CPR. Examples of evaluative measures include:

- Ask the patient about his or her degree of breathlessness. Observe respiratory rate before, during, and after any activity or procedure.

- Ask the patient if the distance ambulated without fatigue has increased.
- Ask the patient to rate breathlessness on a scale of 0 to 10, with 0 being no shortness of breath and 10 being severe shortness of breath.
- Ask the patient which interventions help reduce dyspnea.
- Ask the patient about frequency of cough and sputum production and assess any sputum produced.
- Auscultate lung sounds for improvement in adventitious sounds.
- Evaluate pulse oximetry changes to decreases in oxygen delivery.
- Monitor arterial blood gas levels, pulmonary function tests, chest x-ray films, ECG tracings, and physical assessment data to provide objective measurement of the success of therapies and treatments.

SAFETY GUIDELINES FOR NURSING SKILLS

Ensuring patient safety is an essential role of the professional nurse. To ensure patient safety, communicate clearly with members of the health care team, assess and incorporate the patient's priorities of care and preferences, and use the best evidence when making decisions about your patient's care. When performing the skills in this chapter, remember the following points to ensure safe, individualized patient care.

- Patients with sudden changes in their vital signs, level of consciousness, or behavior are possibly experiencing profound hypoxia. Patients who demonstrate subtle changes over time have worsening of a chronic or existing condition or a new medical condition.
- Perform tracheal suctioning before pharyngeal suctioning whenever possible. The mouth and pharynx contain more bacteria than the trachea. If there is an abundance of oral secretions present before beginning the procedure, suction mouth with separate oral suction device.
- Use caution when suctioning patients with a head injury. Suctioning elevates the intracranial pressure (ICP). Reduce this risk by hyperventilating on a ventilator prior to suctioning. This results in hypocarbia that in turn induces vasoconstriction. Vasoconstriction reduces the potential increase in ICP. It is recommended that you limit the introduction of the catheter to 2 times with each suctioning procedure (Kaiser et al., 2011).

- The routine use of normal saline instillation into the airway before endotracheal and tracheostomy suctioning is not recommended. Use of NSI is associated with the adverse effects of excessive coughing, bronchospasm, spread of organisms to the lower respiratory tract, and decreased oxygen saturation (AARC, 2010b). In certain circumstances, if it is necessary to simulate a cough, normal saline may be indicated. This requires collaboration with the health care team.
- Check your institutional policy before stripping or milking chest tubes. Most institutions have stopped using this practice because stripping the tube greatly increases intrapleural pressure, which can damage the pleural tissue and cause pneumothorax or worsen an existing pneumothorax.
- The most serious tracheostomy complication is airway obstruction, which can result in cardiac arrest. Most tracheostomy tubes are designed with a small plastic inner tube that sits inside the larger one. If the airway becomes occluded, the smaller one can be removed and replaced with a temporary spare. It is important to always have a spare at the bedside for emergency replacement.
- Patients with COPD who are breathing spontaneously should never receive high levels of oxygen therapy because it results in a decreased stimulus to breathe. Do not administer oxygen more than 2 L/min unless a health care provider's order is obtained (AARC, 2007).

| SKILL 41-1 | SUCCIONING | ⏵ |

DELEGATION CONSIDERATIONS

The skill of nasotracheal suctioning and suctioning a new artificial airway cannot be delegated to nursing assistive personnel (NAP). However, when a patient has been assessed by the nurse to be stable, oropharyngeal and permanent tracheostomy tube suctioning can be delegated to NAP. Instruct NAP about:

- Any modifications of the skill such as the need to reapply any supplemental oxygen equipment following the procedure.
- Appropriate suction limits and risk of applying excessive or inadequate suction pressure.
- Reporting any change in patient's respiratory status, level of consciousness, secretion color or volume, or unresolved coughing or gagging.
- Reporting any change in patient's color, vital signs, or complaints of pain.

EQUIPMENT

- Stethoscope
- Pulse oximeter
- Portable or wall suction machine
- Connecting tubing (6 feet)
- Bedside table
- Mask, goggles, gown, or face shield, if indicated

Oropharyngeal (Nonsterile) and Nasotracheal (Sterile) Suctioning

- Oropharyngeal suctioning: Clean, nonsterile suction catheter or Yankauer suction tip catheter
  - One sterile and one clean glove
- Nasotracheal suctioning: Sterile suction catheter (12 to 16 Fr) (smallest diameter that effectively removes secretions)
  - Two sterile gloves
- Sterile basin (e.g., sterile disposable cup)
- Sterile water or normal saline (about 100 mL)
- Clean towel or paper drape

Endotracheal or Tracheostomy Suctioning

- 12- to 16-Fr catheter (approximate; size of the suction catheter in an adult patient should be no more than half of the internal diameter of the artificial airway to minimize decrease in PaO_2) (AARC, 2010a). Formula for suction tracheostomy catheter size: divide internal diameter of the tube by 2 and multiply by 3 (Freeman, 2011).
- Two sterile gloves or one sterile and one clean glove
- Sterile basin
- Sterile normal saline (about 100 mL)
- Clean towel or sterile drape

Closed System or In-Line Suctioning

- Closed-system or in-line suction catheter
- 5- to 10-mL normal saline in syringe or vials
- Two clean gloves

| STEP | RATIONALE |

ASSESSMENT

1. Identify patient using two identifiers (e.g., name and birth date or name and medical record number) according to agency policy.

   Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).

2. Assess for signs and symptoms of upper and lower airway obstruction requiring suctioning: abnormal respiratory rate, adventitious sounds on inspiration or expiration, nasal secretions, gurgling, drooling, restlessness, gastric secretions or vomitus in mouth, and coughing without clearing secretions from airway.

   Physical signs and symptoms result from decreased oxygen to tissues and pooling of secretions in upper and lower airways. Complete these assessment measures before and after suction procedure (AARC, 2004).

3. Assess signs and symptoms associated with hypoxia and hypercapnia: decreased SpO_2, increased pulse and blood pressure, increased respiratory rate, apprehension, anxiety, decreased ability to concentrate, lethargy, decreased level of consciousness (especially acute), increased fatigue, dizziness, behavioral changes (especially irritability), dysrhythmias, pallor, and cyanosis.

   Physical signs and symptoms resulting from decreased oxygen to tissues indicate need for suctioning (AARC, 2004).

4. Assess for risk factors for upper or lower airway obstruction, including chronic obstructive pulmonary disease, pulmonary infection, fluid imbalance, lack of humidity, impaired mobility, decreased level of consciousness, decreased gag or cough reflex, dysphagia, presence of feeding tube.

   The presence of these risk factors impairs a patient's ability to clear secretions from the airway, thickens secretions, or increases risk for retaining secretions and thus requires suctioning.

5. Assess for neuromuscular disease or anatomical factors that influence upper or lower airway function, such as recent surgery; head, chest, or neck trauma; tumors.

   Abnormal anatomy or head and neck trauma impairs normal drainage of secretions. Tumors in or around the lower airway impair secretion removal by occluding or externally compressing lumen of airway.

SKILL 41-1	SUCTIONING—cont'd

STEP	RATIONALE
6. Identify **contraindications to nasotracheal suctioning** (AARC, 2004): occluded nasal passages; nasal bleeding, epiglottitis, or croup; acute head, facial, or neck injury or surgery; coagulopathy or bleeding disorder; irritable airway; laryngospasm or bronchospasm; gastric surgery with high anastomosis; myocardial infarction.	These conditions are **contraindicated because the passage of a catheter through the nasal route** causes trauma to existing facial trauma or surgery, increases nasal bleeding, or causes severe bleeding in the presence of bleeding disorders. In the presence of epiglottitis, croup, laryngospasm, or irritable airway, the entrance of a suction catheter via the nasal route causes intractable coughing, hypoxemia, and severe bronchospasm, necessitating emergency intubation or tracheostomy. Hypoxemia could worsen cardiac damage in myocardial infarction (AARC, 2004).
7. Review sputum microbiology data.	Certain bacteria are easier to transmit or require isolation because of virulence or antibiotic resistance.
8. Assess patient's understanding of procedure.	Reveals need for patient instruction.

PLANNING

1. Explain to patient how procedure will help clear airway and relieve breathing problems and that temporary coughing, sneezing, gagging, or shortness of breath is normal. Encourage patient to cough out secretions.	Encourages cooperation and minimizes risks, anxiety, and pain.
2. Explain importance of and encourage coughing when catheter is introduced. Have patient practice coughing if able and splint surgical incisions (if present).	Facilitates secretion removal and reduces frequency and duration of future suctioning.
3. Assist patient with assuming comfortable position (usually semi-Fowler's or sitting upright with head hyperextended, unless contraindicated). Stand on patient's right if you are right-handed or on patient's left if you are left-handed.	Reduces stimulation of gag reflex, promotes patient comfort and secretion drainage, and prevents aspiration. Hyperextension facilitates insertion of catheter into trachea. Position facilitates catheter insertion.
4. If not already in place, position pulse oximeter on patient's finger. Take reading and leave pulse oximeter in place.	Provides baseline SpO$_2$ to determine patient's response to suctioning.
5. Place towel across patient's chest.	Reduces transmission of microorganisms by protecting gown from secretions.

IMPLEMENTATION

1. Perform hand hygiene. Apply mask, gown, goggles, or face shield if splashing is likely.	Reduces transmission of microorganisms.
2. Connect one end of connecting tubing to suction machine and place other end in convenient location near patient. Turn suction device on and set vacuum regulator to appropriate negative pressure: 120 to 150 mm Hg for adults (AARC, 2010a), 40 to 60 mm Hg for infants, and 60 to 100 mm Hg for children (Hockenberry and Wilson, 2015).	Excessive negative pressure damages nasal, pharyngeal, and tracheal mucosa and induces greater hypoxia. Negative pressures should not exceed 150 mm Hg because higher pressure increases risk for airway trauma, hypoxemia, and atelectasis (AARC, 2010a).
3. If indicated, increase supplemental oxygen therapy to 100% or as ordered by health care provider. Encourage patient to deep breathe.	Hyperoxygenation provides some protection from suction-induced decline in oxygenation. It is most effective in the presence of hyperinflation such as encouraging patient to deep breathe or increase ventilator tidal volume settings (Sole et al., 2014; AARC, 2010a).
4. Preparation for all types of suctioning (except in-line).	
a. Open appropriate suction kit or catheter, using aseptic technique and leaving catheter in sterile wrapper or kit. If sterile drape is available, place it across patient's chest or on over-bed table. Do not allow suction catheter to touch any nonsterile surfaces.	Prepares catheter and prevents transmission of microorganisms. Provides sterile surface on which to lay suction catheter between passes, if needed.
b. Unwrap or open sterile basin and place on bedside table. Fill basin or cup with approximately 100 mL of sterile normal saline solution or water (see illustration).	Solution is used to flush catheter after each suction pass.
c. Open lubricant. Squeeze small amount onto open sterile wrapper or kit without touching it. **NOTE:** Lubricant is not necessary for oropharyngeal or artificial airway suctioning.	Prepares lubricant while maintaining sterility. Use water-soluble lubricant to avoid lipoid aspiration pneumonia. Excessive lubricant application can occlude catheter.

STEP 4b Pouring saline into tray. (Copyright © Mosby's Clinical Skills: Essentials Collection.)

STEP	RATIONALE
5. Apply gloves:	
a. Apply clean glove to each hand or dominant hand for oropharyngeal suctioning.	Suction of oral cavity does not require sterile glove use.
b. Apply sterile glove to each hand or nonsterile glove to nondominant hand and sterile glove to dominant hand for nasopharyngeal, nasotracheal, and artificial airway suctioning.	Reduces transmission of microorganisms and allows nurse to maintain sterility of suction catheter.
6. Pick up suction catheter with dominant hand without touching nonsterile surface. Pick up connecting tubing with nondominant hand. Secure catheter to tubing (see illustration).	
7. Place tip of catheter into sterile basin and suction a small amount of normal saline by occluding suction vent.	Ensures suction is functioning. Lubricates internal catheter and tubing.
8. Suction airway.	
a. Oropharyngeal suctioning	
(1) Remove oxygen mask if present. Keep oxygen mask near patient's face. If patient has a nasal cannula, it may remain in place.	Allows access to patient's mouth while having access to oxygen-delivery system.

CLINICAL DECISION: *Be prepared to quickly reapply oxygen mask if SpO$_2$ falls or respiratory distress develops during or at the end of suctioning.*

STEP	RATIONALE
(2) Insert Yankauer catheter into patient's mouth. Apply suction once the catheter is in patient's mouth, move catheter around mouth along gum line to pharynx. Then apply suction and move catheter around mouth until secretions are cleared.	If catheter does not have a suction control to apply intermittent suction, take care not to allow suction tip to irritate oral mucosal surfaces with continuous suction.
(3) Encourage patient to cough and repeat suctioning if needed. Replace oxygen mask if used.	Coughing moves secretions from lower to upper airways into mouth.
(4) Suction water or saline through catheter until catheter is cleared of secretions.	Clearing secretions before they dry reduces probability of transmission of microorganisms and enhances delivery of preset suction pressures.
(5) Place catheter in a clean, dry area for reuse with suction turned off. If patient is capable of self-oral suctioning, place catheter within reach.	Provides for prompt removal of future oral secretions.
b. Nasopharyngeal and nasotracheal suctioning	
(1) Lightly coat distal 6-8 cm (2-3 inches) of catheter tip with water-soluble lubricant.	Lubricates catheter for easier insertion of catheter and reduces mucosal surface trauma.
(2) If indicated increase supplemental oxygen therapy as ordered by health care provider. Have patient deep breathe with oxygen delivery device or hyperoxygenate with ventilation bag as ordered.	Hyperoxygenation before suctioning can minimize hypoxemia after suctioning (AARC, 2010a).
(3) Remove oxygen-delivery device, if applicable, with nondominant hand. Without applying suction and using dominant thumb and forefinger, gently insert catheter into naris during inhalation. ***Never apply suction during insertion***.	Application of suction pressure while introducing catheter into nasopharyngeal tissues increases risk of damage to mucosa. When advanced into trachea, suction could damage mucosa and increase risk of hypoxia.

STEP 6 Attaching catheter to suction.

SKILL 41-1	**SUCTIONING—cont'd**

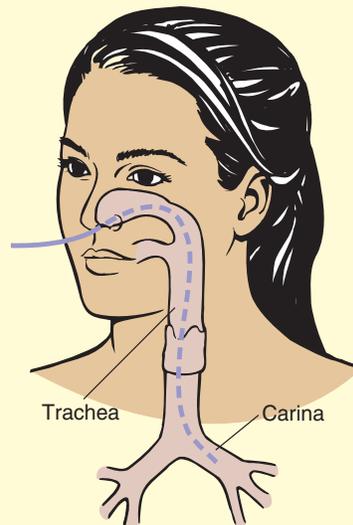
STEP	**RATIONALE**

CLINICAL DECISION: *Be sure to insert catheter during patient inhalation. This closes epiglottis, making it easier to pass catheter through larynx into trachea. Do not insert during swallowing, or catheter will most likely enter the esophagus. If patient gags or becomes nauseated, the catheter is most likely in the esophagus and must be removed.*

(4) *Nasopharyngeal:* As patient takes a deep breath, insert catheter, following natural course of naris; slightly slant catheter downward and advance to back of pharynx. Do not force through naris. In adults insert catheter about 20 cm (6 to 8 inches); in older children, 16 to 20 cm (6 to 8 inches); in infants and young children, 4 to 14 cm (3 to 5 ½ inches) into trachea until resistance is met or patient coughs; then pull back 1 to 2 cm (½ inch).	Proper placement ensures removal of pharyngeal secretions. Pulling back on catheter before initiating suctioning prevents invagination of the tracheal membrane (AARC, 2010a).
(a) Apply intermittent suction for no more than 10 seconds by placing and releasing nondominant thumb over catheter vent (AARC, 2010a). Slowly withdraw catheter while rotating it back and forth between thumb and forefinger.	Intermittent suction up to 10 seconds safely removes pharyngeal secretions. Suction time greater than 10 seconds increases risk for suction-induced hypoxemia (AARC, 2010a).
(5) *Nasotracheal:* As patient takes deep breath, advance catheter following natural course of naris. Advance catheter slightly slanted and downward to just above entrance into larynx and then the trachea. While patient takes a deep breath, quickly insert catheter about 15 to 20 cm (6 to 8 inches in adult) into trachea (see illustration). Patient will begin to cough, then pull back catheter 1 to 2 cm (½ inch) before applying suction.	Ensures that catheter is inserted into trachea with minimum stress to patient. In young children and infants, shallow suctioning is recommended instead of deep tracheal suctioning, which increases the risk of tracheal edema and inflammation (AARC, 2010a).
NOTE: In older children advance the catheter 16 to 20 cm (6 to 8 inches), and in young children and infants, 8 to 14 cm (3 to 5 ½ inches).	Premeasured suction catheters are used in some pediatric settings to avoid deep suctioning (Hockenberry and Wilson, 2015).

CLINICAL DECISION: *When there is difficulty passing the catheter, ask patient to cough or say "ahh" or try to advance during inspiration. Both these measures assist in opening the glottis to permit passage of the catheter into the trachea.*

(a) *Positioning option:* In some instances turning patient's head to right helps suction the left mainstem bronchus; turning head to left helps suction the right mainstem bronchus.	Turning patient's head to the side elevates the bronchial passage on the opposite side and facilitates passage of the catheter.
(b) If you feel resistance after insertion of catheter to maximum recommended distance, catheter has probably hit carina. Pull it back 1 to 2 cm (½ inch) before applying suction.	

CLINICAL DECISION: *Use nasotracheal suctioning before pharyngeal suctioning whenever possible. The mouth and pharynx contain more bacteria than the trachea. If copious oral secretions are present before beginning the procedure, suction mouth with oral suction device.*


STEP 8b(5) Distance of insertion of nasotracheal catheter.

STEP	RATIONALE
(c) Apply intermittent suction for no more than 10 seconds by placing and releasing nondominant thumb over vent of catheter. Slowly withdraw catheter while rotating it back and forth between the dominant thumb and forefinger. Encourage patient to cough. Replace oxygen device if applicable.	Intermittent suction and rotation of catheter prevent injury to mucosa. If catheter "grabs" mucosa, remove thumb to release suction. Suctioning longer than 10 seconds causes cardiopulmonary compromise, usually from hypoxemia or vagal overload.

CLINICAL DECISION: *Monitor patient's vital signs and oxygen saturation during procedure; note whether there is a change of 20 beats/min (either increase or decrease) or if pulse oximetry falls below 90% or 5% from baseline. If this occurs, stop suctioning.*

STEP	RATIONALE
(6) Rinse catheter and connecting tubing with normal saline or water until cleared.	Removes secretions from catheter. Secretions that remain in suction catheter or connecting tubing decrease suctioning efficiency.
(7) Assess for need to repeat suctioning procedure. Do not perform more than two passes with catheter. Allow at least 1 minute between passes for ventilation and oxygenation (AARC, 2010a). Ask patient to deep breathe and cough.	Observe for alterations in cardiopulmonary status. Suctioning induces hypoxemia, dysrhythmias, laryngospasm, and bronchospasm (AARC, 2010a). Hyperoxygenation is recommended before, during, and after open suctioning to reduce risk for suction-induced hypoxemia (Yazdannik et al., 2013). Repeated passes clear the airway of excessive secretions but also remove oxygen and can induce laryngospasm.

c. Artificial airway (tracheostomy or endotracheal [ET] tube) suctioning

CLINICAL DECISION: *Reduces transmission of microorganisms.* **Note:** *If risk for splash is present or patient is on respiratory precautions, gown, face shield or mask, and goggles may be needed.*

STEP	RATIONALE
(1) Check that equipment is functioning properly by placing tip of catheter into basin and suctioning small amount of saline by occluding suction vent.	Ensures equipment function; lubricates catheter and tubing.
(2) Hyperoxygenate patient before suctioning using manual resuscitation bag and increasing FiO_2 for several minutes; or, if mechanically ventilated, use the ventilator to provide additional breaths without increasing tidal volume. Some mechanical ventilators have a button that, when pushed, delivers 100% oxygen for a few minutes and then resets to the previous value.	Hyperoxygenation for 30-60 seconds decreases suction-induced hypoxemia. Most sources recommend hyperoxygenation with 100% oxygen in the adult patient (AARC, 2010a).
(3) If patient is receiving invasive mechanical ventilation, open swivel adapter or, if necessary, remove oxygen- or humidity-delivery device with nondominant hand.	Exposes artificial airway.
(4) Advise patient that you are about to begin suctioning and, without applying suction, gently but quickly insert catheter using dominant thumb and forefinger into artificial airway (see illustration). Insert catheter during inspiration until you meet resistance or patient coughs; then pull back 1 cm ($\frac{1}{2}$ inch) (Ozden and Gorgulu, 2012).	Prepares patient for procedure. Application of suction pressure while introducing catheter into trachea increases risk of damage to tracheal mucosa and increased hypoxia related to removal of entrained oxygen present in airways. Pulling back stimulates cough and removes catheter from mucosal wall so catheter is not resting against tracheal mucosa during suctioning.

STEP 8c(4) Suctioning tracheostomy.

SKILL 41-1	SUCTIONING—cont'd

STEP	RATIONALE

CLINICAL DECISION: *If unable to insert catheter past the end of the ET tube, it is probably caught in the Murphy eye (e.g., side hole at the distal end of the ET tube that allows for collateral airflow in the event of mainstem intubation). If this happens, rotate the catheter to reposition it away from the Murphy eye or withdraw it slightly and reinsert with the next inhalation. Usually the catheter meets resistance at the carina. One indication that the catheter is at the carina is acute onset of coughing because the carina contains many cough receptors. Pull the catheter back 1 cm ($\frac{1}{2}$ inch).*

STEP	RATIONALE
(5) Apply intermittent suction no longer than 10 seconds (Ozden and Gorgulu, 2012). Apply intermittent suction by placing and releasing nondominant thumb over vent of catheter; slowly withdraw catheter while rotating it back and forth between dominant thumb and forefinger (AARC, 2010a). Encourage patient to cough. Watch for respiratory distress.	Intermittent suction and rotation of catheter prevent injury to tracheal mucosal lining. If catheter "grabs" mucosa, remove thumb to release suction.

CLINICAL DECISION: *If patient develops respiratory distress, immediately withdraw catheter and supply additional oxygen and breaths as needed. In an emergency administer oxygen directly through the catheter. Disconnect suction and give 100% oxygen through the catheter.*

STEP	RATIONALE
(6) If patient is receiving invasive mechanical ventilation, close swivel adapter or replace oxygen-delivery device.	Reestablishes the artificial airway.
(7) Encourage patient to deep breathe if able. Some patients respond well to several manual breaths from the mechanical ventilator or bag-valve mask.	Reoxygenates and expands alveoli. Suctioning sometimes causes hypoxemia and atelectasis.
(8) Rinse catheter and connecting tubing with normal saline until clear. Use continuous suction.	Removes catheter secretions. Secretions left in tubing decrease suction and provide environment for microorganism growth. Secretions left in connecting tube decrease suctioning efficiency.
(9) Assess patient's cardiopulmonary status for secretion clearance and complications. Repeat Steps (2) through (5) once or twice more to clear secretions. Allow adequate time (at least 1 full minute) between suction passes for ventilation and hyperoxygenation. Do not perform more than two passes with the catheter (AARC, 2010a).	Suctioning sometimes induces dysrhythmias, hypoxia, and bronchospasm and impairs cerebral circulation or adversely affects hemodynamics (AARC, 2010a). Repeated passes with suction catheter clear airway of excessive secretions and promote improved oxygenation.
(10) Perform nasopharyngeal and oropharyngeal suctioning if necessary. After performing nasopharyngeal and oropharyngeal suctioning, catheter is contaminated; do not reinsert into ET or tracheostomy tube.	Upper airway is "clean," and lower airway is "sterile." Therefore you can use the same catheter to suction from sterile to clean areas but not from clean to sterile areas.
d. Artificial airway (tracheostomy or endotracheal [ET] tube) using inline suctioning	
(1) In many facilities a respiratory therapist attaches catheter to mechanical ventilator circuit. If the catheter is not already in place, open closed-suction catheter package using aseptic technique, attach catheter to ventilator circuit by removing swivel adapter, and place catheter apparatus on endotracheal or tracheostomy tube. Connect Y on mechanical ventilator circuit to closed-suction catheter with flex tubing (see Fig. 41-10).	Attaches suction catheter to the ET or tracheostomy if not already done in order to perform inline suctioning. In some settings the catheter is attached to the closed ventilator circuit by a respiratory therapist.
(2) Connect one end of connecting tubing to suction machine and the other to the end of a closed system or in-line suction catheter, if not already done. Turn suction device on and set vacuum regulator to appropriate negative pressure (see manufacturer directions).	Attaches inline suction catheter to the suction machine if not already done in order to perform inline suctioning. Many closed-system suction catheters require slightly higher suction; consult manufacturer guidelines.
(3) Hyperoxygenate patient (increase FiO_2) with bag-valve mask or manual breathing mechanism on mechanical ventilator according to institution protocol and clinical status (usually 100% oxygen).	Hyperinflation along with hyperoxygenation decreases risk for a decrease in oxygenation saturation. Routine use of hyperinflation is not recommended because of the possibility of trauma resulting from large volumes and high peak pressures (Ozden and Gorgulu, 2012; AARC, 2010a).
(4) Unlock suction control mechanism if required by manufacturer. Open saline port and attach saline syringe or vial.	
(5) Pick up suction catheter enclosed in plastic sleeve with dominant hand.	

STEP	RATIONALE
(6) Wait until patient inhales, then insert catheter using a repeating maneuver of pushing catheter and sliding (or pulling) plastic sleeve back between thumb and forefinger until you feel resistance or patient coughs. Pull back 1 cm (½ inch) before applying suction to avoid tissue damage to carina.	Pushing and sliding the catheter in helps the patient to cough, which aids in bringing up secretions that can then be removed with the inline suction catheter.
(7) Encourage patient to cough and apply suction by squeezing on suction-control mechanism while withdrawing catheter. It is difficult to apply intermittent pulses of suction and nearly impossible to rotate the catheter compared with a standard catheter. Be sure to withdraw catheter completely into plastic sheath so it does not obstruct airflow (AARC, 2004).	Having patient cough helps to bring up additional secretions that can then be suctioned and removed with the inline suction catheter.
(8) Evaluate cardiopulmonary status, including pulse oximetry, to determine need for subsequent suctioning or complications. Repeat Steps (3) through (7) one to two more times to clear secretions. Allow adequate time (at least 1 full minute) between suction passes for ventilation and reoxygenation.	Suctioning sometimes induces dysrhythmias, hypoxia, and bronchospasm and impairs cerebral circulation or adversely affects hemodynamics (AARC, 2010a). Repeated passes with suction catheter clear airway of excessive secretions and promote improved oxygenation.
(9) When airway is clear, withdraw catheter completely into sheath. Be sure that colored indicator line on catheter is visible in the sheath. Squeeze vial or push syringe while applying suction to rinse inner lumen of catheter. Use at least 5 to 10 mL of saline to rinse catheter until it is clear of retained secretions, which cause bacterial growth and increase the risk of infection (AARC, 2004). Lock suction mechanism, if applicable, and turn off suction.	Removes catheter secretions. Secretions left in tubing decrease suction and provide environment for microorganism growth. Secretions left in connecting tube decrease suctioning efficiency.
(10) If patient requires oral or nasal suctioning, perform Skill 41-1 with separate standard suction catheter.	Oral and nasal suctioning require the use of a separate suction catheter in order to maintain the sterility of the inline suction catheter.
(11) Rinse catheter and connecting tubing with normal saline until clear. Use continuous suction.	Removes catheter secretions. Secretions left in tubing decrease suction and provide environment for microorganism growth. Secretions left in connecting tube decrease suctioning efficiency.
9. Complete procedure.	
a. Place Yankauer catheter in a clean, dry area for reuse with suction turned off or within patient's reach with suction on if patient is capable of suctioning self.	Facilitates prompt removal of airway secretions when suctioning is necessary in the future.
b. Disconnect nasal and artificial airway catheters from connecting tubing. Turn off suction. Roll catheter around fingers of dominant hand. Pull glove off inside out so catheter remains in glove. Pull off other glove over first glove in same way to contain contaminants. Discard into appropriate receptacle. Turn off suction device.	Reduces transmission of microorganisms. Do not touch clean equipment with contaminated gloves.
(1) When discarding the inline suction catheter, disconnect by removing it from the ventilator circuit. Dispose of catheter by pulling glove off inside out so catheter remains contained in glove. Before leaving patient's bedside, replace with a new inline catheter as in Step 8d(1).	
c. Remove towel and place in laundry or remove drape and discard in appropriate receptacle.	Reduces transmission of organisms.
d. Reposition patient as indicated by condition. Reapply clean gloves for patient's personal care (e.g., oral hygiene).	Proper positioning based on patient's condition promotes comfort, encourages secretion drainage, and reduces risk of aspiration.
e. If indicated, readjust oxygen to original level.	Helps patient's blood oxygen level return to baseline.

CLINICAL DECISION: *If patient develops respiratory distress during the suctioning procedure, immediately withdraw catheter and supply additional oxygen and breaths as needed. In an emergency administer oxygen directly through the catheter. Disconnect suction and attach oxygen at prescribed flow rate through the catheter.*

f. Discard remainder of normal saline into appropriate receptacle. If basin is disposable, discard into appropriate receptacle. If basin is reusable, rinse and place in soiled utility room.	Solution is contaminated; this reduces transmission of microorganisms.
g. Remove and discard goggles, mask, or face shield and perform hand hygiene.	Reduces transmission of microorganisms.
h. Place unopened suction kit on suction machine table or at head of bed according to institution preference.	Provides for immediate access of suction catheter and equipment in event of an emergency or for next suctioning procedure.

SKILL 41-1	SUCTIONING—cont'd

STEP	RATIONALE

EVALUATION

1. Compare patient's vital signs and SpO$_2$ saturation before and after suctioning.

   Provides objective data about any physiological effects of suctioning.

2. Ask patient if breathing is easier and congestion is decreased.

   Provides subjective confirmation that airway obstruction is relieved with suctioning procedure.

3. Auscultate lungs and compare patient's respiratory assessment before and after suctioning.

   Provides objective information about any improvement in lung sounds.

4. Observe airway secretions.

   Provides data to document presence or absence of respiratory tract infection.

5. Observe patient perform oropharyngeal suctioning.

   Documents patient's ability to correctly perform oral suctioning.

6. Use **Teach Back:** State, "I want to be sure that I explained the suctioning procedure correctly. Squeeze my hand if you understand the steps that we discussed." (You can also use the communication board for a patient with an ETT.) Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.

   Evaluates what the patient is able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Worsening cardiopulmonary status
   - Limit length of suctioning.
   - Determine need for presuctioning hyperoxygenation and hyperinflation.
   - Determine need for more frequent suctioning, possibly shorter duration.
   - Notify health care provider of changes.
2. Return of bloody secretions
   - Determine amount of suction pressure used and adjust accordingly.
   - Evaluate suctioning frequency and reduce if appropriate.
   - Determine other factors that lead to bloody secretions (e.g., prolonged bleeding time).
   - Provide more frequent oral hygiene.
3. Unable to pass suction catheter through first naris attempted
   - Try other naris or oral route.
   - Insert nasal airway, especially if suctioning through patient naris frequently.
   - Guide catheter along naris floor to avoid turbinates.
   - If obstruction is mucus, apply suction to relieve obstruction but do not apply suction to mucosa. If you think obstruction is a blood clot, consult health care provider.
   - Increase lubrication of catheter.

RECORDING AND REPORTING

- Record amount, consistency, color, and odor of secretions and patient's response to procedure in EHR or chart.
- Record and report patient's presuctioning and postsuctioning cardiopulmonary status.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- Adhere to best practices for infection control while weighing cost-effectiveness in the presence of a chronic situation. If a patient has an established tracheostomy or requires long-term nasotracheal suctioning and infection is not present, clean suction technique is appropriate.
- Although most patients with airway clearance problems at home have a tracheostomy, some also require nasal pharyngeal suctioning. Catheters are often used for a 24-hour period and then cleaned and disinfected; or they are cleaned with soapy water after each use and discarded after 24 hours.
- Stress to family caregivers the importance of brief intervals of applying suction pressure. Instruct those performing suction to hold their breath during the application of negative suction pressure to help them remember to not suction too long.
- Instruct patient to clean and disinfect or change the secretion collection container every 24 hours according to home care or institutional protocol.
- Teach patient and family how to practice infection-control measures when emptying the suction container jar. These secretions are emptied in the toilet but have a splash risk. Instruct caregiver to apply mask (shield if available) and gloves and bring the jar as close to the toilet bowel as possible to decrease the risk of splash.

SKILL 41-2	CARE OF AN ARTIFICIAL AIRWAY

DELEGATION CONSIDERATIONS

The skill of performing artificial airway care in an acute care setting cannot be delegated to nursing assistive personnel (NAP). In long-term care settings, patients who have well-established tracheostomy tubes may have their care delegated to the NAP. Instruct the NAP to:

- Report any changes in patient's respiratory status, change in level of consciousness, confusion, restlessness or irritability, change in vital signs (range to report), decreased pulse oximetry level (values to report), or change in level of comfort.
- Report if the endotracheal (ET) tube or tracheostomy tube appears to have becomes dislodged, obstructed, or moved.
- Report any unexpected drainage or secretions from tracheostomy or change in color of stoma.

EQUIPMENT

- Stethoscope
- Face shield, if indicated for splash risk
- Bedside table
- Towel

Endotracheal Tube Care

- ET and oropharyngeal suction equipment
- 1- to 1½-inch (2.5- to 4-cm) adhesive or waterproof tape (not paper or silk tape) or commercial ET holder and mouth guard (follow manufacturer instructions for securing)
- Clean gloves (two pairs)
- Adhesive remover swab
- Mouth care supplies: pediatric toothbrush, toothette for edentulous patients; toothpaste
- 0.12% to 0.20% chlorhexidine mouthwash, rinse, or gel
- Face cleaner (e.g., wet washcloth, towel, soap, shaving supplies)
- Clean 2 × 2 gauze
- Tincture of benzoin, liquid adhesive, or skin preparation pad
- Oral airway

Tracheostomy Care

- Tracheostomy suction supplies
- Sterile tracheostomy care kit, if available, or:
  - Three sterile 4 × 4 gauze pads
  - Sterile cotton-tipped applicators
  - Sterile tracheostomy dressing (precut and sewn surgical dressing)
  - Sterile basin
  - Small sterile brush (or disposable inner cannula)
  - Tracheostomy ties (e.g., twill tape, manufactured tracheostomy ties, Velcro tracheostomy ties)
  - Normal saline (NS)
  - Scissors
  - Pair of sterile and clean gloves

STEP	RATIONALE

ASSESSMENT

1. Identify patient using two identifiers (e.g., name and birth date or name and medical record number) according to agency policy.

Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).

2. Auscultate lung sounds and observe respiratory rate and depth.

Provides baseline measure of ventilation and ease of breathing.

3. Observe condition of tissues surrounding airway insertion site and condition of airway (soiled or loose tape, ties, or dressing; pressure sores on nares, lips, or corner of mouth; excess nasal, oral, or peristomal secretions; patient moving endotracheal tube with tongue; biting tube or tongue; or foul-smelling mouth).

Patient is at risk for potential impaired skin integrity and infection due to inability to control secretions and pressure on skin/mucosa from airway devices (Zaratkiewicz et al., 2012).

4. Observe patency of airway. Excess intratracheal or endotracheal secretions, diminished airflow through airway, signs and symptoms of airway obstruction.

Buildup of secretions in airways impairs oxygenation.

5. Observe for factors that increase risk for complications from ET tube: type and size of tube, movement of tube up and down trachea, cuff size and overinflation or underinflation, duration of tube placement, facial trauma, malnutrition, and neck or thoracic radiation.

Movement of tube predisposes patient to tracheal trauma or tube dislodgement and indicates the need for another size airway. Cuff size indicates the amount of air needed to properly inflate cuff. An underinflated cuff increases patient's risk for aspiration. Cuff overly inflated may cause ischemia or necrosis of tracheal tissue (Hamilton et al., 2012). Longer duration of intubation increases risk for complications. Tissue is prone to breakdown in the presence of malnutrition and radiation.

6. Determine proper ET tube depth, noted by centimeters at lip or gum line. Line is marked on tube and recorded in medical record at time of intubation.

Confirms ET tube position.

7. Assess patient's knowledge of procedure, comfort with procedure, and ability to perform trach care at home, and answer any questions of family.

Reinforces information given to patient and family caregiver and provides opportunity to ask additional questions. Encourages cooperation and minimizes anxiety.

PLANNING

1. Obtain assistance from available staff for this procedure.

Reduces risk for accidental extubation of artificial airway.

2. Assist patient with assuming comfortable position for both patient and you (usually supine or semi-Fowlers).

Provides access to site and facilitates completion of procedure without causing you to have muscle strain or patient discomfort.

SKILL 41-2	CARE OF AN ARTIFICIAL AIRWAY—cont'd

STEP	RATIONALE
3. Place towel across patient's chest.	Reduces transmission of microorganisms to linens and bedclothes.
4. Explain importance of patient's participation, including importance of not biting or moving ET tube with tongue, trying not to cough when tape is temporarily removed from the airway, not pulling on tube with hand.	Reduces anxiety, encourages cooperation, and reduces risks. Removal of tape can be uncomfortable.

IMPLEMENTATION

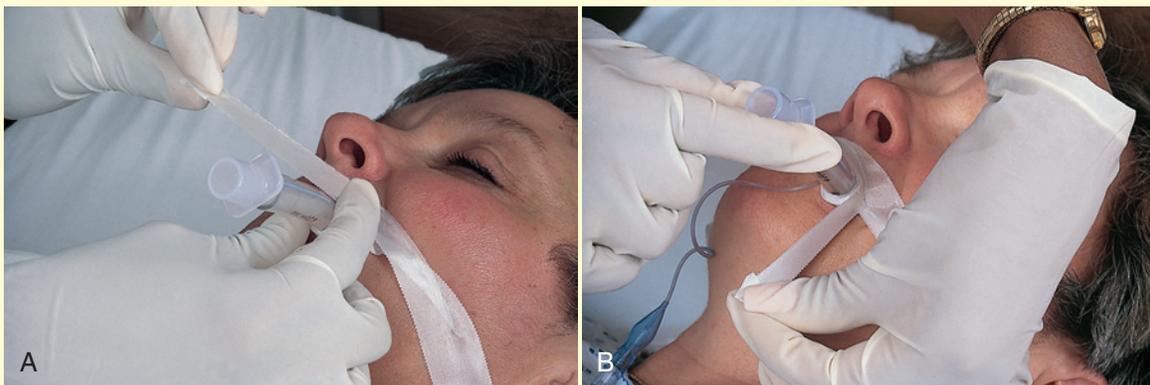
STEP	RATIONALE
1. Perform hand hygiene. Apply mask, goggles, gown, or face shield if indicated.	Reduces transmission of microorganisms.
2. Perform tracheal (tracheostomy), endotracheal (endotracheal tube), nasopharyngeal, or oropharyngeal suction (see Skill 41-1). (After suctioning tracheostomy, remove soiled dressing and discard in glove with coiled catheter.)	Removes secretions and diminishes patient's need to cough during procedure.
3. Connect Yankauer suction catheter to suction source.	Prepares for oropharyngeal suctioning.
4. Care of artificial airways	
a. Endotracheal (ET) tube care	
(1) Prepare equipment at bedside: oral care supplies, securement devices. Then prepare method to secure ET tube (check agency policy).	
(a) Commercially available ET tube holder: Open package per manufacturer instructions. Set device aside with head guard in place and Velcro strips open.	Commercial devices are latex free, fast, and convenient. These devices avoid need for tape and resultant skin breakdown and are easily applied in presence of facial hair.
(b) Tape method: Cut piece of tape long enough to go completely around patient's head from naris to naris plus 15 cm (6 inches): adult, about 30 to 60 cm (1 to 2 feet). Lay adhesive side up on bedside table. Cut and lay 8 to 15 cm (3 to 6 inches) of tape, adhesive sides together, in center of long strip to prevent tape from sticking to hair. Smaller strip of tape covers area between ears around back of head.	Preparing tape ahead will allow you to have one hand positioned on ET tube throughout procedure. Adhesive tape needs to be placed around head from cheek to cheek below ears. Avoid over ears because this results in a pressure sore.
(2) Apply clean gloves and instruct NAP or another RN to apply gloves and hold ET tube firmly at patients' lips or naris throughout the procedure. Note the number marking on ET tube at gum line or lips.	Reduces transmission of microorganisms. Maintains proper tube position and prevents accidental extubation or pushing tube further into airway.
(3) Remove device or old tape.	Provides access to underlying skin for assessment and hygiene. Reduces transmission of microorganisms.
(a) Commercially available device: Remove Velcro strips from ET tube and remove ET tube holder from patient.	Velcro strips secure ET tube in place and provide a marker to measure distance to patient's lips or gums. These devices are latex free and permit access to patient's mouth and lips for ease in oropharyngeal suctioning and oral hygiene.
(b) Tape: Carefully remove tape from ET tube and patient's face. If tape is difficult to remove, moisten with soapy water or adhesive tape remover. Discard tape in appropriate receptacle if nearby.	Adhesive can cause damage to skin and prevent adhesion of new tape.

CLINICAL DECISION: *Do not allow helper to hold the tube away from the lips or naris. Doing so allows too much "play" in the tube and increases the risk for tube movement and accidental extubation. Never let go of the ET tube because it could become dislodged.*

STEP	RATIONALE
(4) Remove excess secretions or adhesive left on patient's face. Use adhesive remover swab to remove excess adhesive left on face after tape removal. Wash adhesive remover from face.	Promotes hygiene. Retained adhesive causes damage to skin and makes it difficult for new tape to adhere.
(5) Remove oral airway or bite block if present and place on towel.	Provides access and complete observation of patient's oral cavity.

CLINICAL DECISION: *Do not remove oral airway if patient is actively biting. Wait until tape or device is partially or completely secured to ET tube.*

STEP	RATIONALE
(6) Keep ET tube cuff inflated. Have assistant continue to hold tube and not let go. Provide oral care. (Have Yankauer suction catheter on and at hand.) Assess oral cavity on side exposed. Brush oral mucosa, gums, and teeth with powdered toothbrush, or brush with nonfoaming antiseptic paste for 3 to 4 minutes (Booker et al., 2013; Needleman et al., 2011). Rinse carefully using sterile water. Suction orally as needed during brushing and rinsing. Moisten brush with sterile water to rinse, then use brush or a clean toothette to apply chlorhexidine rinse or gel (Labeau et al., 2011; Morris et al., 2011; Booker et al., 2013). Perform oral care twice daily at 12-hour intervals minimally (Booker et al., 2013).	Inflated cuff and securing tube reduces risk for aspiration and accidental extubation or pushing tube further into airway. The use of an oral antiseptic for oral care of intubated patients has a beneficial effect in preventing ventilator-associated pneumonia (Labeau et al., 2011; Shi et al., 2013; Morris et al., 2011, Booker et al., 2013).

STEP	RATIONALE
(7) Oral ET tube only: Note "cm" ET tube marking at lips or gums. With help of assistant, move ET tube to opposite side or center of mouth. Do not change tube depth.	Prevents pressure sore formation at sides of patient's mouth. Ensures correct position of tube and allows for quick visual of displaced tube (Cooper, 2013). Measuring tube at lip line can be distorted because of edema, trauma, or disease process.
(8) Repeat oral cleaning as in Step 4a(6) on opposite side of mouth.	Cleanses oral cavity and removes secretions from mouth and oropharynx.
(9) Clean face and neck with soapy washcloth; rinse and dry. Shave male patient as necessary.	Moisture and beard growth prevent adhesive tape adherence.
(10) Secure ET tube (assistant continues to hold ET tube).	
(a) Tape method	
[1] Pour a small amount of skin protectant or liquid adhesive on clean 2 × 2 gauze and dot on upper lip (oral ET tube) or across nose (nasal ET tube) and cheeks to ear. Allow tincture to dry completely.	Protects and makes skin more receptive to tape.
[2] Slip tape under patient's head and neck, adhesive side up. Take care not to twist tape or catch hair. Do not allow tape to stick to itself. It helps to stick tape gently to a tongue blade, which serves as a guide as tape is passed behind patient's head. Center tape so double-faced tape extends around back of neck from ear to ear.	Positions tape to secure ET tube in proper position.
[3] On one side of face, secure tape from ear to naris (nasal ET tube) or over lip to edge of mouth (oral ET tube). Tear remaining tape in half lengthwise, forming two pieces that are $\frac{1}{2}$- to $\frac{1}{4}$-inch (1 to 1.5 cm) wide. Secure bottom half of tape across upper lip (oral ET tube) or across top of nose (nasal ET tube) to opposite ear (see illustration A). Wrap top half of tape around tube (see illustration B). Tape should encircle main part of tube at least 2 times for security.	Secures tape to face. Using top tape to wrap prevents downward drag on ET tube.
[4] Gently pull other side of tape firmly to pick up slack and secure to remaining side of face (see illustration). Have assistant release hold when tube is secure.	Secures tape to face and tube. ET tube should be at same depth as the lips. Check earlier assessment for verification of tube depth in centimeters.


STEP 4a(10)(a)[3] A, Securing bottom half of tape across patient's upper lip. **B,** Securing top half of tape around tube.

STEP 4a(10)(a)[4] Tape securing ET tube.

SKILL 41-2	CARE OF AN ARTIFICIAL AIRWAY—cont'd

STEP	RATIONALE
(b) Commercially available device	
[1] Thread ET tube through opening designed to secure it. Be sure that pilot balloon tube is accessible.	Commercially available holders have a slit in front of holder designed to secure the ET tube.
[2] Place Velcro strips of ET holder under patient at occipital region of the head.	
[3] Verify that ET tube is at established depth, using lip or gum line marker as guide.	Ensures that ET tube remains at correct depth as determined during assessment.
[4] Secure Velcro strips at base of patient's head. Leave 1 cm (½ inch) slack in strips.	
[5] Verify that tube is secure, it does not move forward from patient's mouth or backward down into patient's throat, and there are no pressure areas on the oral mucosa or occipital region of the head (see illustration).	Tube needs to be secure so its position remains at correct depth. It can be secured without being tight and causing pressure.
(11) Remove and clean oral airway in warm soapy water and rinse well. Then rinse in chlorhexidine rinse. Shake excess solution from oral airway. **Option:** Insert new oral airway if secretions are difficult to remove.	Promotes hygiene. Reduces transmission of microorganisms.
(12) For unconscious patient reinsert oral airway without pushing tongue into oropharynx and secure with tape.	Prevents patient from biting ET tube and allows access for oropharyngeal suctioning. An oral airway in a conscious, cooperative patient causes excessive gagging and pressure ulcers to mouth and tongue.
b. Tracheostomy care	Tracheostomy stoma care should be performed a minimum of two times a day to prevent odor, irritation, and infection (Johns Hopkins Medicine, 2015).
(1) Preoxygenate patient for a minimum of 30 seconds, by asking patient to take 5-6 deep breaths or use a manual resuscitation bag connected to 100% oxygen.	Replenishes oxygen lost in suctioning (AARC, 2010a).
(2) Prepare equipment on bedside table.	Preparation and organization of equipment allows completion of tracheostomy care procedure efficiently and reconnection of patient to oxygen source in timely manner.
(a) Open tracheostomy kit. Open two 4 × 4 gauze packages using aseptic technique and pour saline on one package. Leave second package dry. Do not recap NS.	Tracheostomy tube has multiple components (see illustration). Some of these components might be used during tracheostomy care.
(b) Open two packages of cotton-tipped swabs. Keeping contents sterile, pour NS onto one of the packages.	
(c) Open sterile tracheostomy dressing package.	

STEP 4a(10)(b)[5] ET holder in place. (Courtesy Dale Medical Products, Plainesville, Mass.)

Tracheostomy tube   Inner cannula   Obturator

STEP 4b(2)(a) Tracheostomy tube. (Courtesy Mallinckrodt Inc. Shiley Tracheostomy Products, St Louis.)

STEP	RATIONALE
(d) Unwrap sterile basin and pour about 2 cm (1 inch) of NS into it. Open small sterile brush package and place aseptically into sterile basin.	
(e) Prepare fixation equipment.	
[1] Prepare length of twill tape long enough to go around patient's neck two times, about 60 to 75 cm (25 to 30 inches) for an adult. Cut ends on the diagonal. Lay aside in dry area.	Cutting ends of tie on a diagonal aids in inserting tie through eyelet.
[2] If using commercial tracheostomy tube holder, open package according to manufacturer's directions.	
(3) Apply sterile gloves. Keep dominant hand sterile throughout procedure.	Reduces transmission of microorganisms.
(4) Remove oxygen source if present.	

CLINICAL DECISION: *It is important to stabilize the tracheostomy tube at all times during tracheostomy care to prevent injury and unnecessary discomfort. Have another nurse or NAP assist during procedure wearing clean gloves.*

STEP	RATIONALE
(5) Tracheostomy with **inner cannula** care.	
(a) While touching only the outer aspect of tube, unlock and remove inner cannula with nondominant hand. Drop inner cannula into NS basin.	Removes inner cannula for cleaning. Hydrogen peroxide loosens secretions from inner cannula; but, if it is too irritating, use NS only (Morris et al., 2013).
(b) Place tracheostomy collar or T tube and ventilator oxygen source over or near outer cannula. (**NOTE:** T tube and ventilator oxygen devices cannot be attached to all outer cannulas when inner cannula is removed.)	Maintains supply of oxygen to patient.
(c) To prevent oxygen desaturation in affected patients, quickly pick up inner cannula and use small brush to remove secretions inside and outside cannula (see illustration).	Tracheostomy brush provides mechanical force to remove thick or dried secretions.
(d) Hold inner cannula over basin and rinse with NS, using nondominant hand to pour.	Removes secretions from inner cannula (Cleveland Clinic, 2014).
(e) Replace inner cannula (see illustration) and secure "locking" mechanism. Hyperventilate patient if needed. Reapply ventilator or oxygen sources.	Secures inner cannula and reestablishes oxygen supply.
(6) Disposable inner cannula care	
(a) Remove new cannula from manufacturer packaging.	
(b) While touching only the outer aspect of tube, withdraw old inner cannula and replace with new cannula. Lock into position.	Reestablishes airway quickly.
(c) Dispose of contaminated cannula in appropriate receptacle and apply oxygen source or ventilator.	Prevents unnecessary oxygen desaturation.

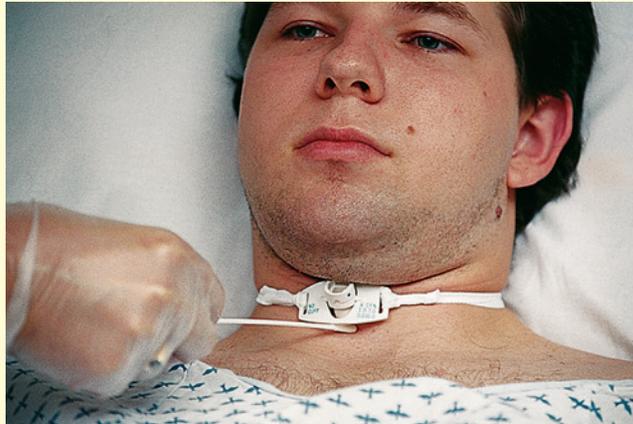
STEP 4b(5)(c) Cleaning tracheostomy inner cannula.

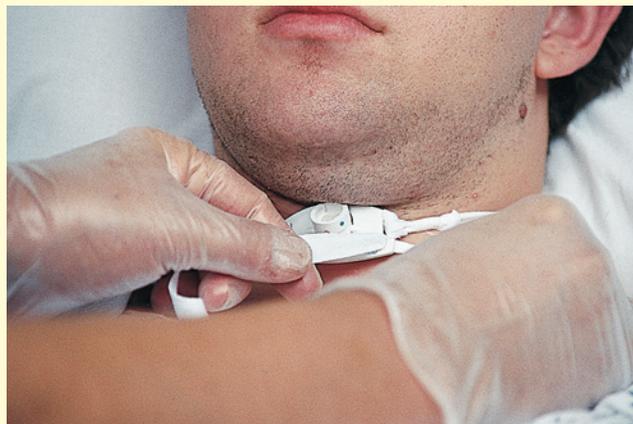
STEP 4b(5)(e) Reinserting inner cannula.

SKILL 41-2	CARE OF AN ARTIFICIAL AIRWAY—cont'd

STEP	RATIONALE
(7) Using NS-saturated cotton-tipped sterile swabs and 4×4 gauze, clean exposed outer cannula surfaces and stoma under faceplate, extending 5 to 10 cm (2 to 4 inches) in all directions from stoma (see illustration). Clean in circular motion from stoma site outward using dominant hand to handle sterile supplies.	Aseptically removes secretions from stoma site. Moving in outward circle pulls mucus and other contaminants from stoma to periphery.
(8) Using NS-prepared cotton-tipped swabs and 4×4 gauze, clean outer tracheostomy tube flange and skin surfaces.	Removes secretions that can be source of infection.
(9) Using dry 4×4 gauze, pat lightly at skin and exposed outer cannula surfaces.	Dry surfaces prohibit formation of moist environment for microorganism growth and skin excoriation.
(10) Securing tracheostomy	
(a) Tracheostomy tie method	
[1] Instruct assistant to securely hold tracheostomy tube in place, then cut old ties.	Secures tracheostomy tube to prevent accidental extubation.

CLINICAL DECISION: *Assistant must not release hold on tracheostomy tube until new ties are firmly tied to reduce risk of accidental extubation. If no assistant is present, do not cut old ties until new ties are in place and securely tied.*

STEP	RATIONALE
[2] Take prepared twill tape, insert one end of tie through faceplate eyelet, and pull ends even (see illustration).	
[3] Slide both ends of ties behind head and around neck to other eyelet and insert one tie through second eyelet.	
[4] Pull snugly.	Secures tracheostomy tube in place.


STEP 4b(7) Cleaning around stoma.


STEP 4b(10)(a)[2] Replacing tracheostomy ties when an assistant is not available. Do not remove old tracheostomy ties until new ones are secure.

STEP	RATIONALE
[5] Tie ends securely in double square knot, allowing space for only one loose or two snug finger widths in tie.	One-finger slack prevents ties from being too tight when tracheostomy dressing is in place and also prevents movement of tracheostomy into lower airway.
(b) Tracheostomy tube holder method (see illustration).	
[1] While wearing gloves, maintain secure hold on tracheostomy tube. This can be done with an assistant or, when an assistant is not available, leave old tracheostomy tube holder in place until new device is secure.	Prevents incidental displacement of tube.
[2] Align strap under patient's neck. Be sure that Velcro attachments are positioned on either side of tracheostomy tube.	
[3] Place narrow end of ties under and through faceplate eyelets. Pull ends even and secure with Velcro closures.	
[4] Verify that there is space for only one loose or two snug finger width(s) under neck strap.	Prevents skin necrosis.
(11) Insert fresh tracheostomy dressing under clean ties/holder and faceplate (see illustration).	Absorbs drainage. Dressing prevents pressure on clavicle heads.
5. Position patient comfortably and evaluate respiratory status.	Promotes comfort. Some patients require post-tracheostomy care suctioning.
6. Replace any oxygen-delivery devices.	Maintains oxygen therapy.
7. Remove and discard gloves. Perform hand hygiene.	Prevents transmission of microorganisms.

CLINICAL DECISION: *Keep tracheostomy obturator at bedside with a fresh tracheostomy to facilitate reinsertion of the outer cannula if dislodged. Keep an additional tracheostomy tube of the same size and shape on hand for emergency replacement (Morris et al., 2013).*

EVALUATON

1. Compare respiratory assessments before and after procedure.	Identifies any changes in presence and quality of breath sounds after procedure. Determines effectiveness of artificial airway care.
2. Observe depth and position of ET tubes according to health care provider's recommendation.	Verifies that position of tube is correct and not altered.
3. Evaluate security of tape/holder securing ET tube by gently tugging at tube.	Artificial airway (ET tube) should not move. Patient may cough.
4. Check fit of new tracheostomy ties and ask patient if tube feels comfortable.	If tracheostomy ties are uncomfortable, ties that are too loose or tight place patient at risk for injury.
5. Evaluate skin around mouth, oral mucosa (ET tube), and tracheostomy stoma for drainage, pressure, irritation, or signs of infection.	Skin breakdown and/or irritation should not be present. Broken skin places patient at risk for infection.
6. Use *Teach Back:* State,"I want to be sure that I explained the importance of changing your family member's tracheostomy tube dressing. Can you tell me why this is important?" Revise your instruction now or develop plan for revised family caregiver education if unable to teach back correctly.	Evaluates what the family caregiver is able to explain or demonstrate.

STEP 4b(10)(b) Tracheostomy tube holder in place. (Courtesy Dale Medical Products, Plainesville, Mass.)

STEP 4b(11) Applying tracheostomy dressing.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Unexpected extubation of ET tube
   - Call for assistance while remaining with patient.
   - Assist respirations with bag-valve mask as needed.
   - Assess patient for airway patency, spontaneous breathing, and vital signs.
   - Prepare for reintubation.
2. Accidental decannulation of tracheostomy tube
   - Call for assistance while remaining with patient.
   - Replace old tracheostomy tube with new spare tube of same size and kind kept at the bedside. Some experienced nurses or respiratory therapists may be able to quickly reinsert tracheostomy tube (Morris et al., 2013).
   - Same-size ET tube can be inserted in stoma in an emergency.
   - Be prepared to manually ventilate patient who develops respiratory distress.
3. Movement of ET tube
   - Repeat taping or securing procedure. **NOTE:** Chest x-ray may be needed to confirm placement.
   - In very active patients without facial injury who are at risk for self-extubation, consider applying a second piece of tape around back of head.
4. Pressure area around tracheostomy tube
   - Increase frequency of tracheostomy care. Keep dressing under faceplate at all times.
   - Consider using double dressing or applying hydrocolloid or stoma adhesive dressing around stoma.

RECORDING AND REPORTING

- Record respiratory assessment measures before and after care.
- Record ET tube care: depth of ET tube, frequency and extent of care, patient tolerance of procedure, and special care of any unexpected outcomes related to presence of the tube.
- Record tracheostomy care: type and size of tracheostomy tube, frequency and extent of care, patient tolerance of procedure, and special care of any unexpected outcomes related to presence of the tube.
- Document your evaluation of family caregiver learning.

HOME CARE CONSIDERATIONS TRACHEOSTOMY ONLY (CLEVELAND CLINIC, 2014).

- Instruct family caregivers in how to obtain supplies. Routine tracheostomy care should be done at least once a day after discharge from hospital. At home clean technique is used with nonsterile gloves.
- Immediately after tracheostomy insertion, patients must communicate with others by writing or use of computer.
- Instruct caregivers in signs and symptoms of respiratory distress, tube dysfunction, and respiratory and stoma infections. Call health care provider if patient feels pain or discomfort longer than a week after insertion, if breathing does not improve after usual method of clearing secretions, or if secretions become thick or mucus plugs are present.
- When outside, use tracheostomy covers to protect from dust or cold air.
- Never remove the outer cannula unless instructed by health care provider to do so.

DELEGATION CONSIDERATIONS

The skill of care of chest tube management cannot be delegated to nursing assistive personnel (NAP). The nurse instructs the NAP about:
- Proper positioning of patient with chest tubes to facilitate chest tube drainage and optimal function of the system.
- How to safely ambulate and transfer patient with chest drainage.
- Reporting changes in vital signs or SpO$_2$, chest pain, sudden shortness of breath, or excessive bubbling in water-seal chamber.
- Immediately notifying nurse if there is disconnection of system, change in type and amount of drainage, sudden bleeding, or sudden cessation of bubbling in water-seal chamber.

EQUIPMENT

- Stethoscope
- Pulse oximeter
- Clean gloves
- Two rubber-tipped (also called *shodded*) hemostats for each tube
- 2-inch (5-cm) adhesive tape for taping connections
- Sterile gauze sponges
- Suction source and setup (wall canister or portable) if physician is inserting chest tube
- Water suction system: Add sterile water or normal saline (NS) solution to cover the lower 2.5 cm (1 inch) of water-seal U tube, sterile water or NS solution to put into the suction-control chamber if suction is to be used (see manufacturer directions)
- Waterless system: Add vial of 30-mL injectable sodium chloride or water, 20-mL syringe, 21-gauge needle, and antiseptic swab

STEP	**RATIONALE**

ASSESSMENT

1. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.

2. Assess pulmonary status.

   a. Signs and symptoms of increased respiratory distress (displaced trachea, decreased breath sounds over affected and nonaffected lungs, marked cyanosis, asymmetrical chest movements).

   b. Assess for sharp, stabbing chest pain or chest pain on inspiration; hypotension; and tachycardia. Ask patient to rate level of comfort on a scale of 0 to 10.

3. Obtain baseline and serial vital signs, level of cognition, and SpO_2.

4. Assess patient's current hemoglobin and hematocrit levels.

5. Observe chest tube status:

   a. Chest tube dressing and site surrounding tube insertion. Apply clean gloves if drainage is present.

   b. Tubing for kinks, dependent loops, or clots.

   c. Check existing drainage system to ensure that it is upright and below level of tube insertion. Note amount of drainage in system (see illustration).

Ensures correct patient. Complies with The Joint Commission Standards and improves patient safety (TJC, 2016).

Baseline measures allow you to determine if signs and symptoms of respiratory distress improve after insertion of chest tube. If respiratory distress is not relieved or worsens or if there is sharp stabbing chest pain with or without decreased blood pressure and increased heart rate, notify health care provider immediately. These symptoms indicate a pneumothorax.

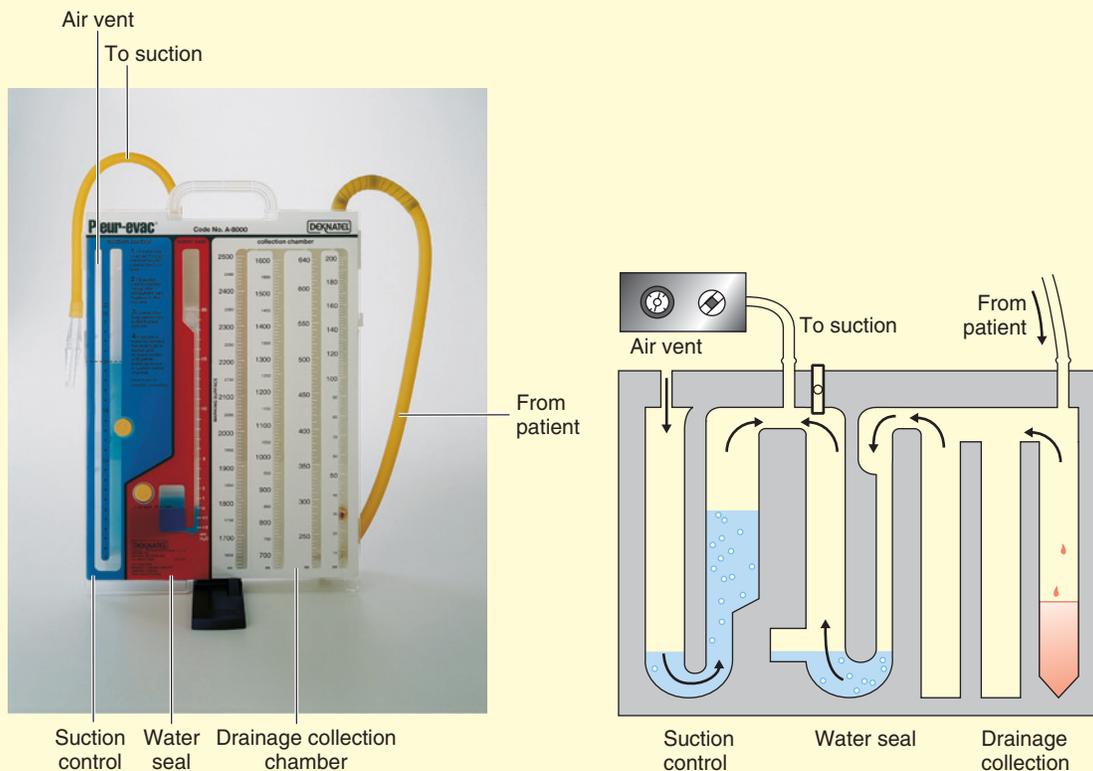
Symptoms may indicate a tension pneumothorax. Presence of a pneumothorax or hemothorax is painful, often causing sharp inspiratory pain.

Changes in pulse, SpO_2, and blood pressure often indicate infection, respiratory distress, or pain. Cognitive changes indicate hypoxia.

Provides measure reflecting blood loss and subsequent levels of oxygenation.

Ensures that dressing is intact, without air or fluid leaks, and that area surrounding insertion site is free of drainage or skin irritation.

Maintains patent, freely draining system, preventing fluid accumulation in chest cavity. Presence of kinks, dependent loops, or clotted drainage increases patient's risk for infection, atelectasis, and tension pneumothorax (Carroll, 2015).

Facilitates drainage. Ensures that system is in this position to function properly.


STEP 5c *Left,* Pleur-Evac drainage system, a commercial three-bottle chest drainage device. *Right,* Schematic of drainage device.

SKILL 41-3	CARE OF PATIENTS WITH CHEST TUBES—cont'd

STEP	RATIONALE

PLANNING

1. Provide two rubber-tipped hemostats or approved clamps for each chest tube, attached to top of patient's bed with adhesive tape. Chest tubes are only clamped under specific circumstances per health care provider's order or nursing policy and procedure:

   a. To assess air leak.

   b. To quickly empty or change disposable systems; performed by a nurse who has received education in the procedure.

   c. To assess if patient is ready to have chest tube removed (which is done by health care provider's order); monitor patient for recurrent pneumothorax (see illustration).

Hemostat has a covering to prevent it from penetrating chest tube. Use of these rubber-tipped hemostats or other clamps prevents air from reentering pleural space in emergencies (Bauman et al., 2011).

2. Position patient.

   a. Semi-Fowler's position to evacuate air (pneumothorax)

   b. High-Fowler's position to drain fluid (hemothorax, effusion)

Permits optimal drainage of fluid and/or air.

Air rises to highest point in chest. Pneumothorax tubes are usually placed on anterior aspect at midclavicular line, second or third intercostal space.

Permits optimal drainage of fluid. Posterior tubes are placed on midaxillary line, eighth or ninth intercostal space.

3. Explain to patient steps for tube management.

Promotes understanding and minimizes patient anxiety.

IMPLEMENTATION

1. Perform hand hygiene. Apply clean gloves.

Reduces transmission of microorganisms.

2. Be sure that tube connection between chest and drainage tube is intact and taped.

Secures chest tube to drainage system and reduces risk of air leak causing breaks in airtight system.

   a. Make sure that water-seal vent on drainage system is not occluded.

Permits displaced air to pass into atmosphere.

   b. Make sure that suction-control chamber vent is not occluded when using suction. Waterless systems have relief valves without caps.

Provides safety factor of releasing excess negative pressure into atmosphere.

3. Coil excess drainage tubing on mattress next to patient. Secure with rubber band, safety pin, or plastic clamp. Allow enough room for patient to reposition.

Prevents excess tubing from hanging over edge of mattress in dependent loop. It is possible for drainage to collect in loop and occlude drainage system (Carroll, 2015).

4. Adjust tubing to hang in straight line from top of mattress to drainage chamber.

Promotes drainage and prevents fluid or blood from accumulating in pleural cavity (Carroll, 2015).

5. If chest tube is draining fluid, indicate time (e.g., 0900) that you began measuring drainage on adhesive tape on drainage bottle or on write-on surface of disposable commercial system.

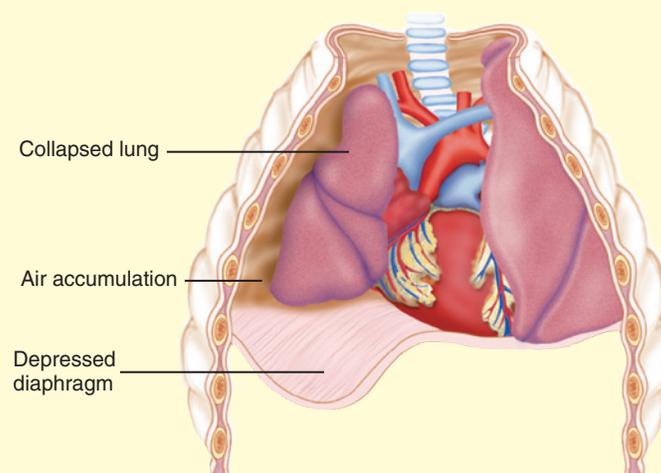
Provides baseline for continuous assessment of type and quality of drainage.

6. Milk chest tube only if indicated (this means compressing along tube to encourage clots to pass through tube) (see agency policy.) Stripping is not recommended. Milking is compressing and releasing tube sequentially.

Stripping may cause complications because it can create excessive negative intra-pleural pressure (over 100 cm H_2O). Milking causes less of a pressure change and is recommended (Kane et al., 2013; Dango et al., 2010).

Collapsed lung

Air accumulation

Depressed diaphragm


STEP 1c   Pneumothorax. (From Ball JW et al: *Seidel's guide to physical examination*, ed 8, St Louis, 2015, Mosby).

STEP	RATIONALE
a. Milk postoperative mediastinal chest tubes if assessment indicates an obstruction or decreased drainage from clots or debris in tubing. Order is necessary (see agency policy).	Stripping is not recommended. There is evidence that milking is associated with a significant increase of pleural fluid drainage; however, it does not improve postoperative morbidity and mortality and therefore cannot be recommended as a routine postoperative procedure (Dango et al., 2010).
7. Remove and discard gloves. Perform hand hygiene.	Reduces transmission of infection.

EVALUATION

1. Monitor vital signs and pulse oximetry as ordered or if patient's condition changes.	Provides ongoing data about patient's level of oxygenation.
2. Evaluate patient for decreased respiratory distress and chest pain and monitor SpO₂.	Increasing respiratory distress, decreased breath sounds, marked cyanosis, asymmetrical chest wall movements, presence of subcutaneous emphysema around insertion site or neck, hypotension, tachycardia, and/or mediastinal shift are critical and indicate a severe change in patient status such as excessive blood loss or tension pneumothorax. Notify health care provider immediately.
3. Auscultate lungs for breath sounds.	Decreased breath sounds indicate lung area is not aerating and can be a sign of respiratory distress.
4. Observe:	
a. Appearance of chest tube dressing.	Drainage is often caused by tube occlusion, causing drainage to exit around tube.

CLINICAL DECISION: *Check the dressing carefully because it needs to remain occlusive. It can come loose from the skin, although this is not readily apparent. Assess for drainage and reinforce to maintain seal. Follow hospital policy as needed.*

b. Make sure that tubing is free of kinks and dependent loops.	Straight and coiled drainage tube positions are optimal for pleural drainage. However, when a dependent loop is unavoidable, periodic lifting and draining the tube promote pleural drainage.
c. Make sure that chest drainage system is upright and below level of tube insertion. Note presence of clots or debris in tubing. Monitor position of system relative to chest tube carefully, especially during patient transport.	System must be in the upright position to function and facilitate proper drainage.
d. Observe water seal for fluctuations with patient's inspiration and expiration.	Indicates appropriate function of negative pressure system.
(1) *Waterless system:* Diagnostic indicator for fluctuations with patient's inspirations and expirations	In nonmechanically ventilated patient, fluid rises in water seal or diagnostic indicator with inspiration and falls with expiration. Opposite occurs in a patient who is mechanically ventilated. This indicates that system is functioning properly (Lewis et al., 2014).
(2) *Water-seal system:* Bubbling in water-seal chamber	When system is initially connected to patient, expect bubbles from the chamber. These are from air present in system and from patient's intrapleural space. After a short time bubbling stops. Fluid continues to fluctuate in water seal on inspiration and expiration until lung reexpands or system is occluded.
(3) *Water-seal system:* Bubbling in suction-control chamber (when using suction)	Suction-control chamber has constant gentle bubbling. Tubing remains free of obstruction, and suction source is turned to appropriate setting.
e. Observe type and amount of fluid drainage: note color of drainage and skin color. Look at fluid in drainage tubing and not just in collection chamber. What is the normal amount of drainage? Is it bright red, dark red, or pink? Is it opaque, or can you see through it?	Character of drainage indicates if it is as expected or if infection or hemorrhage is developing.
(1) *In adult:* less than 50 to 200 mL/hr immediately after surgery in a mediastinal chest tube; approximately 500 mL in first 24 hours.	Dark-red drainage is normal only in postoperative period, turning serous with time.
(2) Between 100 and 300 mL of fluid drains in a pleural chest tube in an adult during first 3 hours after insertion. Rate decreases after 2 hours; expect 500 to 1000 mL in first 24 hours. Drainage is grossly bloody during first several hours after surgery and then changes to serous. Sudden gush of drainage is often retained blood and not active bleeding and is usually the result of patient repositioning (Lewis et al., 2014).	Reexpansion of lungs forces drainage into tube. Coughing also causes large gushes of drainage or air. Report excessive amounts and/or continued presence of frank, bloody drainage the first several hours after surgery to health care provider, along with patient's vital signs and respiratory status.

CLINICAL DECISION: *If drainage increases suddenly or is bright red or if there is more than 100 mL/hr of bloody drainage (except for the first 3 hours after surgery), notify the health care provider, remain with the patient, and assess vital signs and cardiopulmonary status. This may indicate hemorrhage or perforation of the lung.*

SKILL 41-3	CARE OF PATIENTS WITH CHEST TUBES—cont'd

STEP	RATIONALE
f. *Waterless system:* Suction control (float ball) indicates amount of suction that patient's intrapleural space is receiving.	Suction float ball dictates amount of suction in system. Float ball allows no more suction than dictated by its setting. If suction source is set too low, suction float ball cannot reach prescribed setting. In this case increase suction for float ball to reach prescribed setting.
g. Ask patient to rate level of comfort on a scale of 0 to 10.	Indicates need for analgesia. Patient with chest tube discomfort hesitates to take deep breaths and as a result is at risk for pneumonia and atelectasis.
5. Use **Teach Back:** State, "I want to go over what we discussed about keeping your chest tubes open and clear. Tell me how you can help keep the tubes open." Revise your instruction now or develop a plan for revised patient teaching if patient or family is not able to teach back correctly.	Evaluates what the patient is able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Air leak unrelated to patient respirations
- Assess all connections between patient and drainage system to find source and tighten any loose connections (Carroll, 2015).
- If air leak persists, notify health care provider to change drainage system.

2. Tension pneumothorax present
- Determine that chest tubes are not clamped, kinked, or occluded. Obstructed chest tubes trap air in intrapleural space when air leak originates within patient and can cause a tension pneumothorax.
- Notify patient's health care provider immediately.
- Prepare immediately for another chest tube insertion; obtain a flutter (Heimlich) valve or large-gauge needle for short-term emergency release of air in intrapleural space; have emergency equipment (e.g., oxygen, code cart) near patient.

3. Continuous bubbling in water-seal chamber, indicating that leak is between patient and water seal
- Tighten loose connections between patient and water-seal system.
- Check agency policy and, if instructed, cross-clamp chest tube closer to patient's chest using hemostat clamps. If bubbling stops, the air leak is inside patient's thorax or at chest tube insertion site.
- Unclamp chest tube.
- Reinforce dressing.
- Notify health care provider.

RECORDING AND REPORTING

- Record and report patency of chest tube; presence, type, and amount of drainage; presence of fluctuations; patient's vital signs; chest dressing status; amount of suction and/or water seal; and patient's level of comfort.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- Patients with chronic conditions (e.g., uncomplicated pneumothorax, effusions, empyema) that require long-term chest tube may be discharged with smaller mobile drains. These systems do not have a suction-control chamber and use a mechanical one-way valve instead of a water-seal chamber.
- Instruct patient in how to ambulate and remain active with a mobile chest tube drainage system.
- Provide patient with information as to when to contact health care professionals regarding changes in health status or drainage system (e.g., chest pain, breathlessness, change in drainage).

SKILL 41-4	USING HOME OXYGEN EQUIPMENT

DELEGATION CONSIDERATIONS

The skill of administering home oxygen equipment cannot be delegated to nursing assistive personnel (NAP). Instruct the NAP about:

- The unique needs of patient (e.g., amount of assistance in applying nasal cannula or mask) and any assistance needed in filling liquid canisters.
- The type of equipment patient should have in the home and the oxygen flow rate.
- Immediately reporting to the nurse increased rate of breathing, decreased level of consciousness, increased confusion, and pain.

EQUIPMENT

- Nasal cannula equipment (see Procedural Guideline Box 41-9)
- Humidification device if oxygen delivery greater than 4 L/min
- Oxygen tubing available in lengths of 50 feet
- Home low-flow oxygen-delivery system with appropriate equipment

STEP	RATIONALE

ASSESSMENT

1. Identify patient using two identifiers (e.g., name and birth date or name and medical record number) according to agency policy. Compare identifiers with information on patient's MAR or medical record.

Ensures correct patient. Complies with The Joint Commission Standards and improves patient safety (TJC, 2016).

2. While patient is still in the hospital, determine patient's or family caregiver's ability to use oxygen equipment correctly. In home setting reassess for access to and appropriate use of equipment.

Physical or cognitive impairments necessitate instructing family member or significant other how to operate home oxygen equipment. Ongoing assessment enables nurse to determine specific components of skill that patient or family can complete easily.

3. Assess home environment for adequate electrical service if oxygen concentrator is ordered.

Oxygen concentrators require electricity to work. Continuous oxygen therapy must not be interrupted.

4. Assess patient's and family's ability to observe for signs and symptoms of hypoxia: apprehension, anxiety, decreased ability to concentrate, decreased level of consciousness, increased fatigue, dizziness, behavioral changes, increased pulse, increased respiratory rate, pallor, or cyanosis of the mucous membranes.

Hypoxia occurs at home despite use of oxygen therapy. Worsening of patient's physical condition or another underlying condition such as change in the respiratory status can cause hypoxia.

PLANNING

1. Determine appropriate resources in community for equipment and assistance, including maintenance and repair services and medical equipment supplier.

Ensures readily available assistance for patients with home oxygen systems. Delivery and setup with basic instruction on how to use and maintain home oxygen equipment must be in accordance with federal, state, and local laws (AARC, 2007).

2. Instruct family to investigate municipal requirements for home medical equipment, especially oxygen.

Many municipalities require that patients with home oxygen equipment notify emergency medical service (EMS) before bringing equipment home. When there is a power outage, EMS calls the home, and in some cases the home is on a priority list for power restoration.

3. Obtain appropriate referrals to determine if patient meets standards for third-party reimbursement.

Indications include (1) a PaO_2 less than or equal to 55 mm Hg or SaO_2 less than or equal to 88% breathing room air; (2) PaO_2 less than or equal to 56-59 mm Hg or SaO_2 less than or equal to 89% with conditions such as cor pulmonale, heart failure, or hematocrit greater than 56%; (3) oxygen therapy is needed during activities that cause hypoxia such as ambulation, sleep, or exercise causing an SaO_2 of less than or equal to 88% (CMS, 2015; AARC, 2007).

IMPLEMENTATION

1. Perform hand hygiene.

Reduces transmission of infection.

2. Place oxygen-delivery system in clutter-free environment that is well ventilated; away from walls, drapes, bedding, and combustible materials; and at least 8 feet from heat source.

Prevents injury from improper placement of oxygen equipment.

3. Demonstrate each step for preparation and completion of oxygen therapy.

Teaches psychomotor skills and enables patient to ask questions. When patients and family members are adequately informed about supplemental oxygen therapy, the patient consistent use of the therapy is enhanced (Earnest, 2002).

   a. **Compressed oxygen system**—available in large cylinders as stationary units or smaller, lightweight cylinders in carrying bags and/or wheel carts.

Smaller units are used for ambulation and as a backup of stationary unit if there is power failure or equipment malfunction (AARC, 2007).

     (1) Turn cylinder valve counterclockwise two or three turns with wrench. Store wrench with oxygen tank.

Turns on oxygen. Keeps wrench available.

SKILL 41-4	USING HOME OXYGEN EQUIPMENT—cont'd

STEP	RATIONALE
(2) Check cylinders by reading amount on pressure gauge (see illustration).	Verifies adequate oxygen supply for patient use.
b. Oxygen concentrator system—available as stationary unit or portable device.	Extracts oxygen from other gases in atmospheric air (AARC, 2007).
(1) Plug concentrator into appropriate outlet.	Provides power source. Make sure that it is in an open area and never in a closet or other closed space
(2) Turn on power switch.	Starts concentrator motor.
(3) Alarm sounds for a few seconds.	Alarm turns off when desired pressure inside concentrator is reached.
c. Liquid oxygen systems—available in large-reservoir canisters that can be used to refill a smaller portable unit (AARC, 2007). Portable unit weighs 5 to 13 lbs and can be carried with a shoulder strap or pulled on a cart.	When liquid oxygen is warmed, it goes from liquid to gas. More oxygen can be stored as a liquid than gas.
d. Refill oxygen tank	
(1) Check for amount of oxygen in tank.	If not in use, evaporation empties portable canister; thus always check it before use.
(2) Wipe both filling connectors with clean, dry, lint-free cloth.	Removes dust and moisture from system.
(3) Turn off flow selector of ambulatory unit.	
(4) Attach ambulatory unit to stationary reservoir by inserting adapter from ambulatory tank into adapter of stationary reservoir.	
(5) Open fill valve on ambulatory tank and apply firm pressure to top of stationary reservoir (see illustration). Stay with unit while it is filling. You will hear a loud hissing noise. Tank fills in about 2 minutes.	Prevents leaking of oxygen during filling process. If oxygen leaks during filling process, connection between ambulatory tank and reservoir ices up and valves stick together.
(6) Disengage ambulatory unit from stationary reservoir when hissing noise changes and vapor cloud begins to form from stationary unit.	Overfilling causes ambulatory unit to malfunction caused by high pressure in tank.
(7) Wipe both filling connectors with clean, dry, lint-free cloth.	Ice sometimes forms during filling. Removes moisture from oxygen system.

CLINICAL DECISION: *If ambulatory unit does not separate easily, valves from reservoir and ambulatory unit may be frozen together. Wait until valves warm to disengage (about 5 to 10 minutes). Do not touch any frosted areas because contact with skin causes skin damage from frostbite.*

4. Connect oxygen-delivery device to oxygen system.	Connects oxygen source to delivery system.
5. Adjust to prescribed flow rate (L/min).	Ensures appropriate oxygen prescription.
6. Place oxygen-delivery device on patient.	Delivers oxygen to patient.
7. Perform hand hygiene.	Reduces transmission of microorganisms.

STEP 3a(2) Verify oxygen level by reading gauge on top of canister.

STEP 3d(5) Open fill valve on ambulatory tank while applying firm pressure to top of ambulatory unit.

STEP	RATIONALE
8. Instruct patient and family not to change oxygen flow rate.	Can lead to serious oxygenation alterations.
9. Guide patient and family caregiver as they perform each step. Provide written material for reinforcement and review.	Allows you to correct for errors in technique and discuss their implications.
10. Instruct patient and family caregiver to notify health care provider if signs or symptoms of hypoxia or respiratory tract infection (e.g., fever, increased sputum, change in color of sputum, or odor) occur.	Respiratory tract infections increase oxygen demand and affect oxygen transfer from lungs to blood. Can create severe exacerbation of patient's pulmonary disease.
11. Discuss emergency plan for power loss, natural disaster, and acute respiratory distress. Have patient or family/caregiver call 911 and notify health care provider and home care agency.	Ensures appropriate response and prevents worsening of patient's condition.
12. Instruct patient and family caregiver in safe home oxygen practices, including not allowing smoking in the house, keeping oxygen tanks away from open flame, and storing tanks upright.	Ensures safe use of oxygen in the home and prevents injury to patient and family.
13. Monitor oxygen-delivery rate. All oxygen-delivery equipment should be checked at least daily by patient or caregiver.	Determines if patient is using oxygen at prescribed rate.
14. Oxygen-delivery equipment must be maintained and serviced routinely according to manufacturer's guidelines (AARC, 2007).	Routine maintenance ensures proper function of equipment.

EVALUATION

1. Ask patient and family about ease of administering or any problems with the home oxygen delivery system.	Determines ability of patient and family to deal with stressors associated with home oxygen use.
2. Ask patient and family to state safety guidelines, emergency precautions, and emergency plan.	Determines patient's knowledge of what to do if power fails, there is a failure in equipment, or patient's status worsens.
3. Use **Teach Back** to determine patient's and family's ability to use home oxygen equipment. State, "I want to be sure I explained how to administer the home oxygen equipment. Can you show me how to apply your nasal cannula and regulate the oxygen source?" Revise your instruction now or develop a plan for revised patient teaching if patient or family is not able to teach back correctly.	Evaluates what the patient and family are able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Patient reports no oxygen flow.
   - Check tank pressure gauge. If level of oxygen is low, refill tank if portable or provide alternate source of oxygen such as concentrator.
   - Notify home oxygen supplier of need for refill.
   - Reassure patient and family.
2. Patient or family caregiver is unable to fill portable liquid oxygen from main source.
   - Check to see that portable tank is connected correctly.
   - Determine if valve is frozen.
   - Contact home oxygen supplier for service visit.
   - Provide alternate oxygen source if necessary.

RECORDING AND REPORTING

- Record teaching plan and describe patient's and family caregiver's ability to safely use home oxygen equipment.
- Record type of home oxygen equipment being used and oxygen flow rate, knowledge of safety guidelines, how to use equipment, unexpected outcomes to observe, and ability to return demonstrate proper use of oxygen-delivery device.

 KEY POINTS

- The primary function of the lungs is to transfer oxygen from the atmosphere into the alveoli and carbon dioxide out of the body as a waste product.
- Changes in intrapleural and intraalveolar pressures and lung volumes cause the process of inspiration (active process) and expiration (passive process).
- The primary functions of the heart are to deliver deoxygenated blood to the lungs for oxygenation and oxygen and nutrients to the tissues.

- The nursing history includes information about the patient's cough, dyspnea, fatigue, wheezing, chest pain, environmental exposures, respiratory infection, cardiopulmonary risk factors, and use of medications.
- Nursing assessment includes respiratory pattern, thoracic inspection, palpation, and auscultation for deviations from normal.
- Diagnostic and laboratory tests complete the database for a patient with decreased oxygenation.
- Health promotion includes vaccinations against flu and pneumonia, exercise programs, nutrition support, smoking cessation, and environmental assessment for pollutants and air quality.

- Airway maintenance requires mobilization of secretions by increased fluid intake, humidification, or nebulization.
- Breathing exercises improve ventilation, oxygenation, and sensations of dyspnea.
- Chest physiotherapy includes postural drainage, percussion, and vibration to mobilize pulmonary secretions.
- Airway maintenance may require use of artificial airways and suctioning.
- Promotion of lung expansion can be achieved by mobility, positioning, incentive spirometry, and chest tube insertion.
- Nasal cannulas and oxygen masks deliver oxygen therapy, which improves the levels of tissue oxygenation.
- Learning breathing exercises, including pursed-lip breathing and diaphragmatic breathing, benefits patients with chronic pulmonary diseases.

■ CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

Forty-eight hours after admission to the hospital, Mr. Edwards had abnormal lung sounds (crackles) in the left base and both upper lobes; he was dyspneic and coughing up thick yellow sputum. His vital signs were as follows: temperature, 102.4° F (39.1° C); blood pressure, 88/42 mm Hg; pulse, 110 beats/min; respirations, 32 breaths/min; and SpO_2, 82%. He could not lie flat, and it was difficult for him to speak because of dyspnea. He was placed on a nonrebreather mask at an oxygen concentration of 60%. He was also unable to cough up any sputum.

Mr. Edwards's health care provider determined that his pneumonia had worsened. A chest x-ray film and arterial blood gas levels were obtained. His chest x-ray film indicated that both upper lobes and the left lower lobe had infiltrates. The arterial blood gas levels indicated respiratory acidosis (see Chapter 42). His PaO_2 was 55 mm Hg, $PaCO_2$ was 65 mm Hg, pH was 7.30, and SpO_2 was 80%. His WBC count had risen from 7 to 15. He spent 5 days in an intensive care unit (ICU) and 2 weeks in a transitional care unit. He is being discharged on home oxygen therapy. His discharge plan includes an outpatient rehabilitation program to begin 1 month after discharge.

1. Given the acute change in Mr. Edward's condition in the beginning of the case scenario, noting his vital signs and lab level results, along with a diagnosis of pneumonia as the source of infection, what interventions/orders/treatment might you anticipate are needed to care for Mr. Edwards?
2. Based on the initial description of Mr. Edwards condition in the case scenario, determine two priority nursing diagnoses and list two or three appropriate interventions or nursing activities for each that you must implement.
3. What do you need to do to prepare Mr. and Mrs. Edwards for home oxygen therapy? (Refer to the Nursing Care Plan.)

ⓔ *Answers to Clinical Application Questions can be found on the Evolve website.*

■ REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. For which of the following health problems is a patient who has a 40-year history of smoking at risk?
   1. Alcoholism and hypertension
   2. Obesity and diabetes

   3. Stress-related illnesses
   4. Cardiopulmonary disease and lung cancer
2. A patient has been diagnosed with severe iron deficiency anemia. During physical assessment, which of the following symptoms are associated with decreased oxygenation as a result of the anemia?
   1. Increased breathlessness but increased activity tolerance
   2. Decreased breathlessness and decreased activity tolerance
   3. Increased activity tolerance and decreased breathlessness
   4. Decreased activity tolerance and increased breathlessness
3. A patient is admitted to the emergency department with suspected carbon monoxide poisoning. Even though the patient's color is ruddy and not cyanotic, the nurse understands the patient is at a risk for decreased oxygen-carrying capacity of blood because carbon monoxide does which of the following:
   1. Stimulates hyperventilation, causing respiratory alkalosis
   2. Forms a strong bond with hemoglobin, thus preventing oxygen binding in the lungs
   3. Stimulates hypoventilation, causing respiratory acidosis
   4. Causes alveoli to overinflate, leading to atelectasis
4. An 86-year-old woman is admitted to the unit with chills and a fever of 104° F. What physiological process explains why she is at risk for dyspnea?
   1. Fever increases metabolic demands, requiring increased oxygen need.
   2. Blood glucose stores are depleted and the cells do not have energy to use oxygen.
   3. Carbon dioxide production increases due to hyperventilation.
   4. Carbon dioxide production decreases due to hypoventilation.
5. A patient is admitted with the diagnosis of severe left-sided heart failure. What adventitious lung sounds are expected on auscultation?
   1. Sonorous wheezes in the left lower lung
   2. Rhonchi mid sternum
   3. Crackles only in apex of lungs
   4. Inspiratory crackles in lung bases
6. The nurse is caring for a patient who has decreased mobility. Which intervention is a simple and cost-effective method for reducing the risks of pulmonary complication?
   1. Antibiotics
   2. Frequent change of position
   3. Oxygen humidification
   4. Chest physiotherapy
7. A patient is admitted with severe lobar pneumonia. Which of the following assessment findings would indicate that the patient needs airway suctioning?
   1. Coughing up sputum occasionally
   2. Coughing up thin, watery sputum after nebulization
   3. Decreased ability to clear airway through coughing
   4. Lung sounds clear only after coughing
8. A patient was admitted following a motor vehicle accident with multiple fractured ribs. Respiratory assessment includes signs/symptoms of secondary pneumothorax. Which are the most common assessment findings associated with a pneumothorax? (Select all that apply.)
   1. Sharp pleuritic pain that worsens on inspiration
   2. Crackles over lung bases of affected lung
   3. Tracheal deviation toward the affected lung
   4. Worsening dyspnea
   5. Absent lung sounds to auscultation on affected side
9. A patient has been newly diagnosed with chronic lung disease. In discussing the lung disease with the nurse, which of the patient's statements would indicate a need for further education?

    1. "I'll make sure that I rest between activities so I don't get so short of breath."
    2. "I'll practice the pursed-lip breathing technique to improve my exercise tolerance."
    3. "If I have trouble breathing at night, I'll use two or three pillows to prop up."
    4. "If I get short of breath, I'll turn up my oxygen level to 6 L/min."

10. The nurse assesses a new patient and finds the patient short of breath with a respiratory rate of 32 and lying supine in bed. What is the priority nursing action?
    1. Raise the head of the bed to 45 degrees or higher.
    2. Get the oxygen saturation with a pulse oximeter.
    3. Take the blood pressure and respiratory rate.
    4. Notify the health care provider of the shortness of breath.

11. The nurse is caring for a patient who exhibits labored breathing, is using accessory muscles, and is coughing up pink frothy sputum. The patient has diminished breath sounds in bilateral lung bases. What are the priority nursing assessments for the nurse to perform prior to notifying the patient's health care provider? (Select all that apply.)
    1. SpO$_2$ levels
    2. Amount, color, and consistency of sputum production
    3. Fluid status
    4. Change in respiratory rate and pattern
    5. Pain in lower leg

12. Place the following in correct sequence for suctioning a patient.
    1. Open kit and basin
    2. Apply gloves
    3. Lubricate catheter
    4. Verify functioning of suction device and pressure
    5. Connect suction tubing to suction catheter

    6. Increase supplemental oxygen
    7. Reapply oxygen
    8. Suction airway

13. Which of the following skills can the nurse delegate to nursing assistive personnel (NAP)? (Select all that apply.)
    1. Nasotracheal suctioning
    2. Oropharyngeal suctioning of a stable patient
    3. Suctioning a new artificial airway
    4. Permanent tracheostomy tube suctioning
    5. Care of an endotracheal tube

14. Two hours after surgery, the nurse assesses a patient who had a chest tube inserted during surgery. There is 200 ml of dark red drainage in the chest tube at this time. What is the appropriate action for the nurse to perform?
    1. Record the amount and continue to monitor drainage.
    2. Notify the physician.
    3. Strip the chest tube starting at the chest.
    4. Increase the suction by 10 mm Hg.

15. The nurse is reviewing the results of the patient's diagnostic testing. Of the following results, the finding that falls within expected or normal limits is:
    1. Palpable, elevated hardened area around a tuberculosis skin testing site
    2. Sputum for culture and sensitivity identifies mycobacterium tuberculosis
    3. Presence of acid-fast bacilli in sputum
    4. Arterial oxygen tension (PaO$_2$) of 95 mm Hg

Answers: 1. 4; **2.** 4; **3.** 2; **4.** 1; **5.** 4; **6.** 2; **7.** 3; **8.** 1, 4, 5; **9.** 4; **10.** 1; **11.** 1, 2, 4; **12.** 4, 6, 1, 3, 2, 5, 8, 7; **13.** 2, 4; **14.** 1; **15.** 4.

Rationales for Review Questions can be found on the Evolve website.

Fluid, Electrolyte, and Acid-Base Balance

- Describe the processes involved in regulating extracellular fluid volume, body fluid osmolality, and fluid distribution.
- Describe the processes involved in regulating plasma concentrations of potassium, calcium, magnesium, and phosphate ions.
- Describe the processes involved in regulating acid-base balance.
- Describe common fluid, electrolyte, and acid-base imbalances.
- Identify risk factors for fluid, electrolyte, and acid-base imbalances.
- Choose appropriate clinical assessments for specific fluid, electrolyte, and acid-base imbalances.
- Interpret basic fluid, electrolyte, and acid-base laboratory values.

- Apply the nursing process when caring for patients with fluid, electrolyte, and acid-base imbalances.
- Discuss purpose and procedure for initiation and maintenance of intravenous therapy.
- Calculate an intravenous flow rate.
- Describe how to measure and record fluid intake and output.
- Explain how to change intravenous solutions and tubing and discontinue an infusion.
- Describe potential complications of intravenous therapy and what to do if they occur.
- Discuss the procedure for initiating a blood transfusion and interventions to manage a transfusion reaction.

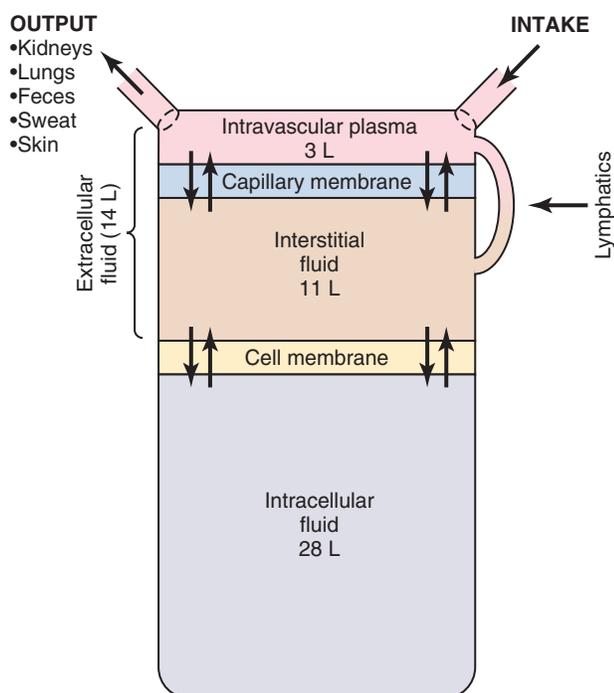
Fluid surrounds all the cells in the body and is also inside cells. Body fluids contain electrolytes such as sodium and potassium and also have a degree of acidity. Fluid, electrolyte, and acid-base balances within the body maintain the health and function of all body systems. The characteristics of body fluids influence body system function because of their effects on cell function. These characteristics include the fluid amount (volume), concentration (osmolality), composition (electrolyte concentration), and degree of acidity (pH). All of these characteristics have regulatory mechanisms that keep them in balance for normal function. In this chapter you learn how the body normally maintains fluid, electrolyte, and acid-base balance. You also learn how imbalances develop; how various fluid, electrolyte, and acid-base imbalances affect patients; and ways to help patients maintain or restore balance safely.

SCIENTIFIC KNOWLEDGE BASE

This section provides the foundation for your critical thinking regarding patients who have or are at risk of having fluid, electrolyte, or acid-base imbalances.

Location and Movement of Water and Electrolytes

Water is a substantial proportion of body weight. In fact, about 60% of the body weight of an adult man is water. This proportion decreases with age; approximately 50% of an older man's weight is water. Women typically have less water content than men. Obese people have less water in their bodies than lean people because fat contains less water than muscle (Hall, 2016). The term **fluid** means water that contains dissolved or suspended substances such as glucose, mineral salts, and proteins.

Fluid Distribution. Body fluids are located in two distinct compartments: **extracellular fluid (ECF)** outside the cells, and **intracellular fluid (ICF)** inside the cells (Figure 42-1). In adults ICF is


approximately two thirds of total body water. ECF is approximately one third of total body water. ECF has two major divisions (**intravascular fluid** and **interstitial fluid**) and a minor division (**transcellular fluids**). Intravascular fluid is the liquid part of the blood (i.e., the plasma). Interstitial fluid is located between the cells and outside the blood vessels. Transcellular fluids such as cerebrospinal, pleural, peritoneal, and synovial fluids are secreted by epithelial cells (Hall, 2016).

Composition of Body Fluids. Fluid in the body compartments contains mineral salts known technically as **electrolytes.** An electrolyte is a compound that separates into **ions** (charged particles) when it dissolves in water. Ions that are positively charged are called **cations;** ions that are negatively charged are called **anions**. Cations in body fluids are sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and magnesium ions (Mg^{2+}). Anions in body fluids are chloride (Cl^-) and bicarbonate (HCO_3^-). Anions and cations combine to make salts. If you put table salt (NaCl) in water, it separates into Na^+ and Cl^-. Other combinations of anions and cations do the same. Clinical laboratories usually report electrolyte measurements in milliequivalents per liter (mEq/L) or millimoles per liter (mmol/L), which are two different units of concentration (Table 42-1). Millimoles per liter represent the number of milligrams of the electrolyte divided by its molecular weight that are contained in a liter of the fluid being measured (usually blood plasma or serum). Milliequivalents per liter are the millimoles per liter multiplied by the electrolyte charge (e.g., 1 for Na^+, 2 for Ca^{2+}). A milliequivalent of one electrolyte can combine with a milliequivalent of another electrolyte, which is why this measurement unit is used.

Fluid that contains a large number of dissolved particles is more concentrated than the same amount of fluid that contains only a few

FIGURE 42-1 Body fluid compartments. (From Hall JE: *Guyton and Hall textbook of medical physiology*, ed 13, Philadelphia, 2016, Saunders.)

TABLE 42-1 Laboratory Normal Values for Adults

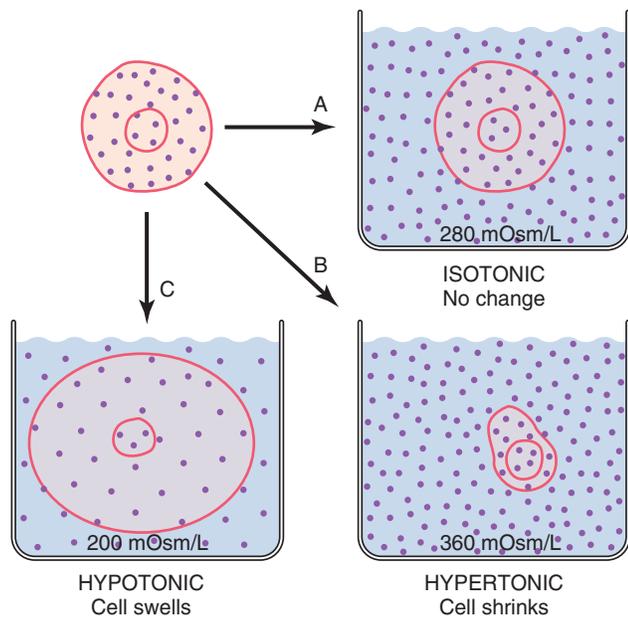
Item Measured	Normal Value in Serum or Blood
Osmolality	280-300 mOsm/kg H_2O (280-300 mmol/kg H_2O)
Electrolytes	
Sodium (Na^+)	136-145 mEq/L (136-145 mmol/L)
Potassium (K^+)	3.5-5.0 mEq/L (3.5-5 mmol/L)
Chloride (Cl^-)	98-106 mEq/L (98-106 mmol/L)
Total CO_2 (CO_2 total content)	22-30 mEq/L (22-30 mmol/L)
Bicarbonate (HCO_3^-)	Arterial 22-26 mEq/L (22-26 mmol/L) Venous 24-30 mEq/L (24-30 mmol/L)
Total calcium (Ca^{2+})	8.4-10.5 mg/dL (2.1-2.6 mmol/L)
Ionized calcium (Ca^{2+})	4.5-5.3 mg/dL (1.1-1.3 mmol/L)
Magnesium (Mg^{2+})	1.5-2.5 mEq/L (0.75-1.25 mmol/L)
Phosphate	2.7-4.5 mg/dL (0.87-1.45 mmol/L)
Anion gap	5-11 mEq/L (5-11 mmol/L)
Arterial Blood Gases	
pH	7.35-7.45
$PaCO_2$	35-45 mm Hg (4.7-6 kPa)
PaO_2	80-100 mm Hg (10.7-133.3 kPa)
O_2 saturation	95%-100% (0.95-1.00)
Base excess	−2 to +2 mm Eq/L (mmol/L)


FIGURE 42-2 Effects of isotonic, hypotonic, and hypertonic solutions. (From Hall JE: *Guyton and Hall textbook of medical physiology*, ed 13, Philadelphia, 2016, Saunders.)

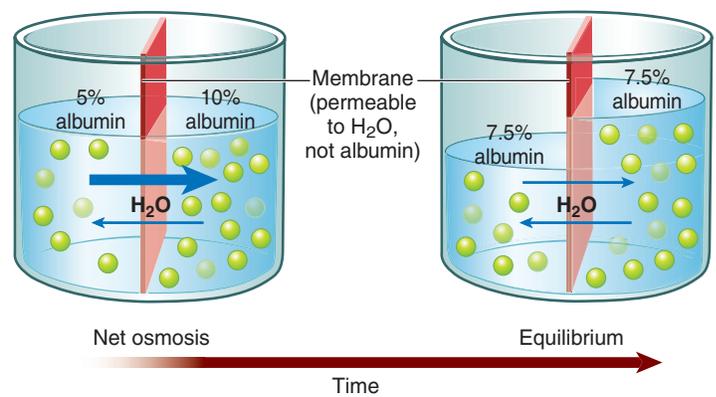
FIGURE 42-3 Osmosis moves water through semi-permeable membrane. (From Patton KT, Thibodeau GA: *Anatomy and physiology*, ed 9, St Louis, 2016, Mosby.)

particles. **Osmolality** of a fluid is a measure of the number of particles per kilogram of water. Some particles (e.g., urea) pass easily through cell membranes; others such as Na^+ cannot cross easily. The particles that cannot cross cell membranes easily determine the tonicity (effective concentration) of a fluid (Davison et al., 2014). A fluid with the same tonicity as normal blood is called **isotonic**. A **hypotonic** solution is more dilute than the blood, and a **hypertonic** solution is more concentrated than normal blood (Figure 42-2).

Movement of Water and Electrolytes. Active transport, diffusion, osmosis, and filtration are processes that move water and electrolytes between body compartments. These processes maintain equal osmolality in all compartments while allowing for different electrolyte concentrations.

Active Transport. Fluids in different body compartments have different concentrations of electrolytes that are necessary for normal function. For example, concentrations of Na^+, Cl^-, and HCO_3^- are higher in the ECF, whereas the concentrations of K^+, Mg^{2+}, and phosphate are higher in the ICF. Cells maintain their high intracellular electrolyte concentration by **active transport**. Active transport requires energy in the form of adenosine triphosphate (ATP) to move electrolytes across cell membranes against the concentration gradient (from areas of lower concentration to areas of higher concentration). One example of active transport is the sodium-potassium pump, which moves Na^+ out of a cell and K^+ into it, keeping ICF lower in Na^+ and higher in K^+ than the ECF.

Diffusion. Diffusion is passive movement of electrolytes or other particles down a concentration gradient (from areas of higher concentration to areas of lower concentration). Within a body compartment electrolytes diffuse easily by random movements until the concentration is the same in all areas. However, diffusion of electrolytes across cell membranes requires proteins that serve as ion channels. For example, when a sodium channel in a cell membrane is open, Na^+ diffuses passively across the cell membrane into the ICF because concentration is lower in the ICF. Opening of ion channels is tightly controlled and plays an important part in muscle and nerve function.


Osmosis. Water moves across cell membranes by **osmosis**, a process by which water moves through a membrane that separates fluids with different particle concentrations (Figure 42-3). Cell membranes are semi-permeable, which means that water crosses them easily but they are not freely permeable to many types of particles, including electrolytes such as sodium and potassium. These semi-permeable cell membranes separate interstitial fluid from ICF. The fluid in each of these compartments exerts **osmotic pressure**, an inward-pulling force caused by particles in the fluid. The particles already inside the cell exert ICF osmotic pressure, which tends to pull water into the cell. The particles in the interstitial fluid exert interstitial fluid osmotic pressure, which tends to pull water out of the cell. Water moves into the compartment that has a higher osmotic pressure (inward-pulling force) until the particle concentration is equal in the two compartments.

If the particle concentration in the interstitial compartment changes, osmosis occurs rapidly and moves water into or out of cells to equalize the osmotic pressures. For example, when a hypotonic solution (more dilute than normal body fluids) is administered intravenously, it dilutes the interstitial fluid, decreasing its osmotic pressure below intracellular osmotic pressure. Water moves rapidly into cells until the two osmotic pressures are equal again. On the other hand, infusion of a hypertonic intravenous (IV) solution (more concentrated than normal body fluids) causes water to leave cells by osmosis to equalize the osmolality between interstitial and intracellular compartments.

Filtration. Fluid moves into and out of capillaries (between the vascular and interstitial compartments) by the process of **filtration** (Figure 42-4). Filtration is the net effect of four forces, two that tend to move fluid out of capillaries and small venules and two that tend to move fluid back into them. **Hydrostatic pressure** is the force of the fluid pressing outward against a surface. Similarly, capillary hydrostatic pressure is a relatively strong outward-pushing force that helps move fluid from capillaries into the interstitial area. Interstitial fluid hydrostatic pressure is a weaker opposing force that tends to push fluid back into capillaries (Hall, 2016).

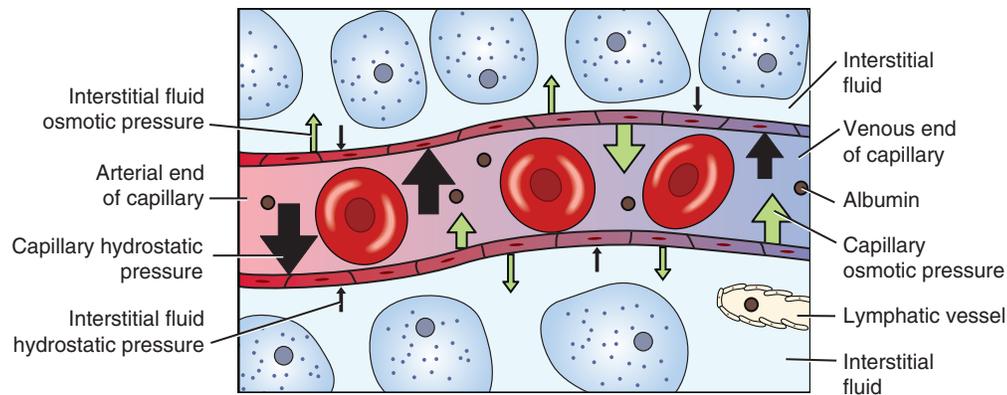
Blood contains albumin and other proteins known as **colloids**. These proteins are much larger than electrolytes, glucose, and other molecules that dissolve easily. Most colloids are too large to leave capillaries in the fluid that is filtered; thus they remain in the blood. Because they are particles, colloids exert osmotic pressure. Blood **colloid osmotic pressure**, also called **oncotic pressure**, is an inward-pulling force caused by blood proteins that helps move fluid from the interstitial area back into capillaries. Interstitial fluid colloid osmotic pressure normally is a very small opposing force.


FIGURE 42-4 Capillary filtration moves fluid between vascular and interstitial compartments. (From Copstead LC, Banasik JL: *Pathophysiology,* ed 5, St Louis, 2013, Saunders.)

At the arterial end of a normal capillary, capillary hydrostatic pressure is strongest; and fluid moves from the capillary into the interstitial area, bringing nutrients to cells. At the venous end capillary hydrostatic pressure is weaker, and the colloid osmotic pressure of the blood is stronger. Thus fluid moves into the capillary at the venous end, removing waste products from cellular metabolism. Lymph vessels remove any extra fluid and proteins that have leaked into the interstitial fluid.

Disease processes and other factors that alter these forces may cause accumulation of excess fluid in the interstitial space, known as *edema*. For example, people with heart failure develop edema. In this situation venous congestion from a weakened heart that no longer pumps effectively increases capillary hydrostatic pressure, causing edema by moving excessive fluid into the interstitial space. Inflammation is another cause of edema. It increases capillary blood flow and allows capillaries to leak colloids into the interstitial space. The resulting increased capillary hydrostatic pressure and increased interstitial colloid osmotic pressure produce localized edema in the inflamed tissues.

Fluid Balance

Fluid homeostasis is the dynamic interplay of three processes: fluid intake and absorption, fluid distribution, and fluid output (Felver, 2013d). To maintain fluid balance, fluid intake must equal output. Because some of the normal daily fluid output (e.g., urine, sweat) is a hypotonic salt solution, people must have an equivalent fluid intake of hypotonic sodium-containing fluid (or water plus foods with some salt) to maintain fluid balance (intake equal to output).

Fluid Intake. Fluid intake occurs orally through drinking but also through eating because most foods contain some water. Food metabolism creates additional water. Average fluid intake from these routes for healthy adults is about 2300 mL, although this amount can vary widely, depending on exercise habits, preferences, and the environment (Table 42-2). Other routes of fluid intake include IV, rectal (e.g., enemas), and irrigation of body cavities that can absorb fluid.

Although you might think that the major regulator of oral fluid intake is thirst, habit and social reasons also play major roles in fluid intake. Thirst, the conscious desire for water, is an important regulator of fluid intake when plasma osmolality increases (osmoreceptor-mediated thirst) or the blood volume decreases (baroreceptor-mediated thirst and angiotensin II– and III–mediated thirst) (Arai et al., 2013). The thirst-control mechanism is located within the hypothalamus in the brain (Figure 42-5). Osmoreceptors continually monitor plasma osmolality; when it increases, they cause thirst by stimulating neurons in the hypothalamus. People who are alert can obtain fluid or communicate their thirst to others, and fluid intake restores fluid

TABLE 42-2 **Healthy Adult Average Fluid Intake and Output**		
	Normal (per Day)	**Prolonged Heavy Exercise (per Hour)**
Fluid Intake		
Fluids Ingested		
Oral	1100-1400 mL	280-1100 mL/hr
Foods	800-1000 mL	Highly variable
Metabolism	300 mL	16-50 mL/hr
TOTAL	2200-2700 mL	300-1150 mL/hr
Fluid Output		
Skin (insensible and sweat)	500-600 mL	300-2100 mL/hour
Insensible lungs	400 mL	20 mL/hr
Gastrointestinal	100-200 mL	Negligible, unless diarrhea during exercise
Urine	1200-1500 mL	20-1000 mL/hr, depending on hydration status
TOTAL	2200-2700 mL	340-3120 mL/hr Rehydration with Na^+-containing fluid necessary after prolonged vigorous exercise

Data from Hall JE: *Guyton and Hall textbook of medical physiology,* ed 13, Philadelphia, 2016, Saunders; American College of Sports Medicine (ACSM): Position stand on exercise and fluid replacement, *Med Sci Sports Exerc* 39(2):377, 2007.

balance. Infants, patients with neurological or psychological problems, and some older adults who are unable to perceive or communicate their thirst are at risk for dehydration.

Fluid Distribution. The term *fluid distribution* means the movement of fluid among its various compartments. Fluid distribution between the extracellular and intracellular compartments occurs by osmosis. Fluid distribution between the vascular and interstitial parts of the ECF occurs by filtration.

Fluid Output. Fluid output normally occurs through four organs: the skin, lungs, gastrointestinal (GI) tract, and kidneys. Examples of

abnormal fluid output include vomiting, wound drainage, or hemorrhage (Felver, 2013d). Table 42-2 shows average amounts of fluid excretion for healthy adults, although urine output varies greatly, depending on fluid intake. Insensible (not visible) water loss through the skin and lungs is continuous. It increases when a person has a fever or a recent burn to the skin (Hale and Hovey, 2013). Sweat, which is visible and contains sodium, occurs intermittently and increases fluid output substantially. The GI tract plays a vital role in fluid balance. Approximately 3 to 6 L of fluid moves into the GI tract daily and returns to the ECF. The average adult normally excretes only 100 mL of fluid each day through feces. However, diarrhea causes a large fluid output from the GI tract.

The kidneys are the major regulator of fluid output because they respond to hormones that influence urine production. When healthy adults drink more water, they increase urine production to maintain fluid balance. If they drink less water, sweat a lot, or lose fluid by vomiting, their urine volume decreases to maintain fluid balance. These adjustments primarily are caused by the actions of antidiuretic hormone (ADH), the renin-angiotensin-aldosterone system (RAAS), and atrial natriuretic peptides (ANPs) (Hall, 2016) (Figure 42-6).

Antidiuretic Hormone. ADH regulates the osmolality of the body fluids by influencing how much water is excreted in urine. It is synthesized by neurons in the hypothalamus that release it from the posterior pituitary gland. ADH circulates in the blood to the kidneys, where it acts on the collecting ducts (Hall, 2016). Its name—antidiuretic hormone—tells you what it does. It causes renal cells to resorb water, taking water from the renal tubular fluid and putting it back in the blood. This action decreases urine volume, concentrating the urine while diluting the blood by adding water to it (see Figure 42-6, *A*).

People normally have some ADH release to maintain fluid balance. More ADH is released if body fluids become more concentrated. Factors that increase ADH levels include severely decreased blood volume (e.g., dehydration, hemorrhage), pain, stressors, and some medications.

ADH levels decrease if body fluids become too dilute. This allows more water to be excreted in urine, creating a larger volume of dilute urine and concentrating the body fluids back to normal osmolality. For example, ethyl alcohol decreases ADH release, which causes people to urinate frequently when they drink alcoholic beverages.

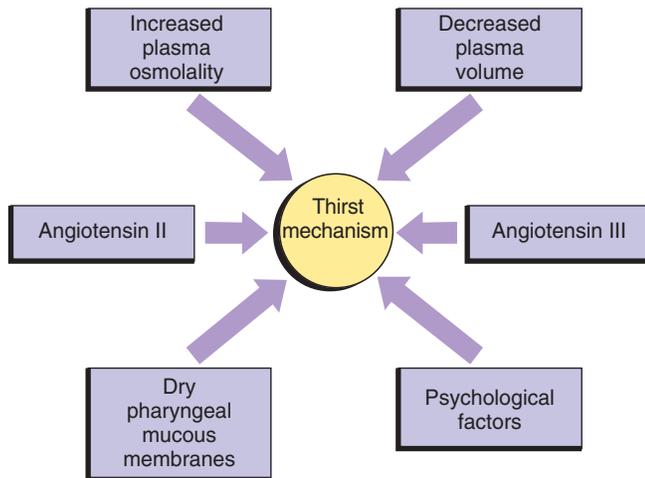
Renin-Angiotensin-Aldosterone System. The RAAS regulates ECF volume by influencing how much sodium and water are excreted in urine. It also contributes to regulation of blood pressure. Specialized cells in the kidneys release the enzyme renin, which acts on angiotensinogen, an inactive protein secreted by the liver that circulates in the blood. Renin converts angiotensinogen to angiotensin I, which is converted to angiotensin II by other enzymes in the lung capillaries (Hall, 2016). Angiotensin II has several functions, one of which is


FIGURE 42-5 Stimuli affecting thirst mechanism.
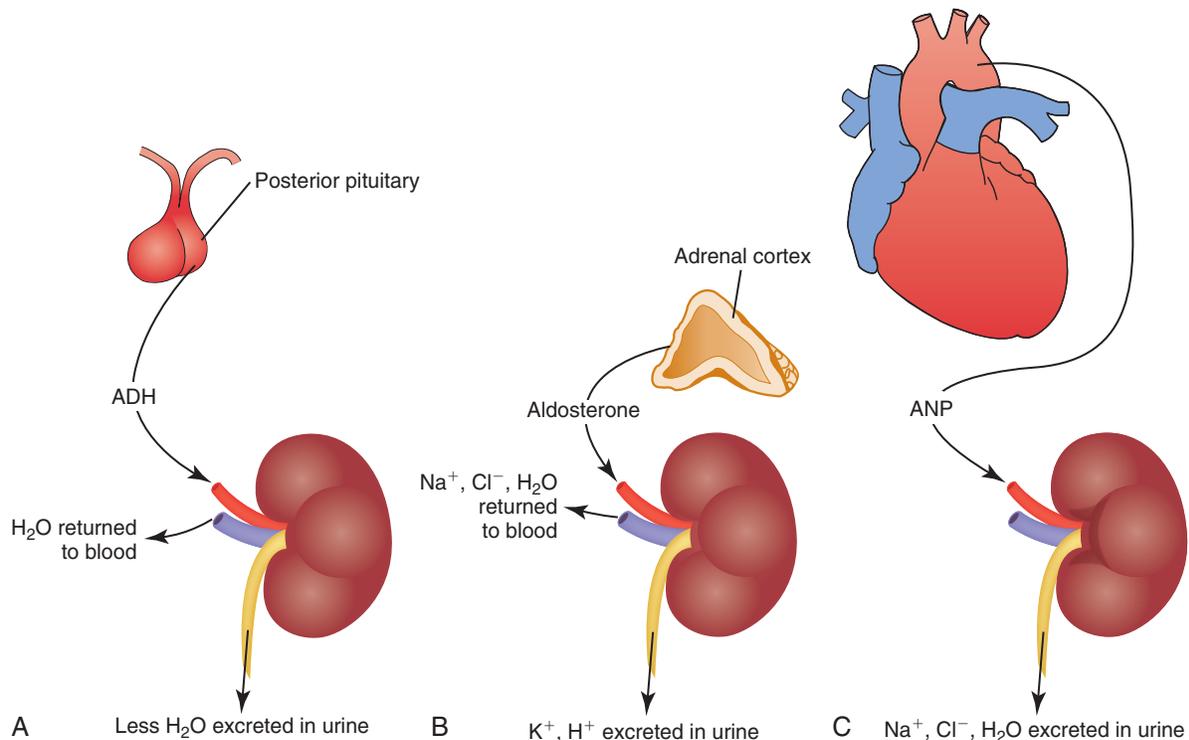

FIGURE 42-6 Major hormones that influence renal fluid excretion. **A,** Antidiuretic hormone (ADH). **B,** Aldosterone. **C,** Atrial natriuretic peptide (ANP).
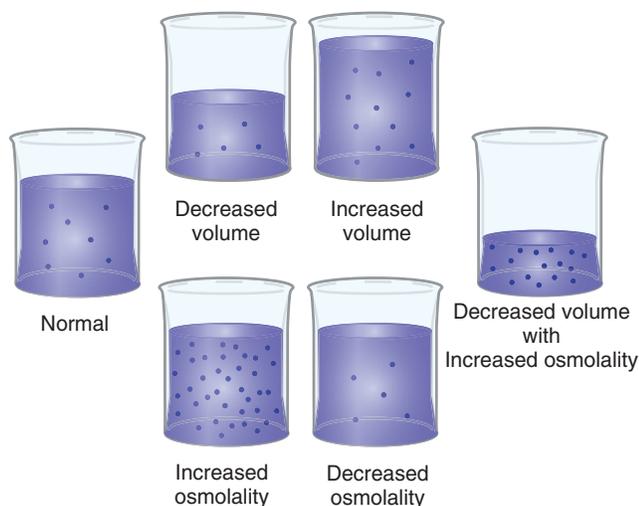

FIGURE 42-7 Fluid volume and osmolality imbalances. (From Copstead LC, Banasik JL: *Pathophysiology online for pathophysiology*, ed 4, St Louis, 2013, Mosby.)

vasoconstriction in some vascular beds. The important fluid homeostasis functions of angiotensin II include stimulation of aldosterone release from the adrenal cortex.

Aldosterone circulates to the kidneys, where it causes resorption of sodium and water in isotonic proportion in the distal renal tubules. Removing sodium and water from the renal tubules and returning it to the blood increases the volume of the ECF (see Figure 42-6, *B*). Aldosterone also contributes to electrolyte and acid-base balance by increasing urinary excretion of potassium and hydrogen ions.

To maintain fluid balance, normally some action of the RAAS occurs. Certain stimuli increase or decrease the activity of this system to restore fluid balance. For example, if hemorrhage or vomiting decreases the extracellular fluid volume (ECV), blood flow decreases through the renal arteries, and more renin is released. This increased RAAS activity causes more sodium and water retention, helping to restore ECV.

Atrial Natriuretic Peptide. ANP also regulates ECV by influencing how much sodium and water are excreted in urine. Cells in the atria of the heart release ANP when they are stretched (e.g., by an increased ECV). ANP is a weak hormone that inhibits ADH by increasing the loss of sodium and water in the urine (see Figure 42-6, *C*). Thus ANP opposes the effect of aldosterone (Hall, 2016).

Fluid Imbalances

If disease processes, medications, or other factors disrupt fluid intake or output, imbalances sometimes occur (Felver, 2013d). For example, with diarrhea there is an increase in fluid output, and a fluid imbalance (dehydration) occurs if fluid intake does not increase appropriately. There are two major types of fluid imbalances: volume imbalances and osmolality imbalances (Figure 42-7). Volume imbalances are disturbances of the *amount of fluid in the extracellular compartment.* Osmolality imbalances are disturbances of the *concentration of body fluids.* Volume and osmolality imbalances occur separately or in combination.

Extracellular Fluid Volume Imbalances. In an ECV imbalance there is either too little (ECV deficit) or too much (ECV excess) isotonic fluid. **ECV deficit** is present when there is insufficient isotonic fluid in the extracellular compartment. Remember that there is a lot of sodium in normal ECF. With ECV deficit, output of isotonic fluid exceeds intake of sodium-containing fluid. Because ECF is both vascular and interstitial, signs and symptoms arise from lack of volume in both of these compartments. Table 42-3 lists specific causes and signs and symptoms of ECV deficit. The term **hypovolemia** means decreased vascular volume and often is used when discussing ECV deficit (Hale and Hovey, 2013).

ECV excess occurs when there is too much isotonic fluid in the extracellular compartment. Intake of sodium-containing isotonic fluid has exceeded fluid output. For example, when you eat more salty foods than usual and drink water, you may notice that your ankles swell or rings on your fingers feel tight and you gain 2 lbs (1 kg) or more overnight. These are manifestations of mild ECV excess. See Table 42-3 for other specific causes and signs and symptoms.

Osmolality Imbalances. In an osmolality imbalance body fluids become hypertonic or hypotonic, which causes osmotic shifts of water across cell membranes. The osmolality imbalances are called *hypernatremia* and *hyponatremia.*

Hypernatremia, also called *water deficit,* is a hypertonic condition. Two general causes make body fluids too concentrated: loss of relatively more water than salt or gain of relatively more salt than water (Felver, 2013d). Table 42-3 lists specific causes under these categories. When the interstitial fluid becomes hypertonic, water leaves cells by osmosis, and they shrivel. Signs and symptoms of hypernatremia are those of cerebral dysfunction, which arise when brain cells shrivel. Hypernatremia may occur in combination with ECV deficit; this combined disorder is called clinical **dehydration**.

Hyponatremia, also called *water excess* or *water intoxication,* is a hypotonic condition. It arises from gain of relatively more water than salt or loss of relatively more salt than water (Felver, 2013d) (see Table 42-3). The excessively dilute condition of interstitial fluid causes water to enter cells by osmosis, causing the cells to swell. Signs and symptoms of cerebral dysfunction occur when brain cells swell.

Clinical Dehydration. ECV deficit and hypernatremia often occur at the same time; this combination is called *clinical dehydration.* The ECV is too low, and the body fluids are too concentrated. Clinical dehydration is common with gastroenteritis or other causes of severe vomiting and diarrhea when people are not able to replace their fluid output with enough intake of dilute sodium-containing fluids. Signs and symptoms of clinical dehydration are those of both ECV deficit and hypernatremia (see Table 42-3).

Electrolyte Balance

You can best understand electrolyte balance by considering the three processes involved in electrolyte homeostasis: electrolyte intake and absorption, electrolyte distribution, and electrolyte output (Table 42-4) (Felver, 2013d). Although sodium is an electrolyte, it is not included here because serum sodium imbalances are the osmolality imbalances discussed previously.

Electrolyte distribution is an important issue. Plasma concentrations of K^+, Ca^{2+}, Mg^{2+}, and phosphate are very low compared with their concentrations in cells and bone (Hall, 2016). These concentration differences are necessary for normal muscle and nerve function. The electrolyte values that you review from laboratory reports are measured in blood serum and do not measure intracellular levels.

Electrolyte output occurs through normal excretion in urine, feces, and sweat. Output also occurs through vomiting, drainage tubes, or fistulas. When electrolyte output increases, electrolyte intake must increase to maintain electrolyte balance. Similarly, if electrolyte output decreases such as with oliguria, electrolyte intake must also decrease to maintain balance (Felver, 2013c).

TABLE 42-3   Fluid Imbalances

Imbalance and Related Causes	Signs and Symptoms
Isotonic Imbalances—Water and Sodium Lost or Gained in Equal or Isotonic Proportions	
Extracellular Fluid Volume Deficit—Body Fluids Have Decreased Volume but Normal Osmolality	
Sodium and Water Intake Less Than Output, Causing Isotonic Loss: Severely decreased oral intake of water and salt	*Physical examination:* Sudden weight loss (overnight), postural hypotension, tachycardia, thready pulse, dry mucous membranes, poor skin turgor, slow vein filling, flat neck veins when supine, dark yellow urine
Increased GI output: vomiting, diarrhea, laxative overuse, drainage from fistulas or tubes	If severe: thirst, restlessness, confusion, hypotension; oliguria (urine output *below* 30 mL/hr); cold, clammy skin; hypovolemic shock
Increased renal output: use of diuretics, adrenal insufficiency (deficit of cortisol and aldosterone)	*Laboratory findings:* Increased hematocrit; increased BUN *above* 25 mg/dL (8.9 mmol/L) (hemoconcentration); urine specific gravity usually *above* 1.030, unless renal cause
Loss of blood or plasma: hemorrhage, burns	
Massive sweating without water and salt intake	
Extracellular Fluid Volume Excess—Body Fluids Have Increased Volume but Normal Osmolality	
Sodium and Water Intake Greater Than Output, Causing Isotonic Gain: Excessive administration of Na⁺-containing isotonic IV fluids or oral intake of salty foods and water	*Physical examination:* Sudden weight gain (overnight), edema (especially in dependent areas), full neck veins when upright or semi-upright, crackles in lungs
Renal retention of Na⁺ and water: heart failure, cirrhosis, aldosterone or glucocorticoid excess, acute or chronic oliguric renal disease	If severe: confusion, pulmonary edema
	Laboratory findings: Decreased hematocrit, decreased BUN *below* 10 mg/dL (3.6 mmol/L) (hemodilution)
Osmolality Imbalances	
Hypernatremia (Water Deficit; Hyperosmolar Imbalance)—Body Fluids Too Concentrated	
Loss of Relatively More Water Than Salt: Diabetes insipidus (ADH deficiency)	*Physical examination:* Decreased level of consciousness (confusion, lethargy, coma), perhaps thirst, seizures if develops rapidly or is very severe
Osmotic diuresis	*Laboratory findings:* Serum Na⁺ level *above* 145 mEq/L (145 mmol/L), serum osmolality *above* 300 mOsm/kg (300 mmol/kg)
Large insensible perspiration and respiratory water output without increased water intake	
Gain of Relatively More Salt Than Water: Administration of tube feedings, hypertonic parenteral fluids, or salt tablets	
Lack of access to water, deliberate water deprivation, inability to respond to thirst (e.g., immobility, aphasia)	
Dysfunction of osmoreceptor-driven thirst drive	
Hyponatremia (Water Excess; Water Intoxication; Hypo-osmolar Imbalance)—Body Fluids Too Dilute	
Gain of Relatively More Water Than Salt: Excessive ADH (SIADH)	*Physical examination:* Decreased level of consciousness (confusion, lethargy, coma), seizures if develops rapidly or is very severe
Psychogenic polydipsia or forced excessive water intake	*Laboratory findings:* Serum Na⁺ level *below* 135 mEq/L (135 mmol/L), serum osmolality *below* 280 mOsm/kg (280 mmol/kg)
Excessive IV administration of D₅W	
Use of hypotonic irrigating solutions	
Tap-water enemas	
Loss of Relatively More Salt Than Water: Replacement of large body fluid output (e.g., diarrhea, vomiting) with water but no salt	
Combined Volume and Osmolality Imbalance	
Clinical Dehydration (ECV Deficit plus Hypernatremia)—Body Fluids Have Decreased Volume and Are Too Concentrated	
Sodium and Water Intake Less Than Output, With Loss of Relatively More Water Than Salt: All of the causes of ECV deficit (see previous causes) plus poor or no water intake, often with fever causing increased insensible water output	*Physical examination and laboratory findings:* Combination of those for ECV deficit plus those for hypernatremia (see previous signs)

ADH, Antidiuretic hormone; *BUN*, blood urea nitrogen; *ECV*, extracellular fluid volume; *GI*, gastrointestinal; *D₅W*, 5% dextrose in water; *IV*, intravenous; *SIADH*, syndrome of inappropriate secretion of antidiuretic hormone.

Electrolyte Imbalances

Factors such as diarrhea, endocrine disorders, and medications that disrupt electrolyte homeostasis cause electrolyte imbalances. Electrolyte intake greater than electrolyte output or a shift of electrolytes from cells or bone into the ECF causes plasma electrolyte excess. Electrolyte intake less than electrolyte output or shift of electrolyte from the ECF into cells or bone causes plasma electrolyte deficit (Felver, 2013c).

Potassium Imbalances.   **Hypokalemia** is abnormally low potassium concentration in the blood. It results from decreased potassium intake and absorption, a shift of potassium from the ECF into cells,

TABLE 42-4 Electrolyte Intake and Absorption, Distribution, and Output

Electrolyte	Intake and Absorption	Distribution	Output/Loss	Important Function
Potassium (K^+)	Fruits Potatoes Instant coffee Molasses Brazil nuts Absorbs easily	Low in ECF, high in ICF. Insulin, epinephrine, and alkalosis shift K^+ into cells. Some types of acidosis shift K^+ out of cells.	Aldosterone, black licorice, hypomagnesemia, and polyuria increase renal excretion; oliguria decreases renal excretion. Acute or chronic diarrhea increases fecal excretion.	Maintains resting membrane potential of skeletal, smooth, and cardiac muscle, allowing normal muscle function
Calcium (Ca^{2+})	Dairy products Canned fish with bones Broccoli Oranges Requires vitamin D for best absorption Undigested fat prevents absorption	Ca^{2+} is low in ECF, mostly in bones and intracellular. Some Ca^{2+} in blood is bound and inactive; only ionized Ca^{2+} is active. Parathyroid hormone shifts Ca^{2+} out of bone; calcitonin shifts Ca^{2+} into bone. Ca^{2+} decreases in blood if phosphate rises and vice versa.	Thiazide diuretics decrease renal excretion. Chronic diarrhea and undigested fat increase fecal excretion.	Influences excitability of nerve and muscle cells; necessary for muscle contraction
Magnesium (Mg^{2+})	Dark green leafy vegetables Whole grains Mg^{2+}-containing laxatives and antacids Undigested fat prevents absorption	Mg^{2+} is low in ECF, mostly in bones and intracellular. Some Mg^{2+} in blood is bound and inactive; only free Mg^{2+} is active.	Rising blood ethanol increases renal excretion; oliguria decreases renal excretion. Chronic diarrhea and undigested fat increase fecal excretion.	Influences function of neuromuscular junctions; is a cofactor for numerous enzymes
Phosphate	Milk Processed foods Aluminum antacids prevent absorption	Phosphate is low in ECF; it is higher in ICF and in bones. Insulin and epinephrine shift phosphate into cells. Decreases in blood if calcium rises and vice versa.	Oliguria decreases renal excretion.	Necessary for production of ATP, the energy source for cellular metabolism

ATP, Adenosine triphosphate; *ECF,* extracellular fluid volume; *ICF,* intracellular fluid.

and an increased potassium output (Table 42-5). Common causes of hypokalemia from increased potassium output include diarrhea, repeated vomiting, and use of potassium-wasting diuretics. People who have these conditions need to increase their potassium intake to reduce their risk of hypokalemia. Hypokalemia causes muscle weakness, which becomes life threatening if it includes respiratory muscles and potentially life-threatening cardiac dysrhythmias.

Hyperkalemia is abnormally high potassium ion concentration in the blood. Its general causes are increased potassium intake and absorption, shift of potassium from cells into the ECF, and decreased potassium output (see Table 42-5). People who have oliguria (decreased urine output) are at high risk of hyperkalemia from the resultant decreased potassium output unless their potassium intake also decreases substantially. Understanding this principle helps you remember to check urine output before you administer IV solutions containing potassium. Hyperkalemia can cause muscle weakness, potentially life-threatening cardiac dysrhythmias, and cardiac arrest.

Calcium Imbalances. **Hypocalcemia** is abnormally low calcium concentration in the blood. The physiologically active form of calcium in the blood is ionized calcium. Total blood calcium also contains inactive forms that are bound to plasma proteins and small anions such as citrate. Factors that cause too much ionized calcium to shift to the bound forms cause symptomatic *ionized hypocalcemia*. Table 42-5 summarizes general causes. People who have acute pancreatitis frequently develop hypocalcemia because calcium binds to undigested fat in their feces and is excreted. This process decreases absorption of dietary calcium and also increases calcium output by preventing resorption of calcium contained in GI fluids. Hypocalcemia increases neuromuscular excitability, the basis for its signs and symptoms.

Hypercalcemia is abnormally high calcium concentration in the blood. Hypercalcemia results from increased calcium intake and absorption, shift of calcium from bones into the ECF, and decreased calcium output (see Table 42-5). Patients with some types of cancers such as lung and breast cancers often develop hypercalcemia because some cancer cells secrete chemicals into the blood that are related to parathyroid hormone. When these chemicals reach the bones, they cause shift of calcium from bones into the ECF. This weakens bones, and the person sometimes develops pathological fractures (i.e., bone breakage caused by forces that would not break a healthy bone). Hypercalcemia decreases neuromuscular excitability, the basis for its other signs and symptoms, the most common of which is lethargy.

Magnesium Imbalances. **Hypomagnesemia** is abnormally low magnesium concentration in the blood. Its general causes are decreased magnesium intake and absorption, shift of plasma magnesium to its inactive bound form, and increased magnesium output (see Table 42-5). Signs and symptoms are similar to those of hypocalcemia because hypomagnesemia also increases neuromuscular excitability.

Hypermagnesemia is abnormally high magnesium concentration in the blood (see Table 42-5). End-stage renal disease causes hypermagnesemia unless the person decreases magnesium intake to match the decreased output. Signs and symptoms are caused by decreased neuromuscular excitability, with lethargy and decreased deep tendon reflexes being most common.

TABLE 42-5 Electrolyte Imbalances

Imbalance and Related Causes	Signs and Symptoms
Hypokalemia—Low Serum Potassium (K⁺) Concentration	
Decreased K⁺ Intake: Excessive use of K⁺-free IV solutions **Shift of K⁺ into Cells:** Alkalosis; treatment of diabetic ketoacidosis with insulin **Increased K⁺ Output:** Acute or chronic diarrhea; vomiting; other GI losses (e.g., nasogastric or fistula drainage); use of potassium-wasting diuretics; aldosterone excess; polyuria; glucocorticoid therapy	*Physical examination:* Bilateral muscle weakness that begins in quadriceps and may ascend to respiratory muscles, abdominal distention, decreased bowel sounds, constipation, dysrhythmias *Laboratory findings:* Serum K⁺ level *below* 3.5 mEq/L (3.5 mmol/L); ECG abnormalities: U waves, flattened or inverted T waves; ST segment depression
Hyperkalemia—High Serum Potassium (K⁺) Concentration	
Increased K⁺ Intake: Iatrogenic administration of large amounts of IV K⁺; rapid infusion of stored blood; excess ingestion of K⁺ salt substitutes **Shift of K⁺ out of Cells:** Massive cellular damage (e.g., crushing trauma, cytotoxic chemotherapy); insufficient insulin (e.g., diabetic ketoacidosis); some types of acidosis **Decreased K⁺ Output:** Acute or chronic oliguria (e.g., severe ECV deficit, end-stage renal disease); use of potassium-sparing diuretics; adrenal insufficiency (deficit of cortisol and aldosterone)	*Physical examination:* Bilateral muscle weakness in quadriceps, transient abdominal cramps, diarrhea, dysrhythmias, cardiac arrest if severe *Laboratory findings:* Serum K⁺ level *above* 5 mEq/L (5 mmol/L); ECG abnormalities: peaked T waves; widened QRS complex; PR prolongation; terminal sine-wave pattern
Hypocalcemia—Low Serum Calcium (Ca²⁺) Concentration	
Decreased Ca²⁺ Intake and Absorption: Calcium-deficient diet; vitamin D deficiency (includes end-stage renal disease); chronic diarrhea; laxative misuse; steatorrhea **Shift of Ca²⁺ into Bone or Inactive Form:** Hypoparathyroidism; rapid administration of citrated blood; hypoalbuminemia; alkalosis; pancreatitis; hyperphosphatemia (includes end-stage renal disease) **Increased Ca²⁺ Output:** Chronic diarrhea; steatorrhea	*Physical examination:* Numbness and tingling of fingers, toes, and circumoral (around mouth) region, positive Chvostek's sign (contraction of facial muscles when facial nerve is tapped), hyperactive reflexes, muscle twitching and cramping; carpal and pedal spasms, tetany, seizures, laryngospasm, dysrhythmias *Laboratory findings:* Total serum Ca²⁺ level *below* 8.4 mg/dL (2.1 mmol/L) or serum ionized Ca²⁺ level *below* 4.5 mg/dL (1.1 mmol/L); ECG abnormalities: prolonged ST segments
Hypercalcemia—High Serum Calcium (Ca²⁺) Concentration	
Increased Ca²⁺ Intake and Absorption: Milk-alkali syndrome **Shift of Ca²⁺ out of Bone:** Prolonged immobilization; hyperparathyroidism; bone tumors; nonosseous cancers that secrete bone-resorbing factors **Decreased Ca²⁺ Output:** Use of thiazide diuretics	*Physical examination:* Anorexia, nausea and vomiting, constipation, fatigue, diminished reflexes, lethargy, decreased level of consciousness, confusion, personality change, cardiac arrest if severe *Laboratory findings:* Total serum Ca²⁺ level *above* 10.5 mg/dL (2.6 mmol/L) or serum ionized Ca²⁺ level *above* 5.3 mg/dL (1.3 mmol/L); ECG abnormalities: heart block, shortened ST segments
Hypomagnesemia—Low Serum Magnesium (Mg²⁺) Concentration	
Decreased Mg²⁺ Intake and Absorption: Malnutrition; chronic alcoholism; chronic diarrhea; laxative misuse; steatorrhea **Shift of Mg²⁺ Into Inactive Form:** Rapid administration of citrated blood **Increased Mg²⁺ Output:** Chronic diarrhea; steatorrhea; other GI losses (e.g., vomiting, nasogastric or fistula drainage); use of thiazide or loop diuretics; aldosterone excess	*Physical examination:* Positive Chvostek's sign, hyperactive deep tendon reflexes, muscle cramps and twitching, grimacing, dysphagia, tetany, seizures, insomnia, tachycardia, hypertension, dysrhythmias *Laboratory findings:* Serum Mg²⁺ level *below* 1.5 mEq/L (0.75 mmol/L); ECG abnormalities: prolonged QT interval
Hypermagnesemia—High Serum Magnesium (Mg²⁺) Concentration	
Increased Mg²⁺ Intake and Absorption: Excessive use of Mg²⁺-containing laxatives and antacids; parenteral overload of magnesium **Decreased Mg²⁺ Output:** Oliguric end-stage renal disease; adrenal insufficiency	*Physical examination:* Lethargy, hypoactive deep tendon reflexes, bradycardia, hypotension Acute elevation in Mg²⁺ levels: Flushing, sensation of warmth Severe acute hypermagnesemia: Decreased rate and depth of respirations, dysrhythmias, cardiac arrest *Laboratory findings:* Serum Mg²⁺ level *above* 2.5 mEq/L (1.25 mmol/L); ECG abnormalities: prolonged PR interval

Data from Felver L: Fluid and electrolyte homeostasis and imbalances. In Copstead LC, Banasik JL: *Pathophysiology,* ed 5, St Louis, 2013, Saunders.

ECG, electrocardiogram, *ECV,* extracellular fluid volume, *GI,* gastrointestinal, *IV,* intravenous.

TABLE 42-6   Arterial Blood Gas Measures

Laboratory Measure	Normal Range in Adult Arterial Blood	Definition and Interpretation
pH	7.35-7.45	pH is a negative logarithm of the free H^+ concentration, a measure of how acid or alkaline the blood is. Values below 7.35 indicate abnormally acid; above 7.45 they indicate abnormally alkaline. Small changes in pH denote large changes in H^+ concentration and are clinically important.
$PaCO_2$	35-45 mm Hg (4.7-6 kPa)	$PaCO_2$ is partial pressure of carbon dioxide (CO_2), a measure of how well the lungs are excreting CO_2 produced by cells. Increased $PaCO_2$ indicates CO_2 accumulation in blood (more carbonic acid) caused by hypoventilation; decreased $PaCO_2$ indicates excessive CO_2 excretion (less carbonic acid) through hyperventilation.
HCO_3^-	22-26 mEq/L (22-26 mmol/L)	HCO_3^- is concentration of the base (alkaline substance) bicarbonate, a measure of how well the kidneys are excreting metabolic acids. Increased HCO_3^- indicates that the blood has too few metabolic acids; decreased HCO_3^- indicates that the blood has too many metabolic acids.
PaO_2	80-100 mm Hg (10-13.3 kPa)	PaO_2 is partial pressure of oxygen (O_2), a measure of how well gas exchange is occurring in the alveoli of the lungs. Values below normal indicate poor oxygenation of the blood.
SaO_2	95%-100%	SaO_2 is oxygen saturation, the percentage of hemoglobin that is carrying as much O_2 as possible. It is influenced by pH, $PaCO_2$, and body temperature. It drops rapidly when PaO_2 falls below 60 mm Hg (8 kPa).
Base excess	−2 to +2 mEq/L (mmol/L)	Base excess is observed buffering capacity minus the normal buffering capacity, a measure of how well the blood buffers are managing metabolic acids. Values below −2 (negative base excess) indicate excessive metabolic acids; values above +2 indicate excessive amounts of bicarbonate.

Acid-Base Balance

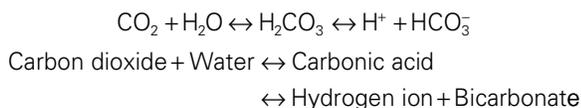
For optimal cell function the body maintains a balance between acids and bases. Acid-base homeostasis is the dynamic interplay of three processes: acid production, acid buffering, and acid excretion (Felver, 2013a). Normal acid-base balance is maintained with acid excretion equal to acid production. Acids release hydrogen (H^+) ions; bases (alkaline substances) take up H^+ ions. The more H^+ ions that are present, the more acidic is the solution.

The degree of acidity in blood and other body fluids is reported from the clinical laboratory as pH. The pH scale goes from 1.0 (very acid) to 14.0 (very alkaline; basic). A pH of 7.0 is considered neutral. The normal pH range of adult arterial blood is 7.35 to 7.45. Maintaining pH within this normal range is very important for optimal cell function. If the pH goes outside the normal range, enzymes within cells do not function properly; hemoglobin does not manage oxygen properly; and serious physiological problems occur, including death. Laboratory tests of a sample of arterial blood called **arterial blood gases (ABGs)** are used to monitor a patient's acid-base balance (Ayers and Dixon, 2012) (Table 42-6).

Acid Production. Cellular metabolism constantly creates two types of acids: carbonic acid and metabolic acids (Figure 42-8). Cells produce carbon dioxide (CO_2), which acts like an acid in the body by converting to carbonic acid (H_2CO_3):

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

Carbon dioxide + Water ↔ Carbonic acid

↔ Hydrogen ion + Bicarbonate


Metabolic acids are any acids that are not carbonic acid. They include citric acid, lactic acid, and many others.

Acid Buffering. **Buffers** are pairs of chemicals that work together to maintain normal pH of body fluids. If there are too many free H^+ ions, a buffer takes them up so they no longer are free. If there are too few, a buffer can release H^+ ions to prevent an acid-base imbalance. Buffers work rapidly, within seconds.

All body fluids contain buffers. The major buffer in the ECF is the bicarbonate (HCO_3^-) buffer system, which buffers metabolic acids. It consists of a lot of bicarbonate and a small amount of carbonic acid (normally a 20 to 1 ratio). Addition of H^+ released by a metabolic acid to a bicarbonate ion makes more carbonic acid. Now the H^+ is no longer free and will not decrease the blood pH:

$$HCO_3^- + H^+ \leftrightarrow H_2CO_3$$

Bicarbonate ion + Hydrogen ion ↔ Carbonic acid
If there are too few H^+ ions, the carbonic acid part of the buffer pair releases some, increasing the bicarbonate, again returning pH to normal.

$$H_2CO_3 \leftrightarrow HCO_3^- + H^+$$

Carbonic acid ↔ Bicarbonate ion + Hydrogen ion
Other buffers include hemoglobin, protein buffers, and phosphate buffers. Cellular and bone buffers also contribute. Buffers normally keep the blood from becoming too acid when acids that are produced by cells circulate to the lungs and kidneys for excretion.

Acid Excretion. The body has two acid-excretion systems: lungs and kidneys. The lungs excrete carbonic acid; the kidneys excrete metabolic acids (see Figure 42-8).

Excretion of Carbonic Acid. When you exhale, you excrete carbonic acid in the form of CO_2 and water. If the $PaCO_2$ (i.e., level of CO_2 in the blood) rises, the chemoreceptors trigger faster and deeper respirations to excrete the excess. If the $PaCO_2$ falls, the chemoreceptors trigger slower and shallower respirations so more of the CO_2 produced by cells remains in the blood and makes up the deficit. These alterations in respiratory rate and depth maintain the carbonic acid part of acid-base balance (Hale and Hovey, 2013). People who have respiratory disease may be unable to excrete enough carbonic acid, which causes the blood to become more acidic and blood CO_2 to increase. If an increased respiratory rate is unable to correct the problem, the kidneys begin some compensatory excretion of metabolic acid.

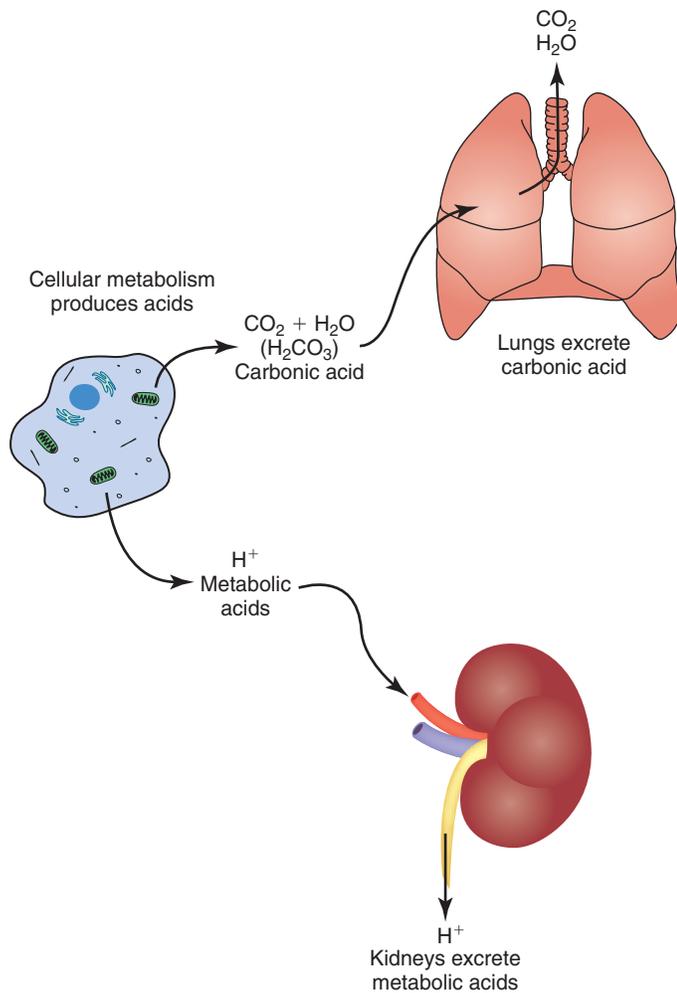
Excretion of Metabolic Acids. The kidneys excrete all acids except carbonic acid. They secrete H^+ into the renal tubular fluid, putting


FIGURE 42-8 Acid production and excretion.

HCO_3^- back into the blood at the same time. If there are too many H^+ ions in the blood, renal cells move more H^+ ions into the renal tubules for excretion, retaining more HCO_3^- in the process. If there are too few H^+ ions in the blood, renal cells secrete fewer H^+ ions.

Phosphate buffers in the renal tubular fluid keep the urine from becoming too acidic when the kidneys excrete H^+ ions. If the kidneys need to excrete a lot of H^+, renal tubular cells secrete ammonia, which combines with the H^+ ions in the tubules to make NH_4^+, ammonium ions. Buffering by phosphate and the creation of NH_4^+ turn free H^+ ions into other molecules in the renal tubular fluid (Hale and Hovey, 2013). This process enables metabolic acid excretion in urine without making urine too acidic. People who have oliguric kidney disease often are unable to excrete metabolic acids normally; and these acids accumulate, making the blood too acidic. If the kidneys are unable to correct this problem, respiratory rate and depth increase, causing compensatory excretion of carbonic acid.

Acid-Base Imbalances

People develop acid-base imbalances when their normal homeostatic mechanisms are dysfunctional or overwhelmed. The term **acidosis** describes a condition that tends to make the blood relatively too acidic. Because our cells produce two types of acid, there are two different types of acidosis: respiratory acidosis and metabolic acidosis. The term **alkalosis** describes a condition that tends to make the blood relatively too basic (alkaline). There are two types of alkalosis: respiratory alkalosis and metabolic alkalosis.

The body has compensatory mechanisms that limit the extent of pH change with acid-base imbalances (Berend et al., 2014). Compensation involves physiological changes that help normalize the pH but do not correct the cause of the problem. If the problem is a respiratory acid-base imbalance, only the lungs can correct the problem, but the kidneys can compensate by changing the amount of metabolic acid in the blood. If the problem is a metabolic acid-base imbalance, only the kidneys can correct the problem, but the lungs can compensate by changing the amount of carbonic acid in the blood. Thus the kidneys compensate for respiratory acid-base imbalances; the respiratory system compensates for metabolic acid-base imbalances. These compensatory mechanisms do not correct the problem, but they help the body survive by moving the blood pH toward normal. However, if the underlying condition is not corrected, these compensatory mechanisms eventually will fail.

Respiratory Acidosis. **Respiratory acidosis** arises from alveolar hypoventilation; the lungs are unable to excrete enough CO_2. The $PaCO_2$ rises, creating an excess of carbonic acid in the blood, which decreases pH (Table 42-7). The kidneys compensate by increasing excretion of metabolic acids in the urine, which increases blood bicarbonate. This compensatory process is slow, often taking 24 hours to show clinical effect and 3 to 5 days to reach steady state. Decreased cerebrospinal fluid (CSF) pH and intracellular pH of brain cells cause decreased level of consciousness.

Respiratory Alkalosis. **Respiratory alkalosis** arises from alveolar hyperventilation; the lungs excrete too much carbonic acid (CO_2 and water). The $PaCO_2$ falls, creating a deficit of carbonic acid in the blood, which increases pH (see Table 42-7). Respiratory alkalosis usually is short lived; thus the kidneys do not have time to compensate. When the pH of blood, CSF, and ICF increases acutely, cell membrane excitability also increases, which can cause neurological symptoms such as excitement, confusion, and paresthesias. If the pH rises high enough, central nervous system (CNS) depression can occur.

Metabolic Acidosis. **Metabolic acidosis** occurs from an increase of metabolic acid or a decrease of base (bicarbonate). The kidneys are unable to excrete enough metabolic acids, which accumulate in the blood, or bicarbonate is removed from the body directly as with diarrhea (see Table 42-7). In either case the blood HCO_3^- decreases, and the pH falls. With an increase of metabolic acids, blood HCO_3^- decreases because it is used to buffer metabolic acids. Similarly, when patients have conditions that cause the removal of HCO_3^-, the amount of HCO_3^- in the blood decreases. To help identify the specific cause, health care providers and the laboratory calculate the **anion gap,** a reflection of unmeasured anions in plasma. You calculate anion gap by subtracting the sum of plasma concentrations of the anions Cl^- and HCO_3^- from the plasma concentration of the cation Na^+ (Berend et al., 2014). When reviewing laboratory reports, check the reference values from the laboratory that measured the electrolyte concentrations (Table 42-8).

The abnormally low pH in metabolic acidosis stimulates the chemoreceptors so the respiratory system compensates for the acidosis by hyperventilation. Compensatory hyperventilation begins in a few minutes and removes carbonic acid from the body. This process does not correct the problem, but it helps limit the pH decrease. Metabolic acidosis decreases one's level of consciousness (see Table 42-7).

Metabolic Alkalosis. **Metabolic alkalosis** occurs from a direct increase of base (HCO_3^-) or a decrease of metabolic acid, which increases blood HCO_3^- by releasing it from its buffering function.

TABLE 42-7   Acid-Base Imbalances

Imbalance and Related Causes	Signs and Symptoms
Respiratory Acidosis—Excessive Carbonic Acid Caused by Alveolar Hypoventilation	
Impaired Gas Exchange: Type B COPD (chronic bronchitis) or end-stage type A COPD (emphysema) Bacterial pneumonia Airway obstruction Extensive atelectasis (collapsed alveoli) Severe acute asthma episode **Impaired Neuromuscular Function:** Respiratory muscle weakness or paralysis from hypokalemia or neurological dysfunction Respiratory muscle fatigue, respiratory failure Chest wall injury or surgery causing pain with respiration **Dysfunction of Brainstem Respiratory Control:** Drug overdose with a respiratory depressant Some types of head injury	*Physical examination:* Headache, light-headedness, decreased level of consciousness (confusion, lethargy, coma), dysrhythmias *Laboratory findings:* Arterial blood gas alterations: pH *below* 7.35, PaCO$_2$ *above* 45 mm Hg (6 kPa), HCO$_3^-$ level normal if uncompensated or *above* 26 mEq/L (26 mmol/L) if compensated
Respiratory Alkalosis—Deficient Carbonic Acid Caused by Alveolar Hyperventilation	
Hypoxemia from any cause (e.g., initial part of asthma episode, pneumonia) Acute pain Anxiety, psychological distress, sobbing Inappropriate mechanical ventilator settings Stimulation of brainstem respiratory control (e.g., meningitis, gram-negative sepsis, head injury, aspirin overdose)	*Physical examination:* Light-headedness, numbness and tingling of fingers, toes, and circumoral region, increased rate and depth of respirations, excitement and confusion possibly followed by decreased level of consciousness, dysrhythmias *Laboratory findings:* Arterial blood gas alterations: pH *above* 7.45, PaCO$_2$ *below* 35 mm Hg (4.7 kPa), HCO$_3^-$ level normal if short lived or uncompensated or *below* 22 mEq/L (22 mmol/L) if compensated
Metabolic Acidosis—Excessive Metabolic Acids	
Increase of Metabolic Acids (High Anion Gap): Ketoacidosis (diabetes, starvation, alcoholism) Hypermetabolic state (severe hyperthyroidism, burns, severe infection) Oliguric renal disease (acute kidney injury, end-stage renal disease) Circulatory shock (lactic acidosis) Ingestion of acid or acid precursors (e.g., methanol, ethylene glycol, boric acid, aspirin overdose) **Loss of Bicarbonate (Normal Anion Gap):** Diarrhea Pancreatic fistula or intestinal decompression Renal tubular acidosis	*Physical examination:* Decreased level of consciousness (lethargy, confusion, coma), abdominal pain, dysrhythmias, increased rate and depth of respirations (compensatory hyperventilation) *Laboratory findings:* Arterial blood gas alterations: pH *below* 7.35, PaCO$_2$ normal if uncompensated or *below* 35 mm Hg (4.7 kPa) if compensated, HCO$_3^-$ level *below* 22 mEq/L (22 mmol/L)
Metabolic Alkalosis—Deficient Metabolic Acids	
Increase of Bicarbonate: Excessive administration of sodium bicarbonate Massive blood transfusion (liver converts citrate to HCO$_3^-$) Mild or moderate ECV deficit (contraction alkalosis) **Loss of Metabolic Acid:** Excessive vomiting or gastric suctioning Hypokalemia Excess aldosterone	*Physical examination:* Light-headedness, numbness and tingling of fingers, toes, and circumoral region; muscle cramps; possible excitement and confusion followed by decreased level of consciousness, dysrhythmias (may be caused by concurrent hypokalemia) *Laboratory findings:* Arterial blood gas alterations: pH *above* 7.45, PaCO$_2$ normal if uncompensated or *above* 45 mm Hg (6.0 kPa) if compensated, HCO$_3^-$ *above* 26 mEq/L (26 mmol/L)

Data from Felver L: Acid-base homeostasis and imbalances. In Copstead LC, Banasik JL: *Pathophysiology,* ed 5, St Louis, 2013, Saunders.
COPD, Chronic obstructive pulmonary disease, *ECV,* extracellular fluid volume.

Common causes include vomiting and gastric suction (see Table 42-7). The respiratory compensation for metabolic alkalosis is hypoventilation. The decreased rate and depth of respiration allow carbonic acid to increase in the blood, as seen by an increased PaCO$_2$. The need for oxygen may limit the degree of respiratory compensation for metabolic alkalosis. Because HCO$_3^-$ crosses the blood-brain barrier with difficulty, neurological signs and symptoms are less severe or even absent with metabolic alkalosis (Hale and Hovey, 2013).

NURSING KNOWLEDGE BASE

You will apply knowledge about fluid, electrolyte, and acid-base imbalance in many clinical settings. Use the scientific knowledge base in clinical decision making to provide safe, optimal fluid therapy. For example, apply knowledge of risk factors for fluid imbalances and physiology of normal aging when assessing older adults, knowing that this age-group has high risk of fluid imbalances (Touhy and Jett, 2014).

TABLE 42-8   Anion Gap in Metabolic Acidosis

Anion Gap Type	Values (Without K+)	Causes
Normal anion gap	3-12 mEq/L (3-12 mmol/L) Varies, depending on laboratory	*Excess output of bicarbonate:* Diarrhea, pancreatic fistula, intestinal decompression, renal tubular acidosis *Increase of chloride-containing acid:* Parenteral HCl therapy
High anion gap	Greater than 5 mEq/L (5 mmol/L) above the laboratory reference range	*Increase of any acid except HCl:* Ketoacids (DKA, starvation, alcoholism), lactic acid (circulatory shock, extreme exercise), excessive normal metabolic acids (oliguric acute kidney injury, end-stage renal disease, severe hyperthyroidism, burns, severe infection), unusual organic acids (salicylate overdose, acids metabolized from methanol, ethylene glycol, paraldehyde)

Data from Berend K, deVries A, Gans, R: Physiological approach to assessment of acid-base disturbances, *New Engl J Med* 371(15): 1434, 2014.
DKA, Diabetic ketoacidosis.

Nursing knowledge includes questions to ask to elicit risk factors for fluid, electrolyte, and acid-base imbalance; specific clinical assessments for signs and symptoms of these imbalances; and nursing and collaborative interventions to maintain or restore fluid and electrolyte and acid-base balance (Felver 2013a,b,c). Skills and techniques for safe IV therapy are a vital area of the nursing knowledge base and the focus of much nursing research to support evidence-based practice.

CRITICAL THINKING

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require you to anticipate the information necessary to analyze the data and make decisions regarding patient care. During assessment consider all elements that build toward making an appropriate nursing diagnosis (Figure 42-9).

In the case of fluid, electrolyte, and acid-base balance, you integrate knowledge of physiology, pathophysiology, and pharmacology and previous experiences and information gathered from patients. Critical analysis of data enables an understanding of how fluid, electrolyte, and acid-base imbalances affect a specific patient and his or her family. In addition, critical thinking attitudes such as accountability, discipline, and integrity, applied during assessment, help you identify appropriate nursing diagnoses and plan successful interventions. Professional standards such as the Infusion Nurses Society (INS) standards of practice (INS, 2011) provide valuable guidance for appropriate assessment.

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care. For patients at high risk for fluid, electrolyte, and/or

Knowledge
- Physiology of fluid, electrolyte, and acid-base balances
- Causes and signs and symptoms of fluid, electrolyte, and acid-base imbalances
- Role of developmental stage in fluid, electrolyte, and acid-base balance
- Role of medications in fluid, electrolyte, and acid-base balance
- Influence common risk factors have on fluid, electrolyte, and acid-base balance

Experience
- Caring for patients with fluid, electrolyte, or acid-base imbalances
- Personal experience with dehydration secondary to high environmental temperature, prolonged physical activity, or vomiting and diarrhea

ASSESSMENT
- Assess risk factors for fluid, electrolyte, and acid-base imbalances, including medication use
- Determine patient experience and attitudes regarding fluid imbalances and fluid therapy
- Assess cultural preferences regarding fluid intake
- Identify signs and symptoms of patient's imbalances and how they change over time
- Monitor relevant laboratory results

Standards
- Apply intellectual standards of accuracy, relevance, and significance when obtaining a patient's health history
- Apply Infusion Nurses Society (INS) standards for assessing fluid balance (INS, 2011)
- Consider laboratory standard normal ranges for electrolyte and acid-base values

Attitudes
- Use discipline to obtain complete and correct assessment data regarding patient's fluid, electrolyte, and acid-base status
- Be responsible for collecting appropriate specimens for diagnostic and laboratory tests related to the patient's fluid, electrolyte, and acid-base status

FIGURE 42-9 Critical thinking model for fluid, electrolyte, and acid-base balance assessment.

acid-base imbalances or those who already have these imbalances, an individualized approach is the foundation for safe and effective patient-centered nursing care.

◆ Assessment

During the assessment process thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care. Using a systematic approach in assessment enables you to help patients maintain or restore fluid, electrolyte, and acid-base balances safely (see Figure 42-9).

Through the Patient's Eyes. A patient's fluid, electrolyte, or acid-base imbalance is sometimes so severe that it prevents initial

discussion of his or her expressed needs, values, and preferences. However, when a patient is alert enough to discuss care, you need to elicit this information through a patient-centered assessment. Focus on the patient's experience with fluid, electrolyte, or acid-base alterations and his or her perceptions of the illness. For example, for a patient who is hospitalized for clinical dehydration from diarrhea, ask if he or she has experienced dehydration previously and assess his or her interpretation of the signs and symptoms experienced and possible causes. Also ask how the person has managed diarrhea at home to assess his or her understanding of how to prevent the imbalances from occurring in the future. Assess potential barriers to rehydration such as concerns regarding IV therapy or lack of availability of favorite fluids at the preferred fluid temperature. Ask about the patient's greatest concerns regarding fluid status to build the basis for active partnership in planning, implementing, and evaluating patient-centered care.

Nursing History. Clinical assessment begins with a patient history designed to reveal risk factors that cause or contribute to fluid, electrolyte, and acid-base imbalances (Table 42-9). Ask specific, focused questions to identify factors that contribute to a patient's potential imbalances (Box 42-1).

Age. First assess a patient's age. An infant's proportion of total body water (70% to 80% total body weight) is greater than that of children or adults. Infants and young children have greater water needs and immature kidneys (Hockenberry and Wilson, 2015). They are at greater risk for ECV deficit and hypernatremia because body water loss is proportionately greater per kilogram of weight.

Children who are between the ages of 2 and 12 frequently respond to illnesses with fevers of higher temperatures and longer duration than those of adults (Hockenberry and Wilson, 2015). At any age fever increases the rate of insensible water loss. Adolescents have increased metabolism and water production because of their rapid growth changes. Fluctuations in fluid balance are greater in adolescent girls because of hormonal changes associated with the menstrual cycle.

Older adults experience a number of age-related changes that potentially affect fluid, electrolyte, and acid-base balances (Box 42-2). They often have more difficulty recovering from imbalances resulting from the combined effects of normal aging, various disease conditions, and multiple medications.

Environment. Hot environments increase fluid output through sweating. Sweat is a hypotonic sodium-containing fluid. Excessive sweating without adequate replacement of salt and water can lead to ECV deficit, hypernatremia, or clinical dehydration. Ask patients about their normal level of physical work and whether they engage in vigorous exercise in hot environments. Do the patients have fluid replacements containing salt available during exercise and activity?

Dietary Intake. Assess dietary intake of fluids; salt; and foods rich in potassium, calcium, and magnesium (see Table 42-4). Ask patients if they follow weight-loss diets. Starvation diets or those with high fat and no carbohydrate content often lead to metabolic acidosis (see Table 42-7). In addition, assess the patient's ability to chew and swallow, which, if altered, interferes with adequate intake of electrolyte-rich foods and fluids.

Lifestyle. Take an alcohol intake history. How many days does a person have an alcoholic drink each week, and how many drinks does he or she have at any one time? Chronic alcohol abuse commonly causes hypomagnesemia, in part because it increases renal magnesium excretion.

Medications. Obtain a complete list of your patient's current medications, including over-the-counter (OTC) and herbal preparations,

TABLE 42-9	Risk Factors for Fluid, Electrolyte, and Acid-Base Imbalances
Age	*Very young:* ECV deficit, osmolality imbalances, clinical dehydration *Very old:* ECV excess or deficit, osmolality imbalances
Environment	Sodium-rich diet: ECV excess Electrolyte-poor diet: Electrolyte deficits *Hot weather:* Clinical dehydration
Gastrointestinal output	*Diarrhea:* ECV deficit, clinical dehydration, hypokalemia, hypocalcemia (if chronic), hypomagnesemia (if chronic), metabolic acidosis *Drainage (e.g., nasogastric suctioning, fistulas):* ECV deficit, hypokalemia; metabolic acidosis if intestinal or pancreatic drainage *Vomiting:* ECV deficit, clinical dehydration, hypokalemia, hypomagnesemia, metabolic alkalosis
Chronic diseases	*Cancer:* Hypercalcemia; with tumor lysis syndrome: hyperkalemia, hypocalcemia, hyperphosphatemia; other imbalances, depending on side effects of therapy *Chronic obstructive pulmonary disease:* Respiratory acidosis *Cirrhosis:* ECV excess, hypokalemia *Heart failure:* ECV excess; other imbalances, depending on therapy *Oliguric renal disease:* ECV excess, hyperkalemia, hypermagnesemia, hyperphosphatemia, metabolic acidosis
Trauma	*Burns:* ECV deficit, metabolic acidosis Crush injuries: Hyperkalemia *Head injuries:* Hyponatremia or hypernatremia, depending on ADH response *Hemorrhage:* ECV deficit, hyperkalemia if circulatory shock
Therapies	Diuretics and other medications (see Box 42-3) *IV therapy:* ECV excess, osmolality imbalances, electrolyte excesses *PN:* Any fluid or electrolyte imbalance, depending on components of solution

ADH, Antidiuretic hormone; *ECV,* extracellular fluid volume; *IV,* intravenous; *PN,* parenteral nutrition.

to assess the risk for fluid, electrolyte, and acid-base imbalances (Box 42-3). Use a drug reference book or reputable online database to check the potential effects of other medications. Ask specifically about the use of baking soda as an antacid, which can cause ECV excess because of its high sodium content that holds water in the extracellular compartments. For an individual who uses laxatives, ask about the type of laxative, the frequency of use, and the consistency and frequency of stools. Multiple loose stools remove fluid and electrolytes from the body, thus causing numerous imbalances.

Medical History

Recent Surgery. Surgery causes a physiological stress response, which increases with extensive surgery and blood loss. In the first 24 to 48 hours after surgery, increased secretion of aldosterone, glucocorticoids, and ADH cause increased ECV, decreased osmolality, and increased potassium excretion (Lewis et al., 2014). In otherwise healthy patients these imbalances resolve without difficulty, but patients who

BOX 42-1   Nursing Assessment Questions

Environment
- Do you work or exercise in a hot environment?
- If so, which type of fluid do you drink during that time?

Dietary Intake
- About how many glasses of fluids do you usually drink every day? Which type of fluids do you normally drink?
- Tell me what you usually eat in a day.
- Which snacks do you usually eat?
- Are you on a special diet because of a medical problem? How does that work for you?
- Are you following any weight loss program?
- Do you use a salt substitute?
- Do you take calcium, magnesium, or potassium supplements? If so, how often?
- Do you have any difficulties chewing or swallowing?

Lifestyle
- How much alcohol do you drink in a typical week?

Gastrointestinal Output
- Have you had recent vomiting or diarrhea? If so, for how long? How many times per day?

Medications and Other Therapies
- Which medicines/herbal remedies do you use regularly? Occasionally?
- Do you take diuretics? Drugs for high blood pressure?
- Do you use antacids? If so, which ones? How often? Do you ever use baking soda as an antacid? Do you use fizzy (effervescent) medications for colds?
- Do you use laxatives? If so, how often? Which type of stool do you get when you use them?
- What do you use for an upset stomach?

Signs and Symptoms
- If you weigh yourself every day, how has your weight changed over the past few days?
- Do you get light-headed when you stand up?
- Do you feel thirsty, have a dry mouth, or notice a lack of tears?
- Have you noticed a change in your urine output: decreased volume, dark color, or concentrated appearance?
- Are you experiencing swelling of your fingers, feet, or ankles?
- Do you have difficulty breathing when you lie down at night?
- Are you having difficulty concentrating, or do you feel confused? What is normal for you?
- Are you having more difficulty than usual standing up from a sofa or soft chair? Do your legs feel unusually heavy when you climb stairs? Do you have muscle weakness that is unusual for you?
- Have you noticed any muscle cramps or unusual sensations such as numbness or tingling fingers?

BOX 42-2   FOCUS ON OLDER ADULTS

Factors Affecting Fluid, Electrolyte, and Acid-Base Balance

- Body composition changes, causing a decreased percentage of body weight as water (50%), which increases risk of extracellular fluid volume (ECV) deficit and dehydration (Felver, 2013d).
- Some older adults restrict fluid intake because of impaired mobility or concerns about bladder control; this increases their risk of hypernatremia and ECV deficit.
- Decreased elasticity of skin alters skin turgor even with normal fluid balance; do not rely on skin turgor to assess ECV deficit or dehydration in older adults.
- Decreased thirst sensation increases risk of hypernatremia and dehydration; do not rely on thirst to assess hypernatremia, ECV deficit, or dehydration in older adults (Touhy and Jett, 2014).
- Baroreceptors become sluggish with age, often causing brief postural hypotension; have older adults arise slowly when you take orthostatic blood pressure measurements.
- Cardiovascular changes with aging often decrease the ability to adapt to a sudden increase in vascular volume, increasing risk of pulmonary edema with rapid infusion of isotonic intravenous fluids.
- Older-adult kidneys are less able to concentrate urine, making them less able to conserve fluid when needed; this increases the risk of hypernatremia, ECV deficit, and dehydration (Touhy and Jett, 2014).
- Kidney changes of normal aging make it more difficult to excrete a large acid load, increasing the risk of metabolic acidosis.
- Increased sensitivity to anticholinergic effects of medications causes dry mouth; use several different assessments for ECV deficit and dehydration rather than relying solely on dry mouth (Burchum and Rosenthal, 2016).
- The combined effects of normal aging, chronic diseases, and multiple medications often pose challenges to maintaining fluid and electrolyte balance.

BOX 42-3   Commonly Used Medications That Cause Fluid, Electrolyte, and Acid-Base Imbalances

- *ACE inhibitors (e.g., captopril [Capoten]) and angiotensin II receptor blockers (e.g., Losartan [Cozaar]):* Hyperkalemia
- *Antidepressants, SSRI (e.g., fluoxetine [Prozac]):* Hyponatremia
- *Calcium carbonate antacids:* Hypercalcemia, mild metabolic alkalosis
- *Corticosteroids (e.g., prednisone):* Hypokalemia, metabolic alkalosis
- *Diuretics, potassium-wasting (e.g., furosemide [Lasix], thiazides):* ECV deficit, hyponatremia (thiazides), hypokalemia, hypomagnesemia, mild metabolic alkalosis
- *Diuretics, potassium-sparing (e.g., spironolactone [Aldactone]):* Hyperkalemia, mild metabolic acidosis
- *Effervescent (fizzy) antacids and cold medications (high Na$^+$ content):* ECV excess
- *Laxatives:* ECV deficit, hypokalemia, hypocalcemia, hypomagnesemia, metabolic acidosis
- *Magnesium hydroxide (e.g., Milk of Magnesia):* Hypermagnesemia
- *Nonsteroidal antiinflammatory drugs (e.g., ibuprofen [Advil]):* Mild ECV excess, hyponatremia
- *Penicillins, high-dose (e.g., carbenicillin):* Hypokalemia, metabolic alkalosis; hyperkalemia with penicillin G (contains K$^+$)

Data from Burchum JR, Rosenthal LD: *Lehne's pharmacology for nursing care*, ed 9, St Louis, 2016, Elsevier.
ACE, Angiotensin-converting enzyme; *ECV,* extracellular fluid volume; *SSRI,* selective serotonin reuptake inhibitor.

have preexisting illnesses or additional risk factors often need treatment during this time period.

Gastrointestinal Output. Increased output of fluid through the GI tract is a common and important cause of fluid, electrolyte, and acid-base imbalances that requires careful assessment. Vomiting and diarrhea, either acute or chronic, can cause ECV deficit, hypernatremia, clinical dehydration, and hypokalemia by increasing the output of fluid, Na$^+$, and K$^+$. In addition, chronic diarrhea can cause hypocalcemia and hypomagnesemia by decreasing electrolyte absorption. Removal of gastric acid from the body through vomiting or nasogastric suction

can cause metabolic alkalosis. In contrast, removal of the bicarbonate-rich intestinal or pancreatic fluids through diarrhea, intestinal suction, or fistula can cause metabolic acidosis.

Acute Illness or Trauma. Acute conditions that place patients at high risk for fluid, electrolyte, and acid-base alterations include respiratory diseases, burns, trauma, GI alterations, and acute oliguric renal disease.

Respiratory Disorders. Many acute respiratory disorders predispose patients to respiratory acidosis. For example, bacterial pneumonia causes alveoli to fill with exudate that impairs gas exchange, causing the patient to retain carbon dioxide, which leads to increased $PaCO_2$ and respiratory acidosis.

Burns. Burns place patients at high risk for ECV deficit from numerous mechanisms, including plasma-to-interstitial fluid shift and increased evaporative and exudate output. The greater the body surface burned, the greater is the fluid loss (Lewis et al., 2014). Patients with burns have cellular damage that releases potassium into the blood, and they may become hyperkalemic. In addition, these patients often develop metabolic acidosis because of greatly increased cellular metabolism, which produces more metabolic acids than their kidneys are able to excrete.

Trauma. Hemorrhage from any type of trauma causes ECV deficit from blood loss. Some types of trauma create additional risks. For example, crush injuries destroy cellular structure, causing hyperkalemia by massive release of intracellular K^+ into the blood.

Head injury typically alters ADH secretion. It may cause diabetes insipidus (deficit of ADH), in which patients excrete large volumes of very dilute urine and develop hypernatremia. In contrast, head injury may cause the syndrome of inappropriate antidiuretic hormone (SIADH), in which excess secretion of ADH causes hyponatremia by retaining too much water and concentrating the urine (Lewis et al., 2014).

Chronic Illness. Many chronic diseases create ongoing risk of fluid, electrolyte, and acid-base imbalances. For example, type B chronic obstructive pulmonary disease (COPD) often causes chronic respiratory acidosis. In addition, the treatment regimens for chronic disease often cause imbalances. Assess patients for the presence of these conditions.

Cancer. The specific fluid and electrolyte imbalances that occur with cancer depend on the type and progression of the cancer and treatment regimen. Many patients with cancer develop hypercalcemia when their cancer cells secrete chemicals that circulate to bones and cause calcium to enter the blood. Other fluid and electrolyte imbalances occur in cancer because some types of tumors cause metabolic and endocrine abnormalities. In addition, patients with cancer are at risk for fluid and electrolyte imbalances as a result of the side effects (e.g., anorexia, diarrhea) of chemotherapy, biological response modifiers, or radiation (Lewis et al., 2014).

Heart Failure. Patients who have chronic heart failure have diminished cardiac output, which reduces kidney perfusion and activates the RAAS. The action of aldosterone on the kidneys causes ECV excess and risk of hypokalemia. Most diuretics used to treat heart failure increase the risk of hypokalemia while reducing the ECV excess. Dietary sodium restriction is important with heart failure because Na^+ holds water in the ECF, making the ECV excess worse. In severe heart failure restriction of both fluid and sodium is prescribed to decrease the workload of the heart by reducing excess circulating fluid volume (Lewis et al., 2014).

Oliguric Renal Disease. Oliguria occurs when the kidneys have a reduced capacity to make urine. Some conditions such as acute nephritis cause sudden onset of oliguria, whereas other problems such as chronic kidney disease lead to chronic oliguria. Oliguric renal disease prevents normal excretion of fluid, electrolytes, and metabolic acids, resulting in ECV excess, hyperkalemia, hypermagnesemia, hyperphosphatemia, and metabolic acidosis. The severity of these imbalances is proportional to the degree of renal failure. Although chronic kidney disease is progressive, successful management of imbalances is possible with dietary restriction of sodium and other electrolytes, fluid restriction in severe cases, and eventually dialysis or renal transplant (Lewis et al., 2014).

Physical Assessment. Data gathered through a focused physical assessment validates and extends the information collected in the patient history. Table 42-10 summarizes focused assessments for patients with fluid, electrolyte, and acid-base imbalances. Focus your assessment on the areas pertinent to each patient situation. For example, for patients at risk of fluid imbalances, focus your assessment on body weight changes, clinical markers of vascular and interstitial volume, thirst, behavior changes, and level of consciousness. Additional focused assessments for patients at high risk of electrolyte and acid-base imbalances include specific cardiac, respiratory, neuromuscular, and GI markers. Grouping your assessments under these categories helps you know which assessments to prioritize and enables you to assess effectively.

Daily Weights and Fluid Intake and Output Measurement. Daily weights are an important indicator of fluid status (Felver, 2013c). Each kilogram (2.2 lbs) of weight gained or lost overnight is equal to 1 L of fluid retained or lost. These fluid gains or losses indicate changes in the amount of total body fluid, usually ECF, but do not indicate shift between body compartments. Weigh patients with heart failure and those who are at high risk for or actually have ECV excess daily. Daily weights are also useful for patients with clinical dehydration or other causes or risks for ECV deficit. Weigh the patient at the same time each day with the same scale after a patient voids. Calibrate the scale each day or routinely. The patient needs to wear the same clothes or clothes that weigh the same; if using a bed scale, use the same number of sheets on the scale with each weighing. Compare the weight of each day with that of the previous day to determine fluid gains or losses. Look at the weights over several days to recognize trends. Interpretation of daily weights guides medical therapy and nursing care. Teach patients with heart failure to take and record their daily weights at home and to contact their health care provider if their weight increases suddenly by a set amount (obtain parameters from their health care providers). Recognizing trends in daily weights taken at home is important. Patients who are hospitalized for decompensated heart failure often experience steady increases in daily weights during the week before hospitalization.

Measuring and recording all liquid intake and output (I&O) during a 24-hour period is an important aspect of fluid balance assessment. Compare a patient's 24-hour intake with his or her 24-hour output. The two measures should be approximately equal if the person has normal fluid balance (Felver, 2013c). To interpret situations in which I&O are substantially different, consider the individual patient. For example, if intake is substantially greater than output, there are two possibilities: the patient may be gaining excessive fluid or returning to normal fluid status by replacing fluid lost previously from the body. Similarly, if intake is substantially smaller than output, there are also two possibilities: the patient may be losing needed fluid from the body and developing ECV deficit and/or hypernatremia or returning to normal fluid status by excreting excessive fluid gained previously.

In most health care settings I&O measurement is a nursing assessment. Some agencies require a health care provider's order for I&O. If you want to measure I&O for a patient with compromised fluid status,

TABLE 42-10   Focused Nursing Assessments for Patients with Fluid, Electrolyte, and Acid-Base Imbalances

Assessment	Imbalances
Body Weight Changes from Previous Day	
Loss of 2.2 lbs (1 kg) or more in 24 hours for adults	ECV deficit
Gain of 2.2 lbs (1 kg) or more in 24 hours for adults	ECV excess
Clinical Markers of Vascular Volume	
Blood pressure:	
Hypotension or orthostatic hypotension	ECV deficit
Light-headedness on sitting upright or standing	ECV deficit
Pulse rate and character:	
Rapid, thready	ECV deficit
Bounding	ECV excess
Fullness of neck veins:	
Flat or collapsing with inhalation when supine	ECV deficit
Full or distended when upright or semi-upright	ECV excess
Other assessments of vascular volume:	
Capillary refill: Sluggish	ECV deficit
Lung auscultation, dependent lobe: Crackles or rhonchi with progressive dyspnea	ECV excess
Urine output: Small volume of dark yellow urine	ECV deficit
Clinical Markers of Interstitial Volume	
Presence of edema: Present in dependent areas (ankles or sacrum) and possibly fingers or around eyes	ECV excess
Mucous membranes: Dry between cheek and gum, decreased or absent tearing	ECV deficit
Skin turgor: Pinched skin fails to return to normal position within 3 seconds	ECV deficit
Presence of thirst: Thirst present	Hypernatremia, severe ECV deficit
Behavior and level of consciousness	
Restlessness and mild confusion	Severe ECV deficit
Decreased level of consciousness (lethargy, confusion, coma)	Hyponatremia, hypernatremia, hypercalcemia, acid-base imbalances
Cardiac and Respiratory Signs of Electrolyte or Acid-Base Imbalances	
Pulse rhythm and ECG: Irregular pulse and ECG changes	K^+, Ca^{2+}, Mg^{2+}, and/or acid-base imbalances
Rate and depth of respirations:	
Increased rate and depth	Metabolic acidosis (compensatory mechanism); respiratory alkalosis (cause)
Decreased rate and depth	Metabolic alkalosis (compensatory mechanism); respiratory acidosis (cause)
Neuromuscular Markers of Electrolyte or Acid-Base Imbalances	
Muscle strength bilaterally, especially quadriceps muscles:	
Muscle weakness	Hypokalemia, hyperkalemia
Reflexes and sensations:	
Decreased deep tendon reflexes	Hypercalcemia, hypermagnesemia
Hyperactive reflexes, muscle twitching and cramps, tetany	Hypocalcemia, hypomagnesemia
Numbness, tingling in fingertips, around mouth	Hypocalcemia, hypomagnesemia, respiratory alkalosis
Muscle cramps, tetany	Hypocalcemia, hypomagnesemia, respiratory alkalosis
Tremors	Hypomagnesemia
Gastrointestinal Signs of Electrolyte Imbalances	
Inspection and auscultation:	
Abdominal distention	Hypokalemia, third-spacing of fluid
Decreased bowel sounds	Hypokalemia
Motility: Constipation	Hypokalemia, hypercalcemia

ECG, Electrocardiogram; *ECV,* extracellular fluid volume.

FIGURE 42-10 Containers for measuring urine output.

check your agency policies to determine whether you can set it up or if you need a health care provider's order.

Fluid intake includes all liquids that a person eats (e.g., gelatin, ice cream, soup), drinks, (e.g., water, coffee, juice), or receives through nasogastric or jejunostomy feeding tubes (see Chapter 45). IV fluids (continuous infusions and intermittent IV piggybacks) and blood components also are sources of intake. Water swallowed while taking pills and liquid medications counts as intake. A patient receiving tube feedings often receives numerous liquid medications, and water is used to flush the tube before and/or after medications. Over a 24-hour period these liquids amount to significant intake and always are recorded on the I&O record. Ask patients who are alert and oriented to help with measuring their oral intake and explain to families why they should not drink or eat from the patient's meal trays or water pitcher.

Fluid output includes urine, diarrhea, vomitus, gastric suction, and drainage from postsurgical wounds or other tubes (see Chapter 50). Record a patient's urinary output after each voiding. Instruct patients who are alert, oriented, and ambulatory to save their urine in a calibrated insert, which attaches to the rim of the toilet bowl (Figure 42-10). Teach patients and families the purpose of I&O measurements. Also teach them to notify the nurse or nursing assistive personnel (NAP) to empty any container with voided fluid or how to measure and empty the container themselves and report the result appropriately. Patients need to have good vision and motor skills to perform these measurements. Active involvement of patient and family is an aspect of patient-centered care that is essential to maintaining accurate I&O measurements. When a patient has an indwelling urinary catheter, drainage tube, or suction, record output (e.g., at the end of each nursing shift or every hour) as the patient's condition requires.

You can delegate parts of I&O measurement and recording to NAP with competent skills in measurement. Actual measurement of fluid volumes is more accurate than visual estimates. In many institutions NAP record oral intake but not intake through feeding or IV tubes, which are nursing responsibilities. Similarly NAP often record urine, diarrhea, and vomitus output but not drainage through tubes. The responsible registered nurse (RN) or licensed practical nurse/licensed vocational nurse (LPN/LVN) and the NAP work as a team to record measurements in the designated location in the electronic health record (EHR), often on a flow sheet with other information. The EHR program usually calculates the 24-hour totals. If an EHR is not used, record I&O on paper forms attached to the bedside chart or room door. You or the NAP calculates the 24-hour totals (see agency policy). Accurate I&O facilitates ongoing evaluation of a patient's hydration status.

Laboratory Values. Review the patient's laboratory test results and compare them with the normal ranges to obtain further objective data about fluid, electrolyte, and acid-base balances. Normal and abnormal test results are summarized in Tables 42-1, 42-3, and 42-5 to 42-7. The frequency of electrolyte level measurements depends on the severity of a patient's illness. Analysis of laboratory results requires a good medical clinician, especially if a person develops an acute imbalance while also having a chronic disease. Serum electrolyte tests usually are performed routinely on patients entering a hospital to screen for imbalances and serve as a baseline for future comparisons.

◆ **Nursing Diagnosis**

When caring for patients with suspected fluid, electrolyte, and acid-base imbalances, it is particularly important to use critical thinking to formulate nursing diagnoses. The assessment data that establish the risk for or the actual presence of a nursing diagnosis in these areas may be subtle, and patterns and trends emerge only when there has been astute assessment. Multiple body systems often are involved; careful clustering of defining characteristics leads to selection of the appropriate diagnoses (Box 42-4).

In addition to the accurate clustering of assessment data, an important part of formulating nursing diagnoses is identifying the relevant causative or related factor (when a diagnosis is problem focused) or risk factors (when a diagnosis is a risk diagnosis). You choose interventions that treat or modify the related factor for the diagnosis to be resolved. For example, *Deficient Fluid Volume related to loss of GI fluids from vomiting* requires therapies that manage the patients' emesis and restore fluid volume with IV therapy. In contrast, the diagnosis of *Deficient Fluid Volume related to elevated body temperature* requires therapies to lower the patient's body temperature and replace lost body fluids through oral fluid replacement or possibly IV therapy. Possible nursing diagnoses for patients with fluid, electrolyte, and acid-base alterations include the following:

- *Decreased Cardiac Output*
- *Acute Confusion*
- *Risk for Electrolyte Imbalance*
- *Deficient Fluid Volume*
- *Excess Fluid Volume*
- *Impaired Gas Exchange*
- *Risk for Injury*
- *Deficient Knowledge Regarding Disease Management*

Knowledge
- Role of other health care professionals
- Effect of specific fluid replacement regimens on fluid, electrolyte, and acid-base status
- Effects of medications on fluid, electrolyte, and acid-base balance
- Scientific and nursing knowledge of fluid, electrolyte, and acid-base balance and imbalances

Experience
- Previous patient responses to planned nursing therapies for improving fluid, electrolyte, and acid-base balance (what worked and what did not work)

PLANNING
- Select individualized nursing interventions to maintain or restore fluid, electrolyte, and acid-base balance
- Consult with pharmacists, registered dietitians, and intravenous therapy specialists
- Involve the patient and family in designing culturally appropriate interventions

Standards
- Individualize therapies based on desired patient outcomes
- Use therapies consistent with CDC guidelines for prevention of intravascular infections
- Apply Infusion Nurses Society (INS) standards of practice (INS, 2011)

Attitudes
- Use creativity to plan interventions that achieve fluid, electrolyte, and acid-base balance and that are integrated into the patient's activities of daily living
- Be responsible for planning nursing interventions consistent with the patient's fluid, electrolyte, and acid-base status and standards of practice

FIGURE 42-11 Critical thinking model for fluid, electrolyte, and acid-base balance planning. *CDC,* Centers for Disease Control and Prevention.

◆ Planning

During the planning process use critical thinking to synthesize information from multiple resources (Figure 42-11). Ensure that the patient's plan of care integrates both scientific and nursing knowledge and all of the information that you collected about the individual patient.

Goals and Outcomes. Establish an individual patient plan of care for each nursing diagnosis (see the Nursing Care Plan) that includes mutually established patient goals for each diagnosis. Collaborate with and inform patients as you individualize goals with realistic, measurable outcomes. For example, with a nursing diagnosis of *Deficient Fluid Volume,* the following related outcomes might be established for the goal, "The patient achieves normal hydration status at discharge":
- The patient is free of complications associated with the IV device throughout the duration of IV therapy.

- The patient demonstrates balanced I&O measurements within 48 hours.
- The patient has serum electrolytes within the normal range within 48 hours.

Setting Priorities. The patient's clinical condition determines which of the nursing diagnoses takes the greatest priority. Many nursing diagnoses in the area of fluid, electrolyte, and acid-base balances are of highest priority because the consequences for the patient can be serious or even life threatening. For example, in the concept map (Figure 42-12) for Mrs. Beck, the occurrence of vomiting and diarrhea created a high-priority nursing diagnosis of *Deficient Fluid Volume.* The priority for Mrs. Beck is to restore her fluid balance. To achieve this priority, her vomiting and diarrhea must be controlled and resolved, and her fluid volume replaced. If these goals are unmet, Mrs. Beck's fluid imbalance likely will worsen.

Teamwork and Collaboration. Consultation with a patient's health care provider helps to set realistic time frames for the goals of care, particularly when the patient's physiological status is unstable. Ongoing communication and consultation are important because the patient's condition can change quickly. Collaboration with the patient and family and other members of the interprofessional health care team such as IV therapist and pharmacist helps in achieving patient outcomes. Patient and family are very helpful in identifying approaches for successful therapies such as ways to increase fluid intake. Incorporate patient preferences and resources into the plan of care. Do not delegate administration of IV fluid and hemodynamic assessment to NAP. When the patient is stable, you can delegate daily weights, I&O, and direct physical care to NAP.

Begin discharge planning early for patients with acute or chronic fluid and electrolyte disturbances by anticipating the needs of the patient and family as they transition to another setting. In the hospital collaboration with other members of the health care team ensures that care will continue in the home or long-term care setting with few disruptions. You ensure that therapeutic regimens established in one setting continue through completion at the next setting. For example, for a patient who is discharged on IV therapy, you assess the knowledge and skills of the family member or friend who is to assume caregiving responsibilities and initiate a referral to home IV therapy as soon as possible. Close collaboration with members of the health care team such as the patient's health care provider, registered dietitian, and pharmacist is essential to ensure positive patient outcomes. A registered dietitian is a valuable resource in recommending food sources to increase or reduce intake of specific electrolytes, incorporating the patient's preferences when possible (see Chapter 45). A pharmacist helps identify medications or combinations of medications likely to cause electrolyte or acid-base disturbances and offers information regarding patient education about side effects to anticipate for prescribed drugs. The patient's health care provider directs the treatment of fluid, electrolyte, or acid-base imbalances.

◆ Implementation

Health Promotion. Health promotion activities focus primarily on patient education on the basis of your assessment of patient and family health literacy. Use plain language to teach patients and caregivers to recognize risk factors for developing imbalances and implement appropriate preventive measures. For example, parents of infants need to understand that GI losses quickly lead to serious imbalances; therefore, when vomiting or diarrhea occurs in an infant, they need to promptly rehydrate with sodium-containing fluid or seek health care

Deficient Fluid Volume

ASSESSMENT

Mrs. Hilda Beck is a 72-year-old seen by her health care provider this morning after falling at home and telephoning a neighbor for assistance. She lives alone in an apartment and has no chronic disease except for osteoarthritis of her hands. She has had diarrhea and vomiting for over 24 hours and has not eaten anything. Despite feeling slightly nauseated, she tried to drink a little water, because she knew she needed fluid. Mrs. Beck is admitted for intravenous (IV) fluid therapy. X-ray films indicate that she has no broken bones. Review of laboratory findings: hematocrit 55% (hemoconcentration caused by hypovolemia; sodium 148 mEq/L, and potassium 3 mEq/L. (NOTE: Mrs. Beck has hypokalemia in addition to extracellular fluid volume [ECV] deficit and hypernatremia [clinical dehydration].)

Assessment Activities	*Findings/Defining Characteristics**
Ask Mrs. Beck to describe when her vomiting and diarrhea began and any accompanying signs and symptoms.	She states that her gastrointestinal (GI) problems began suddenly yesterday and that she **gets weak and light-headed when she stands or sits upright,** which is why she fell. She feels **weak** and has a **dry mouth.**
Ask her about current status of vomiting and diarrhea.	Says she still was vomiting earlier this morning. Has not done so for the past 3 hours. Feels slightly nauseated. Had three episodes of watery diarrhea this morning and more than six yesterday.
Assess Mrs. Beck's vital signs.	**Heart rate 110** beats/min with regular rhythm and a **weak pulse; supine blood pressure (BP) is 90/58.** Temperature and respirations within normal limits. Postural BP measurement not taken since patient says that she **gets light-headed when she sits upright.**
Evaluate physical signs of extracellular fluid volume (ECV).	Neck veins flat when she is supine; **100 mL of dark yellow urine** in past 4 hours; dry mucous membranes between cheek and gum; prolonged capillary refill time of 5 seconds.
Weigh Mrs. Beck using a bed scale.	Weight 120 lbs (54.5 kg). States usual weight at home is 127 lbs (46.27 kg) **(7 lbs [3.17 kg] weight loss).**

*Defining characteristics** are shown in bold type.

NURSING DIAGNOSIS: Deficient fluid volume related to increased output of GI fluids from vomiting and diarrhea

PLANNING

Goals	*Expected Outcomes (NOC)[†]*
Fluid Balance	
Mrs. Beck's fluid volume will return to normal by hospital discharge.	Heart rate and BP return to normal within 24 hours.
	Mrs. Beck does not report light-headedness when sitting or standing within 24 hours.
	Urine color becomes light yellow within 24 hours.
	Daily urine output equals intake of at least 1500 mL by discharge.
Mrs. Beck will describe how to manage fluid balance at home before hospital discharge.	Mrs. Beck describes how to replace GI fluid loss with fluids that contain sodium.
	She describes signs and symptoms indicating need to increase fluid and sodium intake.

[†]Outcome classification labels from Moorhead S et al: *Nursing outcomes classification (NOC)*, ed 5, St Louis, 2013, Mosby.

INTERVENTIONS[‡] (NIC)	**RATIONALE**
Fluid/Electrolyte Management	
Provide Mrs. Beck her favorite fluids at her preferred temperature.	Patient-centered care takes individual preferences into account. Offer cultural preferences regarding temperature of oral fluid influence fluid intake (Giger, 2013). In contrast to popular belief, moderate amounts of caffeinated beverages are not likely to have excessive diuretic effect (Killer et al., 2014).
Provide pitcher and glass of water at Mrs. Beck's preferred temperature at her bedside; ensure that she can access and pour from it easily; provide straw if she wishes.	Weakness or chronic disease such as osteoarthritis of hands may make it difficult to manipulate a full water pitcher. Make fluid available in form that is easy for patient to access (Felver, 2013c).
Administer IV therapy as prescribed, monitoring closely for early side effects of complications.	IV fluid replacement augments oral replacement when ECV deficit exists. Age-appropriate care is needed because of older adult's anatomical and physiological changes that affect volume delivery (INS, 2011).
Discuss different ways to prevent and treat dehydration at home. Provide written handout of information.	Patient education is enhanced in older adults when you use multiple senses during teaching sessions (Touhy and Jett, 2014).

[‡]Intervention classification labels from Bulechek GM et al.: *Nursing interventions classification (NIC)*, ed 6, St Louis, 2013, Mosby.

EVALUATION

Nursing Actions	*Patient Response/Finding*	*Achievement of Outcome*
Monitor vital signs, intake and output (I&O), daily weight, and postural BP when no longer light-headed.	T 37° C (98.6° F), RR 10, HR 72 beats/min, BP 120/78 sitting, 122/78 standing, denies light-headedness	Vital signs returned to normal range. No postural hypotension.
	Intake 2000 mL, output 2000 mL of light yellow urine	I&O measurements are balanced, urine is light yellow.
	Today's weight 129 lbs (58.5 kg)	Daily weight returned to Mrs. Beck's normal.
Assess neck vein fullness when supine, mucous membranes.	Neck veins full when supine; mucous membranes moist	Additional markers of ECV are normal.
Evaluate effectiveness of teaching regarding maintaining fluid balance at home.	Mrs. Beck identified salty broth and commercial electrolyte replacement fluids for replacing GI fluid loss and indicated need to increase her intake if her urine becomes dark yellow or she becomes light-headed when sitting upright.	Mrs. Beck describes effective home management of fluid balance.

CONCEPT MAP

Nursing diagnosis: Nausea related to gastric irritation
- Little interest in eating
- Increased salivation with nausea and vomiting
- Reports currently feeling "slightly nauseated"

▼

Interventions
- Avoid sudden position changes
- Provide comfortable environment: keep room cool, keep linen clean; reduce noise, odors, vibrations
- Provide oral hygiene every 2 hours

Nursing diagnosis: Deficient fluid volume related to vomiting and diarrhea
- Reports light-headedness when moves to a sitting position
- BP 90/58 mm Hg supine
- Heart rate 102 beats/min, pulse weak
- Dry oral mucous membranes
- Decreased urine output <50 mL/hr, dark yellow urine

▼

Interventions
- Initiate ordered peripheral IV, administer 1000 mL 0.9% NaCl with 10 mEq KCl
- Provide oral fluids at preferred temperature
- Offer fluid frequently in small amounts as tolerated
- Provide antiemetics as ordered

Primary health problem: Gastroenteritis and dehydration
Priority assessments: Fluid balance, elimination function, comfort

Nursing diagnosis: Risk for impaired skin integrity
- Skin intact, area of redness, 3-cm diameter over perianal area
- Skin exposed to diarrheal stool
- Decreased skin turgor

▼

Interventions
- Provide safe access to bedpan until light-headedness resolves
- Administer skin care, apply moisture barrier to skin
- Position off inflamed area

Nursing diagnosis: Diarrhea related to intestinal inflammation
- Watery, brown stools >6/day yesterday; 3 this morning
- Abdominal cramping
- Hyperactive bowel sounds on auscultation in all four quadrants

▼

Interventions
- Administer ordered antidiarrheal agents
- Measure stool output
- Diet: Easily digested foods; avoid high-fiber food

——— Link between medical diagnosis and nursing diagnosis   - - - - Link between nursing diagnoses

FIGURE 42-12 Concept map for Mrs. Beck.

to restore normal balance. People of any age need to learn to replace body fluid losses with sodium-containing fluid and water.

Patients with chronic health alterations often are at risk for developing fluid, electrolyte, and acid-base imbalances. They need to understand their own risk factors and the measures to be taken to avoid imbalances. For example, patients with end-stage renal disease often need to restrict intake of fluid, sodium, potassium, magnesium, and phosphate. Through diet education these patients learn the types of

foods to avoid and the suitable volume of fluid that they are permitted daily (see Chapter 45). Teach patients with chronic diseases and their family caregivers the early signs and symptoms of the fluid, electrolyte, and acid-base imbalances for which they are at risk and what to do if these occur.

Acute Care. Although fluid, electrolyte, and/or acid-base imbalances occur in all settings, they are common in acute care. Acute care

FIGURE 42-13 Central venous lines deliver intravenous fluid into superior vena cava near heart. *CVAD,* Central venous access device.

excess sometimes have both sodium and fluid restrictions. Fluid restriction often is difficult for patients, particularly if they take medications that dry the oral mucous membranes or if they are mouth breathers. Explain the reason that fluids are restricted. Make sure that the patient, family, and visitors know the amount of fluid permitted orally and understand that ice chips, gelatin, and ice cream are fluids. Help the patient decide the amount of fluid to drink with each meal, between meals, before bed, and with medications. It is important to allow patients to choose preferred fluids unless contraindicated. Frequently patients on fluid restriction can swallow a number of pills with as little as 1 oz (30 mL) of liquid.

In acute care settings fluid restrictions usually allot half the total oral fluids between 7 AM and 3 PM (i.e., the period when patients are more active, receive two meals, and take most of their oral medications). Offer the remainder of the fluids during the evening and night shifts. Patients on fluid restriction need frequent mouth care to moisten mucous membranes, decrease the chance of mucosal drying and cracking, and maintain comfort (see Chapter 40).

Parenteral Replacement of Fluids and Electrolytes. Fluid and electrolytes may be replaced through infusion of fluids directly into veins (intravenously) rather than via the digestive system. Parenteral replacement includes parenteral nutrition (PN), IV fluid and electrolyte therapy (**crystalloids**), and blood and blood component (colloids) administration. IV devices are called *peripheral IVs* when the catheter tip lies in a vein in one of the extremities; they are called *central venous IVs* when the catheter tip lies in the central circulatory system (e.g., in the vena cava close to the right atrium of the heart) (Figure 42-13).

Practice standard body fluid precautions when preparing and administering parenteral fluids (see Chapter 29) to minimize your own risk for exposure to bloodborne pathogens. Read and understand the policy and procedures for parenteral infusions at the agency for which you work.

Parenteral Nutrition. PN, also called *total PN (TPN),* is IV administration of a complex, highly concentrated solution containing nutrients and electrolytes that is formulated to meet a patient's needs. Depending on their osmolality, PN solutions are administered through a central IV catheter (high osmolality) or peripherally (lower osmolality). Chapter 45 reviews principles and guidelines for PN administration, which is used when patients are unable to receive enough nutrition orally or through enteral feeding.

Intravenous Therapy (Crystalloids). The goal of IV fluid administration is to correct or prevent fluid and electrolyte disturbances. It

nurses administer medications and oral and IV fluids to replace fluid and electrolyte deficits or maintain normal homeostasis; they also help with restricting intake as part of therapy for excesses.

Enteral Replacement of Fluids. Oral replacement of fluids and electrolytes is appropriate as long as the patient is not so physiologically unstable that they cannot be replaced rapidly. Oral replacement of fluids is contraindicated when a patient has a mechanical obstruction of the GI tract, is at high risk for aspiration, or has impaired swallowing. Some patients unable to tolerate solid foods are still able to ingest fluids. Strategies to encourage fluid intake include offering frequent small sips of fluid, popsicles, and ice chips. Record one half the volume of the ice chips in I&O measurement. For example, if a patient ingests 240 mL of ice chips, you record 120 mL of intake. Encourage patients to keep their own record of intake to involve them actively. Family members who are properly instructed can also help. Pay attention to each patient's preferred temperature of oral fluids. Cultural beliefs regarding appropriate fluids and fluid temperature may become a barrier to achieving adequate fluid intake unless the fluid with the preferred temperature is available (Box 42-5).

When replacing fluids by mouth in a patient with ECV deficit, choose fluids that contain sodium (e.g., Pedialyte and Gastrolyte). Liquids that contain lactose or have low-sodium content are not appropriate when a patient has diarrhea.

A feeding tube is appropriate when a patient's GI tract is healthy but he or she cannot ingest fluids (e.g., after oral surgery or with impaired swallowing). Options for administering fluids include gastrostomy or jejunostomy instillations or infusions through small-bore nasogastric feeding tubes (see Chapter 45).

Restriction of Fluids. Patients who have hyponatremia usually require restricted water intake. Patients who have very severe ECV

TABLE 42-11   Intravenous Solutions

Solution	Concentration	Comments
Dextrose in Water Solutions		**Dextrose is another name for glucose.**
Dextrose 5% in water (D₅W)	Isotonic	Isotonic when first enters vein; dextrose enters cells rapidly, leaving free water, which dilutes ECF; most of water then enters cells by osmosis.
Dextrose 10% in water (D₁₀W)	Hypertonic	Hypertonic when first enters vein, dextrose enters cells rapidly, leaving free water, which dilutes ECF; most of water then enters cells by osmosis.
Saline Solutions		**Saline is sodium chloride in water.**
0.225% sodium chloride (quarter normal saline; ¼ NS; 0.225% NaCl)	Hypotonic	Expands ECV (vascular and interstitial) and rehydrates cells.
0.45% sodium chloride (half normal saline; ½ NS; 0.45% NaCl)	Hypotonic	Expands ECV (vascular and interstitial) and rehydrates cells.
0.9% sodium chloride (normal saline; NS; 0.9% NaCl)	Isotonic	Expands ECV (vascular and interstitial); does not enter cells.
3% or 5% sodium chloride (hypertonic saline; 3% or 5% NaCl)	Hypertonic	Draws water from cells into ECF by osmosis.
Dextrose in Saline Solutions		
Dextrose 5% in 0.45% NaCl sodium chloride (D₅ ½ NS; D₅0.45% NaCl)	Hypertonic	Dextrose enters cells rapidly, leaving 0.45% sodium chloride.
Dextrose 5% in 0.9% sodium chloride (D₅NS; D₅0.9% NaCl)	Hypertonic	Dextrose enters cells rapidly, leaving 0.9% sodium chloride.
Balanced Electrolyte Solutions		
Lactated Ringer's (LR)	Isotonic	Contains Na⁺, K⁺, Ca²⁺, Cl⁻, and lactate, which liver metabolizes to HCO₃⁻. Expands ECV (vascular and interstitial); does not enter cells.
Dextrose 5% in lactated Ringer's (D₅LR)	Hypertonic	Dextrose enters cells rapidly, leaving lactated Ringer's.

ECF, Extracellular fluid; *ECV,* extracellular fluid volume.

allows for direct access to the vascular system, permitting the continuous infusion of fluids over a period of time. IV therapy requires a health care provider's order for type, amount, and speed of administration of the solution. You regulate IV fluid therapy continuously because of ongoing changes in a patient's fluid and electrolyte balance. To provide safe and appropriate therapy to patients who require IV fluids, you need knowledge of the correct ordered solution, the reason the solution was ordered, the equipment needed, the procedures required to initiate an infusion, how to regulate the infusion rate and maintain the system, how to identify and correct problems, and how to discontinue the infusion.

Types of Solutions. Many prepared IV solutions are available for use (Table 42-11). An IV solution is isotonic, hypotonic, or hypertonic. Isotonic solutions have the same effective osmolality as body fluids. Sodium-containing isotonic solutions such as normal saline are indicated for ECV replacement to prevent or treat ECV deficit. Hypotonic solutions have an effective osmolality less than body fluids, thus decreasing osmolality by diluting body fluids and moving water into cells. Hypertonic solutions have an effective osmolality greater than body fluids. If they are hypertonic sodium-containing solutions, they increase osmolality rapidly and pull water out of cells, causing them to shrivel (Wunderlich, 2013). The decision to use a hypotonic or hypertonic solution is made on the basis of a patient's specific fluid and electrolyte imbalance. For example, a patient with hypernatremia that cannot be treated with oral water generally receives a hypotonic IV solution to dilute the ECF and rehydrate cells. Too-rapid or excessive infusion of any IV fluid has the potential to cause serious patient problems.

Additives such as potassium chloride (KCl) are common in IV solutions (e.g., 1000 mL D₅ ½ NS with 20 mEq KCl at 125 mL/hr).

Administer KCl carefully because hyperkalemia can cause fatal cardiac dysrhythmias. *Under no circumstances should KCl be administered by IV push* (directly through a port in IV tubing). Verify that a patient has adequate kidney function and urine output before administering an IV solution containing potassium. Patients with normal renal function who are receiving nothing by mouth should have potassium added to IV solutions. The body cannot conserve potassium, and the kidneys continue to excrete it even when the plasma level falls. Without potassium intake, hypokalemia develops quickly.

Vascular Access Devices. **Vascular access devices (VADs)** are catheters or infusion ports designed for repeated access to the vascular system. Peripheral catheters are for short-term use (e.g., fluid restoration after surgery and short-term antibiotic administration). Devices for long-term use include central catheters and implanted ports, which empty into a central vein. Remember that the term *central* applies to the location of the catheter tip, not to the insertion site. Peripherally inserted central catheters (PICC lines) enter a peripheral arm vein and extend through the venous system to the superior vena cava where they terminate. Other central lines enter a central vein such as the subclavian or jugular vein or are tunneled through subcutaneous tissue before entering a central vein. Central lines are more effective than peripheral catheters for administering large volumes of fluid, PN, and medications or fluids that irritate veins. Proper care of central line insertion sites is critical for the prevention of central line–associated bloodstream infection (CLABSI). The National Quality Forum (NQF) (2015) emphasized prevention of CLABSIs with evidence-based interventions as an important patient safety measure. The Centers for Medicare and Medicaid Services (CMS) does not reimburse hospitals for the added costs and hospital days needed to treat a CLABSI (Hadaway, 2012b). Nurses require specialized education regarding care

BOX 42-6   EVIDENCE-BASED PRACTICE

Preventing Central Line–Associated Bloodstream Infections (CLABSI)

PICO Question: In hospitalized adult patients, which interventions for central IV site care are best to prevent central line–associated bloodstream infection (CLABSI)?

Evidence Summary

CLABSI is a serious complication of intravenous (IV) therapy that increases morbidity, hospital length of stay, and health care costs. Research shows that effective strategies for prevention of CLABSI include the use of several evidence-based practices together as a "bundle" or "checklist" (Chopra et al., 2013). Such bundles are effective in reducing CLABSIs at the time of insertion of central lines and also during their maintenance (TJC, 2012). For example, a recommended bundle at *insertion* of a central line is hand hygiene before catheter insertion; use of maximum sterile barrier precautions on insertion; chlorhexidine skin antisepsis before insertion and during dressing changes; avoidance of the femoral vein for central venous access for adults; and daily evaluation of line necessity, with prompt removal of nonessential lines (Chopra et al., 2013). Maintenance bundles are similar, with attention to hand hygiene, catheter hub asepsis, dressing and line change, and continued daily evaluation of line necessity. For the most effective reduction of CLABSIs, research demonstrates the necessity for organized educational strategies and attention to institutional support and culture in addition to the use of bundled central line insertion and maintenance practices. One hospital had instituted the central line insertion bundle but still had not achieved zero CLABSI rate in the intensive care unit (ICU); with addition of a collaborative program involving staff education, daily surveillance, single-use line insertion kits, and updated policies and protocols, a zero CLABSI rate was achieved (Matocha, 2013). Dumyati et al. (2014) reduced CLABSI rate by 50% with a multimodal intervention that included involvement of nursing leadership and staff, education on the central line maintenance bundle components, competency evaluation, and line care audits. Zingg et al. (2014) achieved a hospital-wide clinically relevant reduction of CLABSIs with an interdisciplinary multimodal program that included educational components, single-use insertion kits, catheter insertion checklist, and catheter maintenance bundle.

Application to Nursing Practice

- If CLABSI prevention bundles are not used for central line insertion and maintenance at your agency, review the current research in a nursing practice committee or with your IV therapy team to influence policy and procedures and implement these bundles.
- Extend use of central line maintenance bundles to hospital units outside the ICU where patients have central lines.
- Work with infection control personnel and medical and nursing administration to establish a multidisciplinary CLABSI prevention program that includes institutional support for education, competency demonstration, use of insertion and maintenance bundles, and daily line audits.

FIGURE 42-14 Over-the-needle catheter for venipuncture.

available in a variety of gauges such as the commonly used 20 and 22 gauges. A larger gauge indicates a smaller-diameter catheter. A peripheral VAD is called an over-the-needle catheter; it consists of a small plastic tube or catheter threaded over a sharp stylet (needle). Once you insert a stylet and advance the catheter into the vein, you withdraw the stylet, leaving the catheter in place. These devices have a safety mechanism that covers the sharp stylet when withdrawing it to reduce the risk of needlestick injury (Figure 42-14). Needleless systems allow you to make connections without using needles, which reduces needlestick injuries (Hadaway, 2012a).

The main IV fluid used in a continuous infusion flows through tubing called the *primary line.* The primary line connects to the IV catheter. Injectable medications such as antibiotics are usually added to a small IV solution bag and "piggybacked" as a secondary set into the primary line or as a primary intermittent infusion to be administered over a 30- to 60-minute period (see Chapter 32). The type and amount of solution are prescribed by the patient's health care provider and depend on the medication added and the patient's physiological status. If an IV infusion is connected to an EID, use the tubing designated for that EID. For gravity-flow IVs (not using an EID), select tubing as described in the equipment list of Skill 42-1 on pp. 967-977. Add IV extension tubing to increase the length of the primary line, which reduces pulling of the tubing and increases a patient's mobility when changing positions.

Initiating the Intravenous Line. After you collect the equipment at the patient's bedside, prepare to insert the IV line by assessing the patient for a venipuncture site (see Skill 42-1). The most common IV sites are on the inner arm (Figure 42-15). Do not use hand veins on older adults or ambulatory patients. IV insertion in a foot vein is common with children, but avoid these sites in adults because of the increased risk of thrombophlebitis (INS, 2011).

As you assess a patient for potential venipuncture sites, consider conditions that exclude certain sites. Venipuncture is contraindicated in a site that has signs of infection, infiltration, or thrombosis. An infected site is red, tender, swollen, and possibly warm to the touch. Exudate may be present. Do not use an infected site because of the danger of introducing bacteria from the skin surface into the bloodstream. Avoid using an extremity with a vascular (dialysis) graft/fistula or on the same side as a mastectomy. Avoid areas of flexion if possible (INS, 2011; Wallis et al., 2014). Choose the most distal appropriate site (INS, 2011). Using a distal site first allows for the use of proximal sites later if the patient needs a venipuncture site change.

Venipuncture is a technique in which a vein is punctured through the skin by a sharp rigid stylet (e.g., metal needle). The stylet is partially

of central venous catheters and implanted infusion ports. Nursing responsibilities for central lines include careful monitoring, flushing to keep the line patent, and site care and dressing changes to prevent CLABSIs (Box 42-6).

Equipment. Correct selection and preparation of IV equipment helps in safe and rapid placement of an IV line. Because fluids infuse directly into the bloodstream, sterile technique is necessary. Organize all equipment at the bedside for an efficient insertion. IV equipment includes VADs; tourniquet; clean gloves; dressings; IV fluid containers; various types of tubing; and electronic infusion devices (EIDs), also called *infusion pumps.* VADs that are short, peripheral IV catheters are

BOX 42-7 FOCUS ON OLDER ADULTS

Protection of Skin and Veins During Intravenous Therapy

- Use the smallest-gauge catheter or needle possible (e.g., 22 to 24 gauge). Veins are very fragile, and a smaller gauge allows better blood flow to provide increased hemodilution of the intravenous (IV) fluids or medications (Gresser, 2014).
- Avoid the back of the hand, which may compromise a patient's need for independence and mobility.
- Avoid placement of IV line in veins that are easily bumped because older adults have less subcutaneous support tissue (Gresser, 2014).
- Avoid vigorous friction while cleaning a site to prevent tearing fragile skin.
- If a patient has fragile skin and veins, use minimal or no tourniquet pressure (Gresser, 2014).
- If using a tourniquet, place it over the patient's sleeve or use a blood pressure cuff.
- With loss of supportive tissue, veins tend to lie more superficially; lower the insertion angle for venipuncture to 10 to 15 degrees after penetrating the skin (Gresser, 2014).
- Veins roll away from the needle easily because of loss of subcutaneous tissue. To stabilize a vein, apply traction to the skin below the projected insertion site (Gresser, 2014).
- Secure IV site with a catheter stabilization device, avoiding excessive use of tape on fragile skin; consider covering the site additionally with surgical stretch mesh (Gresser, 2014).
- Numerous medications and supplements (e.g., anticoagulants, antibiotics, glucocorticoids, and garlic) increase the likelihood of bruising and bleeding (Burchum and Rosenthal, 2016).

---

covered either with a plastic catheter or a needle attached to a syringe. General purposes of venipuncture are to collect a blood specimen, start an IV infusion, provide vascular access for later use, instill a medication, or inject a radiopaque or other tracer for special diagnostic examinations. Skill 42-1 on pp. 967-977 describes venipuncture for peripheral IV fluid infusion, incorporating INS (2011) standards of practice. It takes practice to become proficient in venipuncture. Only experienced practitioners perform it for patients whose veins are fragile or collapse easily such as older adults. Box 42-7 describes principles to follow for venipuncture in older adults.

Nurses require specialized knowledge and education to place PICCs. Some central lines and implanted ports require insertion by physicians or advanced practice nurses. Both types of central catheters require close monitoring and maintenance. This chapter focuses on peripheral catheters.

Regulating the Infusion Flow Rate. After initiating a peripheral IV infusion and checking it for patency, regulate the rate of infusion according to the health care provider's orders (see Skill 42-2 on pp. 977-980). For patient safety avoid uncontrolled flow of IV fluid into a patient. You are responsible for calculating the flow rate (mL/hr) that delivers the IV fluid in the prescribed time frame. The correct IV infusion rate ensures patient safety by preventing too-slow or too-rapid administration of IV fluids. An infusion rate that is too slow often leads to further physiological compromise in a patient who is dehydrated, in circulatory shock, or critically ill. An infusion rate that is too rapid overloads the patient with IV fluid, causing fluid and electrolyte imbalances and cardiac complications in vulnerable patients (e.g., older adults or patients with preexisting heart disease).

Electronic infusion devices (EIDs), also called *IV pumps* or *infusion pumps,* deliver an accurate hourly IV infusion rate. EIDs use positive pressure to deliver a measured amount of fluid during a specified unit of time (e.g., 125 mL/hr). Familiarize yourself with the brand of EID in use at your agency so you are able to set the flow rate accurately. Many EIDs have capabilities that allow for single- and multiple-solution infusions at different rates. Electronic detectors and alarms respond to air in IV lines, occlusion, completion of infusion, high and low pressure, and low battery power.

When you open a roller clamp or other type of clamp on an infusion tubing that is not yet properly inserted in an EID or on a gravity-flow IV system, the IV fluid infuses very rapidly. Nonelectronic volume-control devices are used occasionally with an IV solution infused by gravity to prevent accidental infusion of a large fluid volume. These devices hang between the IV bag and the patient and hold only a small volume of fluid that can infuse into the patient. Regardless of the device in use, monitor the patient regularly to verify correct infusion of IV fluids. Patency of an IV catheter means that IV fluid flows easily through it. For patency there must be no clots at the tip of the catheter, and the catheter tip must not be against the vein wall. A blocked catheter slows or stops the rate of infusion of the IV fluids. IV flow rate also can be slowed by infiltration, vasospasm, a knot or kink in the tubing, external pressure on the tubing, and position changes of the patient's extremity. If the flow decreases or stops and the EID is working correctly, inspect the tubing. Sometimes the patient is lying or sitting on it. The tubing may be kinked or caught in or under equipment. Also inspect the area around the insertion site for anything that obstructs the flow of IV fluids. For gravity flow, the height of the container influences flow rate. Raising the container usually increases the rate because of increased driving pressure.

Flexion of an extremity, particularly at the wrist or elbow, can decrease IV flow rate by compressing the vein. Although VAD placement in areas of flexion is discouraged, occasionally it becomes necessary. In that case INS standards specify use of an arm board or other joint stabilization device to protect the IV site by keeping the joint extended (INS, 2011). Use padding with arm boards because they may cause skin or nerve damage from pressure. Starting an infusion in a new location rather than relying on a site that causes problems may be more comfortable for a patient. Before discontinuing the current infusion, choose another site and start the infusion to verify that the patient has other accessible veins.

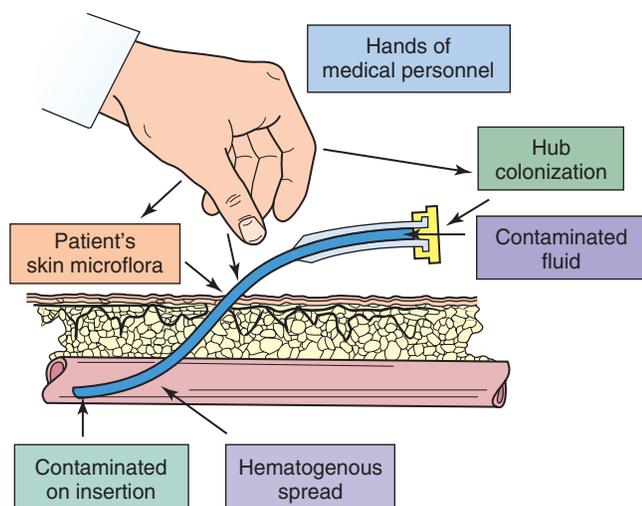
Maintaining the System. After placing an IV line and regulating the flow rate, maintain the IV system. Line maintenance involves (1) keeping the system sterile and intact; (2) changing IV fluid containers, tubing, and contaminated site dressings; (3) helping a patient with self-care activities so as not to disrupt the system; and (4) monitoring


FIGURE 42-16 Potential sites for contamination of vascular access device.

FIGURE 42-17 Catheter stabilization device. (Copyright © C.R. Bard, Inc. Used with permission.)

for complications of IV therapy. The frequency and options for maintaining the system are identified in agency policies.

An important component of patient care is maintaining the integrity of an IV line to prevent infection. Potential sites for contamination of a VAD are shown in Figure 42-16. Inserting an IV line under appropriate aseptic technique reduces the chances of contamination from the patient's skin. After insertion, prevent infection by the conscientious use of infection control principles such as thorough hand hygiene before and after handling any part of the IV system and maintaining sterility of the system during tubing and fluid container changes.

Always maintain the integrity of an IV system. Never disconnect tubing because it becomes tangled or it might seem more convenient for positioning or moving a patient or applying a gown. If a patient needs more room to maneuver, use aseptic technique to add extension tubing to an IV line. However, keep the use of extension tubing to a minimum because each connection of tubing provides opportunity for contamination. *Never let IV tubing touch the floor.* Do not use stopcocks for connecting more than one solution to a single IV site because they are sources of contamination (INS, 2011). IV tubing contains needle-less injection ports through which syringes or other adaptors can be inserted for medication administration. Clean an injection port thoroughly with 2% chlorhexidine (preferred), 70% alcohol, or povidone-iodine solution and let it dry before accessing the system (INS, 2011).

Protective devices designed to prevent movement or accidental dislodgement of a VAD are called *catheter stabilization devices* (Figure 42-17). These devices are available in many hospitals, and nurses decide whether or not to use them when starting an IV line. This is a patient safety issue (Billingsley and Kinchen, 2014). Movement of the VAD in a vein can cause phlebitis and infiltration; VAD dislodgement requires using another VAD at a new IV infusion site. INS standards indicate that use of these devices is preferable over taping when feasible (INS, 2011).

Changing Intravenous Fluid Containers, Tubing, and Dressings. Patients receiving IV therapy over several days require periodic changes of IV fluid containers (see Skill 42-3 on pp. 981-986). It is important to organize tasks so you can change containers rapidly before a thrombus forms in the catheter.

Recommended frequency of IV tubing change depends on whether it is used for continuous or intermittent infusion. INS (2011) standards specify that continuous infusion tubing changes occur *no more frequently* than every 96 hours unless the tubing has been compromised

or become contaminated, which requires immediate tubing change (Ullman et al., 2013). In contrast, change tubing for *intermittent* infusion every 24 hours because of the increased risk of contamination from opening the IV system (INS, 2011). Blood, blood components, and lipids are likely to promote bacterial growth in tubing. INS standards (2011) specify tubing changes every 4 hours for blood and blood components and every 24 hours for continuous IV lipids. For lipids use tubing that is free of diethylhexyl-phthalate (DEHP), a toxin that leaches into lipid solutions (INS, 2011). Whenever possible, schedule tubing changes when it is time to hang a new IV container to decrease risk of infection (INS, 2011). To prevent entry of bacteria into the bloodstream, maintain sterility during tubing and IV fluid container changes (INS, 2011).

A sterile dressing over an IV site reduces the entrance of bacteria into the insertion site. Transparent dressings, the most common type, help secure the VAD, allow continuous visual inspection of the IV site, and are less easily soiled or moistened than gauze dressings (Bernatchez, 2014). Leave transparent dressings in place until the IV tubing is replaced (INS, 2011). If a gauze dressing is used, change it every 48 hours (INS, 2011). Both types of dressings must be changed when the IV device is removed or replaced or when the dressing becomes damp, loosened, or soiled (INS, 2011) (see Skill 42-4 on pp. 987-989).

Helping Patients to Protect Intravenous Integrity. To prevent the accidental disruption of an IV system, a patient often needs help with hygiene, comfort measures, meals, and ambulation. Changing gowns is difficult for a patient with an IV in the arm. Teach NAP and patients that they must not break the integrity of an IV line to change a gown because it leads to contamination. It helps to use a gown with snaps along the top sleeve seam to facilitate changing the gown without disturbing the venipuncture site. Change regular gowns by following these steps for maximum speed and arm mobility:

1. *To remove a gown,* remove the sleeve of the gown from the arm without the IV line, maintaining the patient's privacy.
2. Remove the sleeve of the gown from the arm with the IV line.
3. Remove the IV solution container from its stand and pass it and the tubing through the sleeve. (If this involves removing the tubing from an EID, use the roller clamp to slow the infusion to prevent the accidental infusion of a large volume of solution or medication).
4. *To apply a gown,* place the IV solution container and tubing through the sleeve of the clean gown and hang it on its stand.

TABLE 42-12 Complications of Intravenous Therapy with Nursing Interventions

Complication	Description	Assessment Findings	Nursing Interventions
Circulatory overload of IV solution	IV solution infused too rapidly or in too great an amount	Depends on type of solution ECV excess with Na+-containing isotonic fluid (crackles in dependent parts of lungs, shortness of breath, dependent edema) Hyponatremia with hypotonic fluid (confusion, seizures) Hypernatremia with Na+-containing hypertonic fluid (confusion, seizures) Hyperkalemia from K+-containing fluid (cardiac dysrhythmias, muscle weakness, abdominal distention)	If symptoms appear, reduce IV flow rate and notify patient's health care provider. With ECV excess raise head of bed; administer oxygen and diuretics if ordered. Monitor vital signs and laboratory reports of serum levels. Health care provider may adjust additives in IV solution or type of IV fluid; watch for and implement order.
Infiltration or extravasation	IV fluid entering subcutaneous tissue around venipuncture site Extravasation: technical term used when a vesicant (tissue-damaging) drug (e.g., chemotherapy) enters tissues (Coyle et al., 2014)	Skin around catheter site taut, blanched, cool to touch, edematous; may be painful as infiltration or extravasation increases; infusion may slow or stop	Stop infusion. Discontinue IV infusion if no vesicant drug (see Skill 42-3). If vesicant drug, disconnect IV tubing and aspirate drug from catheter (Dychter et al., 2012). Agency policy and procedures may require delivery of antidote through catheter before removal. Elevate extremity. Contact health care provider if solution contained KCl, a vasoconstrictor, or other potential vesicant. Apply warm, moist or cold compress according to procedure for type of solution infiltrated. Start new IV line in other extremity.
Phlebitis	Inflammation of inner layer of a vein	Redness, tenderness, pain, warmth along course of vein starting at access site; possible red streak and/or palpable cord along vein	Stop infusion and discontinue IV line (see Skill 42-3). Start new IV line in other extremity or proximal to previous insertion site if continued IV therapy is necessary. Apply warm, moist compress or contact IV therapy team or health care provider if area needs additional treatment.
Local infection	Infection at catheter-skin entry point during infusion or after removal of IV catheter	Redness, heat, swelling at catheter-skin entry point; possible purulent drainage	Culture any drainage (if ordered). Clean skin with alcohol; remove catheter and save for culture; apply sterile dressing. Notify health care provider. Start new IV line in other extremity. Initiate appropriate wound care (see Chapter 48) if needed.
Bleeding at venipuncture site	Oozing or slow, continuous seepage of blood from venipuncture site	Fresh blood evident at venipuncture site, sometimes pooling under extremity	Assess if IV system is intact. If catheter is within vein, apply pressure dressing over site or change dressing. Start new IV line in other extremity or proximal to previous insertion site if VAD is dislodged, IV is disconnected, or bleeding from site does not stop.

ECV, Extracellular volume; *IV,* intravenous; *VAD,* vascular access device.

(If the IV line is controlled by an EID, reassemble, turn on the pump, and open the roller clamp.)

5. Place the arm with the IV line through the gown sleeve.
6. Place the arm without the IV line through the gown sleeve.

A patient with an arm or a hand infusion is able to walk unless contraindicated. Offer a rolling IV pole on wheels. Help the patient get out of bed and place the IV pole next to the involved arm. Teach him or her to hold the pole with the involved hand and push it while walking. Check that the IV container is at the proper height, there is no tension on the tubing, and the flow rate is correct. Instruct the patient to report any blood in the tubing, a stoppage in the flow, or increased discomfort.

Complications of Intravenous Therapy. Table 42-12 presents complications of IV therapy, with assessments and nursing interventions. A potentially dangerous complication of IV therapy is circulatory overload with IV solution, which occurs when a patient receives too-rapid administration or an excessive amount of fluids. Assessment findings depend on the type of IV solution that infuses in excess (see Table 42-12). The signs and symptoms often arise rapidly, which highlights the importance of frequent assessment of patients receiving IV therapy.

QSEN: BUILDING COMPETENCY IN SAFETY

You have an order to change an intravenous (IV) fluid container for Mrs. Jamison, age 48, who has no oral intake. The new IV fluid is 1000 mL NS with 20 mEq KCl; the previous IV fluid was 1000 mL NS and did not contain KCl. Which nursing assessments related to fluid and electrolyte imbalances do you need to make before you hang the new IV fluid container? Why?

Answers to QSEN Activities can be found on the Evolve website.

TABLE 42-13	**Infiltration Scale**
Grade	**Clinical Criteria**
0	No symptoms
1	Skin blanched Edema <2.54 cm (1 inch) in any direction Cool to touch With or without pain
2	Skin blanched Edema 2.54-15.2 cm (1-6 inches) in any direction Cool to touch With or without pain
3	Skin blanched, translucent Gross edema >15.2 cm (6 inches) in any direction Cool to touch Mild-moderate pain Possible numbness
4	Skin blanched, translucent Skin tight, leaking Skin discolored, bruised, swollen Gross edema >15.2 cm (6 inches) in any direction Deep pitting tissue edema Circulatory impairment Moderate-to-severe pain Infiltration of any amount of blood product, irritant, or vesicant

From Groll D et al: Evaluation of the psychometric properties of the phlebitis and infiltration scales for the assessment of complications of peripheral vascular access devices, *J Infus Nurs* 33(6):385, 2010.

Infiltration occurs when an IV catheter becomes dislodged or a vein ruptures and IV fluids inadvertently enter subcutaneous tissue around the venipuncture site. When the IV fluid contains additives that damage tissue, **extravasation** occurs (Dychter et al., 2012). Infiltration or extravasation causes coolness, paleness, and swelling of the area. When infiltration occurs, immediately assess for any additives in the infiltrated fluid to determine the type of action necessary to prevent local tissue damage and sloughing. Vasoconstrictors, high-dose potassium, and other IV additives in subcutaneous tissue need different treatments from those needed for an infiltrated additive-free IV (Dychter et al., 2012) (see Table 42-12). Although the INS removed their previous infiltration scale from their 2011 standards because of insufficient research validation, the society does recommend use of an infiltration scale to provide objectivity in infiltration measurement (Table 42-13).

Phlebitis (i.e., inflammation of a vein) results from chemical, mechanical, or bacterial causes. Risk factors for phlebitis include acidic or hypertonic IV solutions; rapid IV rate; IV drugs such as KCl, vancomycin, and penicillin; VAD inserted in area of flexion, poorly secured catheter; poor hand hygiene; and lack of aseptic technique (Wallis et al., 2014). The typical signs of inflammation (i.e., heat, erythema [redness], tenderness) occur along the course of a vein (Table 42-14). Phlebitis can be dangerous because blood clots (thrombophlebitis) form along the vein and in some cases cause emboli. This may cause permanent damage to veins. Routine changes of peripheral IV catheters to reduce infection are not recommended (O'Grady et al., 2011). The INS Standards of Practice (2011) recommend avoiding routine replacement of peripheral IV catheters in infants and children and replacement of a peripheral IV catheter in adults only if clinically indicated (Rickard et al., 2012; Webster et al., 2013). An INS position

TABLE 42-14	**Phlebitis Scale**

0	No symptoms
1	Erythema at access site with or without pain
2	Pain at access site with erythema and/or edema
3	Pain at access site with erythema and/or edema; streak formation; palpable venous cord
4	Pain at access site with erythema and/or edema; streak formation; palpable venous cord >2.54 cm (1 inch) in length; purulent drainage

From Infusion Nurses Society: Infusion nursing standards of practice, *J Infus Nurs* 34(1S):S1, 2011.

paper provides the following guidelines for how frequently to assess the peripheral VAD site to see if its replacement is clinically indicated (Gorski et al., 2012):

- At least every 4 hours for alert, oriented adults who are able to report problems at the VAD site and are not receiving vesicant (tissue-damaging) infusions
- At least every 1 to 2 hours for critically ill patients and adults who are receiving sedatives, are unable to report problems at the VAD site, or have VADs in high-risk locations such as areas of flexion
- At least every hour for neonates and children
- Every 5 to 10 minutes during infusions of vesicants or vasoconstrictors
- During every home or outpatient visit

In the absence of phlebitis, local infection at the venipuncture site is usually caused by poor aseptic technique during catheter insertion, daily monitoring, or catheter removal. Early recognition of local infection and treatment is important to prevent bacteria from entering the bloodstream (see Table 42-12). Bloodstream infections may arise from short peripheral IV catheter sites (Hadaway, 2012b).

Bleeding can occur around the venipuncture site during the infusion or through the catheter or tubing if these become disconnected inadvertently (see Table 42-12). Bleeding is more common in patients who receive heparin or other anticoagulants or who have a bleeding disorder (e.g., hemophilia or thrombocytopenia).

Discontinuing Peripheral Intravenous Access. Discontinue IV access after infusion of the prescribed amount of fluid; when infiltration, phlebitis, or local infection occurs; or if the IV infusion slows or stops, indicating the catheter has developed a thrombus at its tip. Skill 42-3 presents the steps for discontinuing peripheral IV access. You help patients and families understand that moving from IV infusion to oral fluid intake is a sign of progress toward recovery.

Blood Transfusion. Blood transfusion, or blood component therapy, is the IV administration of whole blood or a blood component such as packed red blood cells (RBCs), platelets, or plasma. Objectives for administering blood transfusions include (1) increasing circulating blood volume after surgery, trauma, or hemorrhage; (2) increasing the number of RBCs and maintaining hemoglobin levels in patients with severe anemia; and (3) providing selected cellular components as replacement therapy (e.g., clotting factors, platelets, albumin).

Caring for patients receiving blood or blood-product transfusion is a nursing responsibility. You must be thorough in patient assessment, checking the blood product against prescriber's orders, checking it against patient identifiers, and monitoring for any adverse reactions. Blood transfusions are never regarded as routine; overlooking any

TABLE 42-15   ABO Compatibilities for Transfusion Therapy

Component	Compatibilities

ABO, Blood group consisting of groups A, AB, B, and O.

minor detail can have dangerous and life-threatening events for a patient (AABB, 2014a,b).

Blood Groups and Types. Blood transfusions must be matched to each patient to avoid incompatibility. RBCs have antigens in their membranes; the plasma contains antibodies against specific RBC antigens. If incompatible blood is transfused (i.e., a patient's RBC antigens differ from those transfused), the patient's antibodies trigger RBC destruction in a potentially dangerous **transfusion reaction** (i.e., an immune response to the transfused blood components).

The most important grouping for transfusion purposes is the ABO system, which identifies A, B, O, and AB blood types. Determination of blood type is made on the basis of the presence or absence of A and B RBC antigens. Individuals with type A blood have A antigens on their RBCs and anti-B antibodies in their plasma. Individuals with type B blood have B antigens on their RBCs and anti-A antibodies in their plasma. A person who has type AB blood has both A and B antigens on the RBCs and no antibodies against either antigen in the plasma. A type O individual has neither A nor B antigens on RBCs but has both anti-A and anti-B antibodies in the plasma (Alexander et al., 2014). Table 42-15 shows the compatibilities between blood types of donors and recipients. People with type O blood are considered universal blood donors because they can donate packed RBCs and platelets to people with any ABO blood type. People with type AB blood are called *universal blood recipients* because they can receive packed RBCs and platelets of any ABO type.

Another consideration when matching blood components for transfusions is the Rh factor, which refers to another antigen in RBC membranes. Most people have this antigen and are Rh positive; a person without it is Rh negative. People who are Rh negative receive only Rh-negative blood components.

Autologous Transfusion. Autologous transfusion (autotransfusion) is the collection and reinfusion of a patient's own blood. Blood for an autologous transfusion most commonly is obtained by preoperative donation up to 6 weeks before a scheduled surgery (e.g., heart,

orthopedic, plastic, or gynecological). A patient can donate several units of blood, depending on the type of surgery and his or her ability to maintain an acceptable hematocrit. Blood for autologous transfusion is also obtained at the time of surgery by normovolemic hemodilution or through blood salvage (e.g., during surgery for liver transplantation, trauma, or vascular and orthopedic conditions). After surgery blood is salvaged from drainage from chest tubes or joint cavities. Autologous transfusions are safer for patients because they decrease the risk of mismatched blood and exposure to bloodborne infectious agents (Alexander et al., 2014).

Transfusing Blood. Transfusion of blood or blood components is a nursing procedure that requires an order from a health care provider. Patient safety is a nursing priority; and patient assessment, verification of health care provider's order, and verification of correct blood products for the correct patient are imperative (AABB, 2014a,b).

Perform a thorough patient assessment before initiating a transfusion and monitor carefully during and after the transfusion. Assessment is critical because of the risk of transfusion reactions. Pretransfusion assessment includes establishing whether a patient knows the reason for the blood transfusion and whether he or she has ever had a previous transfusion or transfusion reaction. A patient who has had a transfusion reaction is usually at no greater risk for a reaction with a subsequent transfusion. However, he or she may be anxious about the transfusion, requiring nursing intervention. Before beginning a transfusion, explain the procedure and instruct the patient (if alert) to report any side effects (e.g., chills, dizziness, or fever) once the transfusion begins. Have a professional translator available if the patient does not speak English. Ensure that he or she has signed an informed consent. Patients with certain cultural or religious backgrounds may refuse blood transfusions (see Box 42-5).

Because of the danger of transfusion reactions, your pretransfusion assessment always includes the patient's baseline vital signs. These data allow you to identify when vital sign changes occur as a result of a transfusion reaction.

Always check agency policy and procedures before initiating any blood therapy. For patient safety always verify three things: (1) that blood components delivered are the ones that were ordered, (2) that blood delivered to a patient is compatible with the blood type listed in the medical record, and (3) that the right patient receives the blood. Together two RNs or one RN and an LPN (check agency policy and procedures) must check the label on the blood product against the medical record and the patient's identification number, blood group, and complete name. If even a minor discrepancy exists, do not give the blood; notify the blood bank immediately to prevent infusion errors.

When administering a transfusion, you need an appropriate-size IV catheter and blood administration tubing that has a special in-line filter (Figure 42-18). Adults require a large catheter (e.g., 18- or 20-gauge) because blood is more viscous than crystalloid IV fluids. Children with small veins need a smaller catheter. Prime the tubing with 0.9% sodium chloride (normal saline) to prevent hemolysis or breakdown of RBCs. Initiate a transfusion slowly to allow for the early detection of a transfusion reaction. Maintain the ordered infusion rate, monitor for side effects, assess vital signs, and promptly record all findings. It is important to stay with the patient during the first 15 minutes because this is the time when a reaction is most likely to occur. After the initial time period, continue to monitor the patient and obtain vital signs periodically during the transfusion as directed by agency policy. If a transfusion reaction is anticipated or suspected, obtain vital signs more frequently (Table 42-16).

The transfusion rate usually is specified in the health care provider's orders. Ideally a unit of whole blood or packed RBCs is transfused in 2 hours. This time can be lengthened to 4 hours if the patient is at risk

FIGURE 42-18 Filling tubing for blood administration.

for ECV excess. Beyond 4 hours there is a risk for bacterial contamination of the blood.

When patients have a severe blood loss such as with hemorrhage, they often receive rapid transfusions through a central venous catheter. A blood-warming device often is necessary because the tip of the central venous catheter lies in the superior vena cava, above the right atrium. Rapid administration of cold blood can cause cardiac dysrhythmias. Patients who receive large-volume transfusion of citrated blood have high risk of hyperkalemia, hypocalcemia, hypomagnesemia, and metabolic alkalosis; therefore they need careful monitoring.

Transfusion Reactions and Other Adverse Effects. A transfusion reaction is an immune system reaction to the transfusion that ranges from a mild response to severe anaphylactic shock or acute intravascular hemolysis, both of which can be fatal (Clark, 2011). Table 42-16 presents the causes, manifestations, management, and prevention of transfusion reactions. Prompt intervention when a transfusion reaction occurs maintains or restores a patient's physiological stability. When you suspect acute intravascular hemolysis, do the following (Alexander et al., 2014):

- Stop the transfusion immediately.
- Keep the IV line open by replacing the IV tubing down to the catheter hub with new tubing and running 0.9% sodium chloride (normal saline).
- *Do not* turn off the blood and simply turn on the 0.9% sodium chloride (normal saline) that is connected to the Y-tubing infusion set. This would cause blood remaining in the IV tubing to infuse into the patient. Even a small amount of mismatched blood can cause a major reaction.
- Immediately notify the health care provider or emergency response team.
- Remain with the patient, observing signs and symptoms and monitoring vital signs as often as every 5 minutes.

- Prepare to administer emergency drugs such as antihistamines, vasopressors, fluids, and corticosteroids per health care provider order or protocol.
- Prepare to perform cardiopulmonary resuscitation.
- Save the blood container, tubing, attached labels, and transfusion record for return to the blood bank.
- Obtain blood and urine specimens per health care provider order or protocol.

Acute adverse effects that do not involve an immune response to the blood components also can occur during a transfusion (see Table 42-16). Circulatory overload is a risk when a patient receives massive whole blood or packed RBC transfusions for massive hemorrhagic shock or when a patient with normal blood volume receives blood. Patients particularly at risk for circulatory overload are older adults and those with cardiopulmonary diseases. Transfusion of blood components that are contaminated with bacteria, especially gram-negative bacteria, can cause sepsis.

Another category of adverse transfusion effects is diseases transmitted by blood from infected donors who are asymptomatic. Symptoms of these conditions may arise long after the transfusion. Diseases transmitted through transfusions include hepatitis B and C, human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS), and cytomegalovirus infection. In the United States all units of blood for blood banks undergo screening for HIV, hepatitis B and C viruses, syphilis, and West Nile virus, which reduces the risk of acquiring these bloodborne infections (CDC, 2013).

Interventions for Electrolyte Imbalances. In addition to the administration of prescribed medical therapies, there are nursing interventions for preserving or restoring electrolyte imbalance (Felver, 2013c). For example, people who have hypokalemia or hypercalcemia often need bowel management for constipation. Patient safety interventions to prevent falls (see Chapter 27) are vital for patients who become lethargic from hypercalcemia and those with muscle weakness. Patients who have hypercalcemia need an increased fluid intake to prevent renal damage; nurses can help them meet the oral fluid intake goals. Teach patients the reasons for their therapies and the importance of balancing electrolyte I&O to prevent imbalances in the future.

Interventions for Acid-Base Imbalances. Nursing interventions to promote acid-base balance support prescribed medical therapies and aim at reversing the existing acid-base imbalance while providing for patient safety (Felver, 2013b). When these imbalances are life threatening, they require rapid treatment. Maintain a functional IV line and check the health care provider's orders frequently for new medications or fluids. Give fluid and electrolyte replacement and prescribed drugs such as insulin promptly. In addition, monitor patients closely for changes in their status. Use protective measures such as side rails for patients with decreased level of consciousness. Support compensatory hyperventilation for patients with metabolic acidosis by keeping their oral mucous membranes moist and positioning them to facilitate chest expansion. Chapter 41 reviews appropriate therapies for patients with respiratory acidosis. Patients with acid-base imbalances often require repeated ABG analysis.

Arterial Blood Gases. Determination of a patient's acid-base status requires obtaining a sample of arterial blood for laboratory testing. ABG analysis reveals acid-base status and the adequacy of ventilation and oxygenation. A qualified RN or other health care provider draws arterial blood from a peripheral artery (usually the radial) or from an existing arterial line (see agency policy and procedures). Before an arterial blood draw, perform an Allen test, which assesses arterial circulation in the hand (Pagana et al., 2015). When performing the Allen test, apply pressure to both the ulnar and radial arteries in the selected hand. The fingers to the hand should be pale and blanched,

TABLE 42-16 Acute Adverse Effects of Transfusions

Adverse Effect	Cause	Clinical Manifestations	Management	Prevention
Transfusion Reactions—Caused by Immune Response to Blood Components				
Acute intravascular hemolytic	Infusion of ABO-incompatible whole blood, RBCs, or components containing 10 mL or more of RBCs Antibodies in recipient's plasma attach to antigens on transfused RBCs, causing RBC destruction	Chills, fever, low back pain, flushing, tachycardia, tachypnea, hypotension, hemoglobinuria, hemoglobinemia, sudden oliguria (acute kidney injury), circulatory shock, cardiac arrest, death	Stop transfusion and save blood bag and administration set for follow-up. Keep IV site open with normal saline infused through new tubing. Maintain BP and treat shock as ordered, if present. Obtain blood samples **slowly** to avoid hemolysis; send for serological testing. Send urine specimen to laboratory. Give diuretics as prescribed to maintain urine flow. Insert indwelling urinary catheter or measure each voiding to monitor hourly urine output. Dialysis may be required if acute kidney injury occurs. *Patient safety alert:* Do not transfuse additional RBC-containing components until transfusion service provides newly cross-matched units.	Meticulously verify and document patient identification from sample collection to component infusion.
Febrile nonhemolytic (most common)	Antibodies against donor white blood cells	Sudden shaking chills (rigors), fever (rise in temperature 0.5° C [1° F] or more from start), headache, flushing, anxiety, muscle pain	Stop transfusion. Give antipyretics as prescribed; avoid aspirin in thrombocytopenic patients. *Patient safety alert:* Do not restart transfusion.	Consider leukocyte-poor blood products (filtered, washed, or frozen). Pretreat with antipyretics if prior history.
Mild allergic	Antibodies against donor plasma proteins	Flushing, itching, urticaria (hives)	Stop transfusion temporarily. Give antihistamine as directed. If symptoms are mild and transient, restart transfusion slowly. *Patient safety alert:* Do not restart transfusion if fever, pulmonary symptoms, or hypotension develop.	Treat prophylactically with antihistamines.
Anaphylactic	Antibodies to donor plasma, especially anti-IgA	Anxiety, urticaria, dyspnea, wheezing progressing to cyanosis, severe hypotension, circulatory shock, possible cardiac arrest	Stop transfusion. Have epinephrine ready for injection (0.4 mL of 1:1000 solution subcutaneously or 0.1 mL of 1:1000 solution diluted to 10 mL with saline for IV use). Provide blood pressure support as ordered. Initiate CPR if indicated. *Patient safety alert:* Do not restart transfusion.	Transfuse extensively washed RBC products from which all plasma has been removed. Alternately use blood from IgA-deficient donor.
Other Acute Adverse Effects				
Circulatory overload	Blood administered faster than circulation can accommodate	*Dyspnea,* cough, crackles, or rales in dependent lobes of lungs; distended neck veins when upright	Turn down transfusion rate or stop transfusion. Place patient upright with feet in dependent position. Administer prescribed diuretics, oxygen, morphine. Phlebotomy may be indicated.	Adjust transfusion volume and flow rate on basis of patient size and clinical status. Have transfusion service divide unit into smaller aliquots for better spacing of fluid input.
Sepsis	Bacterial contamination of transfused blood components	Rapid onset of chills, high fever, severe hypotension, and circulatory shock *May occur:* Vomiting, diarrhea, sudden oliguria (acute kidney injury), disseminated intravascular coagulation (DIC)	Stop transfusion. Obtain culture of patient's blood and send bag with remaining blood to transfusion service for further study. Treat as ordered: antibiotics, IV fluids, vasopressors, glucocorticoids.	Collect, process, store, and transfuse blood products according to blood-banking standards and infuse within 4 hours of starting time.

Data from Alexander et al: *Core curriculum for infusion nursing*, ed 4, Philadelphia, 2014, Lippincott.
ABO, Blood group consisting of groups A, AB, B, and O; *BP,* blood pressure; *CPR,* cardiopulmonary resuscitation; *DIC,* disseminated intravascular coagulation; *IgA,* immunoglobulin A; *IV,* intravenous; *RBC,* red blood cell.

indicating a lack of arterial blood flow. Release the pressure on the ulnar artery and observe for color to return to the fingers and hand, which indicates that there is adequate circulation to the hand and fingers via the ulnar artery. The Allen test ensures that a patient will have adequate blood flow to the hand if the radial artery is damaged. If color does not return, do not perform radial artery puncture on that arm. After the ABG puncture, apply pressure to the puncture site for at least 5 minutes to reduce the risk of hematoma formation. A longer time is necessary if the patient takes anticoagulant medications. Reassess the radial pulse after removing the pressure. After obtaining the specimen, take care to prevent air from entering the syringe because this alters the blood gas values. To reduce oxygen usage by blood cells, submerge the syringe in crushed ice and transport it immediately to the laboratory.

Restorative Care. After experiencing acute alterations in fluid, electrolyte, or acid-base balance, patients often require ongoing maintenance to prevent a recurrence of health alterations. Older adults require special considerations to prevent complications from developing (see Box 42-2).

Home Intravenous Therapy. IV therapy often continues in the home setting for patients requiring long-term hydration, PN, or long-term medication administration. Initiate patient referral for discharge planning to social services, counselors, or a home care coordinator for assessment of patient and community resources (Petroulias et al., 2013). A home IV therapy nurse works closely with a patient to ensure that a sterile IV system is maintained and complications can be avoided or recognized promptly. Box 42-8 summarizes patient education guidelines for home IV therapy.

Nutritional Support. Most patients who have had electrolyte disorders or metabolic acid-base imbalances require ongoing nutritional support. Depending on the type of disorder, fluid or food intake may be encouraged or restricted (see Chapter 45). Patients or family members who are responsible for meal preparation need to learn to understand nutritional content of foods and read the labels of commercially prepared foods.

Medication Safety. Numerous medications, OTC drugs, and herbal preparations contain components or create potential side effects that can alter fluid and electrolyte balance. Patients with chronic disease who are receiving multiple medications and those with renal disorders are at significant risk for imbalances. Once patients return to restorative care settings, whether in the home, long-term care, or other setting, drug safety is very important. Patient and family education regarding potential side effects and drug interactions that can alter fluid, electrolyte, or acid-base balance is essential. Review all medications with patients and encourage them to consult with their local pharmacist, especially if they wish to try a new OTC drug or herbal preparation (Chapter 32).

◆ Evaluation

Through the Patient's Eyes. Review with patients how well their major concerns and expectations regarding fluid, electrolyte, or acid-base situations were alleviated or addressed. For example, ask a person admitted with dehydration who was concerned about falling because of light-headedness, "How confident are you in your ability to stand without getting light-headed now?" If the patient's concern was feeling uncomfortable with very dry mouth, ask, "How does your mouth feel now?" If the patient's concerns involved having a better understanding of a chronic problem, focus the evaluation on his or her view of the patient education provided. A patient's perspectives regarding care often depend in part on involvement of family and friends. If patients have concerns about returning home or to a different care setting, it is

important to evaluate how well prepared they feel for the transition from acute care.

Patient Outcomes. Evaluate the effectiveness of interventions using the goals and outcomes established for the patient's nursing diagnoses. Evaluation of a patient's clinical status is especially important if acute fluid, electrolyte, and/or acid-base imbalances exist. A patient's condition can change very quickly, and it is important to recognize impending problems by integrating information about his or her presenting risk factors, clinical status, effects of the present

---

BOX 42-8 PATIENT TEACHING

Home Intravenous Therapy

Objective
- The patient and/or family caregiver will demonstrate competence with administering intravenous (IV) therapy safely in the home.

Teaching Strategies
- Explain the importance of IV therapy in maintaining hydration and access for the delivery of medications.
- Emphasize the risks involved when the IV system is not kept sterile.
- Be sure that the patient and/or family caregiver is able to manipulate the required equipment.
- Instruct in aseptic technique and hand hygiene in the handling of all IV equipment.
- Teach how to change IV solutions, tubing, and dressing when they become soiled or dislodged (Alexander et al., 2014). (NOTE: As the home care nurse, you may be able to visit frequently enough to perform scheduled tubing changes.)
- Teach procedures for safe disposal in appropriate containers of all sharps and IV materials exposed to blood. Keep sharps containers away from children (see Chapter 29).
- Instruct to apply pressure with sterile gauze if catheter falls out and, if patient is on anticoagulants, to tape pieces of sterile gauze in place for at least 20 minutes with pressure or until bleeding stops.
- Instruct about signs and symptoms of infiltration, phlebitis, and infection and reporting symptoms immediately.
- Instruct patient and/or family caregiver to report if the infusion slows or stops or if blood is seen in the tubing.
- Teach patient with family caregiver's assistance how to ambulate, perform hygiene, and participate in other activities of daily living without dislodging or disconnecting catheter and tubing:
  - For showering, protect the IV site and dressing from getting wet by covering it completely with plastic. If using an electronic infusion device, unplug around water.
  - Wear clothes that avoid pressure on the IV site and avoid trauma to the site when changing clothes.
  - Have patient avoid strenuous exercise of the arm with the IV line.

Evaluation
- Ask patient and family caregiver why it is necessary to maintain hydration and IV access for the delivery of medications.
- Ask what to do if the IV infusion stops.
- Ask patient and family caregiver to describe signs and symptoms of complications and the action they should take.
- Observe the patient or family caregiver changing the IV container, tubing, and dressing.
- Observe the patient ambulating and participating in activities of daily living to see how he or she protects and manipulates the IV catheter and apparatus.

---

treatment regimen, and potential causative agent. For evaluation, apply knowledge of how various pathophysiological conditions affect fluid, electrolyte, and acid-base balance; the effects of medications and fluids; and the patient's presenting clinical status when making clinical decisions (Figure 42-19).

Compare your current evaluation findings with the previous patient assessment. For example, a patient's hypokalemia demonstrates improvement when the serum potassium is increasing toward normal and the physical signs and symptoms of hypokalemia begin to disappear or lessen in intensity. Specifically the patient's heart rhythm becomes more regular, and normal bowel function returns.

For patients with less acute alterations, evaluation likely occurs over a longer period of time. In this situation evaluation may be more focused on behavioral changes (e.g., the patient's adherence to dietary restrictions and medication schedules). Another important element of evaluation is the family's ability to anticipate alterations and prevent problems from recurring.

The patient's level of progress determines whether the plan of care needs to continue or be revised. If goals are not met, you may need to consult a health care provider to discuss additional methods such as increasing the frequency of an intervention (e.g., providing more fluids to a dehydrated patient), introducing a new therapy (e.g., initiating insertion of an IV line), or discontinuing a particular therapy. Once outcomes are met, the nursing diagnosis is resolved, and you are able to focus on other priorities, including maintaining normal fluid, electrolyte, and acid-base balance. If established outcomes are not achieved, explore factors that contributed to why the planned outcomes were not met. Modification of the care plan occurs after this evaluation. If outcomes are not achieved, the questions asked may include the following:

- "What difficulties are you having with measuring your I&O daily and keeping a record?"
- "What barriers are you experiencing to obtaining the potassium-rich foods you need?"
- "Are you continuing to have frequent loose stools or diarrhea?"
- "Have you purchased an antacid, or are you still using baking soda as an antacid?"

Knowledge
- Characteristics of fluid, electrolyte, and acid-base imbalances
- Effects of pathophysiology on fluid, electrolyte, and acid-base balances
- Effects of nursing and medical interventions on fluid, electrolyte, and acid-base balances

Experience
- Previous patient responses to planned nursing therapies for improving fluid, electrolyte, and acid-base balance (what worked and what did not work)

EVALUATION
- Reassess signs and symptoms of the patient's fluid, electrolyte, and acid-base imbalance
- Ask the patient for perceptions of fluid balance after interventions
- Ask how well patient's expectations have been addressed
- Observe the most current laboratory results

Standards
- Use established expected outcomes to evaluate the patient's response to care (e.g., oral mucous membranes will be moist, postural hypotension and tachycardia will not occur upon standing)

Attitudes
- Display integrity when identifying those interventions that were not successful
- Be independent when redesigning successful hospital-based interventions for the home care setting

FIGURE 42-19 Critical thinking model for fluid, electrolyte, and acid-base balances evaluation.

SAFETY GUIDELINES FOR NURSING SKILLS

Ensuring patient safety is an essential role of the professional nurse. To ensure patient safety, communicate clearly with members of the health care team, assess and incorporate the patient's priorities of care and preferences, and use the best evidence when making decisions about your patient's care. When performing the skills in this chapter, remember the following points to ensure safe, individualized patient care:

- Check that you have the necessary information, a health care provider's order if required, and equipment available for the procedure before beginning.
- Before initiation of therapy, check patient identification using two patient identifiers (TJC, 2016) and assess the appropriate route and rate of infusion and potential incompatibilities between infusing fluids and medications (INS, 2011).
- Determine if the patient has a latex allergy and use nonlatex items if allergy is present (INS, 2011).

- Use special designated tubing for the brand of EID and for blood transfusions and some medications.
- Review the steps of the procedure mentally before entering a patient's room (i.e., consider modifications that you may need to make for this specific patient and verify that the type of IV solution is appropriate for this patient).
- Maintain strict aseptic and sterile techniques when required and sterility and integrity of the IV system to prevent bloodstream infections (INS, 2011).
- If you contaminate a sterile object during the procedure, do not use it. Use a new sterile one.
- Use standard body fluid precautions during procedures and place all disposable blood-contaminated items and sharp items in designated puncture-resistant biohazard containers (INS, 2011).

SKILL 42-1	INITIATING INTRAVENOUS THERAPY

DELEGATION CONSIDERATIONS

The skill of initiating peripheral intravenous (IV) therapy cannot be delegated to nursing assistive personnel (NAP). Delegation to licensed practical nurses (LPNs) varies by state Nurse Practice Act. Instruct the NAP to inform you if:

- Patient indicates burning, bleeding, swelling, or coolness at the catheter insertion site.
- An intravenous (IV) dressing becomes wet or loose.
- Electronic infusion device (EID) alarm signals.
- Fluid container is almost empty.

EQUIPMENT

- Agency-approved vascular access device (VAD) for venipuncture such as an over-the-needle catheter of appropriate gauge, depending on vein size; for continuous fluid infusions: peripheral 20-gauge catheter for an adult, 22-gauge for older adults and children (Alexander et al., 2014)
- IV start kit (available in some agencies)—contains a sterile drape to place under patient's arm, tourniquet, cleaning and antiseptic preparations, sterile dressings, and a small roll of sterile tape
- If IV kit not available:
  - Disposable drape or towel
  - Tourniquet (Determine type of tourniquet on basis of patient assessment [e.g., blood pressure [BP] cuff—older adult, rubber band—infants]. Use single-use tourniquets to prevent transfer of microorganisms between patients.) (Alexander et al., 2014)
  - Antiseptic swabs (2% chlorhexidine preferred) (INS, 2011)]
  - Transparent dressing or, less commonly, 2×2 or 4×4 gauze sponge
  - Nonallergenic tape and sterile tape
- Local anesthetic (e.g., intradermal lidocaine, topical transdermal anesthetic, vapocoolant) *(optional)*
- Short extension tubing with fused or separate needleless connector (also called *saline lock, heparin lock, IV plug, injection cap, prn adapter, buff cap,* or *buffalo cap)*
- Prefilled 5-mL syringe with flush agent (preservative-free sterile 0.9% sodium chloride (normal saline) for adults) (INS, 2011)
- Manufactured catheter stabilization device (e.g., STATLOCK), if available (INS, 2011). (see Figure 42-17)
- Personal protective equipment: clean gloves, goggles, mask *(optional,* check agency policy)
- Patient gown with snaps at shoulder seams if available
- Needle disposal container (sharps container) **For continuous IV fluid infusion, in addition to previous equipment:**
  - Correct type and amount of IV fluid
  - EID
- IV tubing administration set with tubing specific for type of EID
- If using gravity-flow, use microdrip tubing for small or very precise volumes and macrodrip tubing to infuse fluid more rapidly.
  - In-line filter if particulate matter is likely or long-term or high-volume IV therapy is expected or required by agency policy; size appropriate to type of solution (e.g., 0.22 micron for nonlipid solution, 1.2 microns for lipid solution)
  - Long extension tubing if desired for patient mobility
  - IV pole, rolling, ceiling mounted, or attached to bed
  - Bar-code scanner, if using bar-code system

STEP	RATIONALE

ASSESSMENT

1. Review accuracy and completeness of health care provider's order for patient name, type and amount of IV fluid, medication additives, infusion time, and purpose of infusion. Follow six rights of medication administration (see Chapter 32).	Ensures that correct IV fluid is administered.

CLINICAL DECISION: *In most institutions health care providers do not write orders to "initiate peripheral access" or "perform venipuncture." The statement "Start IV" usually is written followed by the exact IV therapy order. The order to perform the venipuncture is implied. If the order is confusing or in question, clarify with the health care provider before proceeding.*

2. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy. Compare identifiers with information on patient's MAR or medical record.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
3. Assess for clinical variables that respond to or are affected by IV fluid administration:	Provides baseline to determine effect that IV fluids have on patient's fluid and electrolyte balance.

SKILL 42-1	INITIATING INTRAVENOUS THERAPY—cont'd

STEP	RATIONALE
a. Body weight	Daily weights reflect fluid retention or loss. A 1-L amount of fluid weighs 2.2 lbs (1 kg). Compare with previous day's weight if available. Gain or loss of 2 lbs (1 kg) in 24 hours indicates gain or loss of 1 L of fluid. Body fat gain or loss takes longer.
b. Clinical markers of vascular volume:	Assess signs and symptoms as a group to interpret them accurately. Infusion of Na^+-containing IV fluid expands extracellular fluid volume (ECV) (vascular and interstitial).
(1) BP	Decreased BP or orthostatic hypotension may indicate ECV deficit caused by decreased stroke volume. Increased BP may indicate ECV excess.
(2) Pulse	Baroreceptor response causes rapid, thready pulse with ECV deficit; bounding, full pulse with ECV excess.
(3) Fullness of neck veins (normally neck veins are full when person is supine and flat when person is upright or semi-upright)	Indicator of fluid volume status: flat or collapsing with inhalation when supine with ECV deficit; full or distended when upright or semi-upright with ECV excess.
(4) Capillary refill	Provides an indirect measure of tissue perfusion. Can indicate poor tissue perfusion (sluggish with ECV deficit).
(5) Auscultation of lungs	Crackles or rhonchi in dependent lobes of lung may signal fluid buildup in lungs caused by ECV excess.
(6) Urine output (decreased; dark yellow with ECV deficit)	Kidneys respond to ECV deficit by reducing urine production and concentrating the urine. Average daily adult urine output is 1500 mL; oliguria is urine output of less than 400 mL/24 hr. Kidney disease and syndrome of inappropriate antidiuretic hormone (SIADH) also can cause oliguria. Dark yellow indicates concentrated urine.
c. Clinical markers of interstitial volume:	Assess signs and symptoms as a group to interpret them accurately. Infusion of Na^+-containing IV fluid expands ECV (vascular and interstitial).
(1) Dependent edema (rate severity by assessing pitting over bony prominences (i.e., 1+ indicates barely detectable edema; 4+ indicates deep persistent pitting) (see Chapter 31).	Edema, indicating expanded interstitial fluid volume, is most evident in dependent areas bilaterally (i.e., feet and ankles if sitting) or sacrum if bedfast.
(2) Oral mucous membranes between cheek and gum	More reliable indicator than dry lips or skin. Dry between cheek and gums indicates ECV deficit.
(3) Skin turgor (pinch skin over sternum or inside of forearm) (Failure of skin to return to normal position within 3 seconds indicates ECV deficit.)	Pinched skin that stays elevated for several seconds is called *poor skin turgor* or *"tenting."* May occur from ECV deficit, rapid weight loss, or normal aging.
d. Thirst	Occurs with hypernatremia and severe ECV deficit. Not a reliable indicator for older adults because thirst sensation decreases with age (Touhy and Jett, 2014).
e. Behavior and level of consciousness	
(1) Restlessness and mild confusion	Occurs with severe ECV deficit caused by lack of blood flow to brain.
(2) Decreased level of consciousness (lethargy, confusion, coma)	May occur with osmolality imbalances (hyponatremia and hypernatremia) and acid-base imbalances.
f. Cardiac signs of electrolyte or acid-base imbalances (e.g., irregular pulse and electrocardiogram [ECG] changes)	Rhythm and ECG changes may occur with K^+, Ca^{2+}, Mg^{2+}, and/or acid-base imbalances. Should improve as IV fluid replaces deficient electrolytes or occur if electrolyte infusion is excessive.
4. Assess patient's previous experience with and perceptions of IV therapy, understanding of purpose of IV therapy, and arm placement preference.	Provides patient-centered care by determining level of emotional support and instruction necessary. If patient is apprehensive about venipuncture, use a local anesthetic.
5. Obtain information from approved online database, drug reference book, or pharmacist about composition of IV fluids, purposes of administration, potential incompatibilities, side effects, monitoring guidelines, and need for special catheter or tubing for administration.	Allows detection of an inadvisable IV fluid order and helps to determine priority assessments.
6. Determine if patient is to undergo any planned surgeries or procedures.	Allows anticipation and placement of appropriate VAD and gauge for fluid infusion and avoids placement in an area that will interfere with medical procedures.
7. Assess for following risk factors: child or older adult; presence of heart failure or oliguric renal disease; skin lesions or infection near potential venipuncture sites; low platelet count or patient receiving anticoagulants.	Older adults have proportionately less body water; people with heart failure cannot adapt to sudden increases in vascular volume; and people with oliguria cannot eliminate excess extracellular fluid, K^+, or Mg^{2+}. Skin lesions or infection influence choice of access site. Low platelet count or anticoagulant use increases patient's risk for bleeding from VAD site and seepage of blood from puncture site during venipuncture.
8. Assess laboratory electrolyte or acid base balance data.	Helps determine priority assessments, establishes baseline for determining if therapy is effective, and may allow detection of an inadvisable fluid order.

STEP	RATIONALE

CLINICAL DECISION: *If the current K^+, Ca^{2+}, or Mg^{2+} serum values are high, clarify order with health care provider before administering an IV solution containing the elevated electrolyte to avoid worsening the electrolyte excess.*

STEP	RATIONALE
9. Assess patient's history of allergies, especially to iodine, adhesive, or latex.	Equipment used during insertion of VAD may contain substances to which patient is allergic. Use alternatives if patient has allergy.
10. Assess patient's medical history for chronic illnesses and all prescribed and over-the-counter medications.	Reveals background information that might cause adverse effects on patient (e.g., heart failure may require slower infusion rate) or conflict with prescribed therapy such as drug-drug interactions.

PLANNING

STEP	RATIONALE
1. Collect appropriate equipment. Be sure that you have the correct infusion set for the EID that will be used. If the IV container is rigid rather than collapsible, you need a vented spike on the IV tubing.	Provides patient safety.
2. Explain to patient and family the rationale for IV fluids and medications, procedure for initiating an IV infusion, signs and symptoms of complications, what is expected of patient, and which sensations patient should expect.	Cognitive and sensory information decreases anxiety and helps promote cooperation.
3. Help patient to comfortable sitting or supine position. Position a chair so you are level with patient. Provide adequate lighting.	Promotes comfort and relaxation for patient. Provides proper body mechanics for nurse. Aids in successful vein location.

IMPLEMENTATION

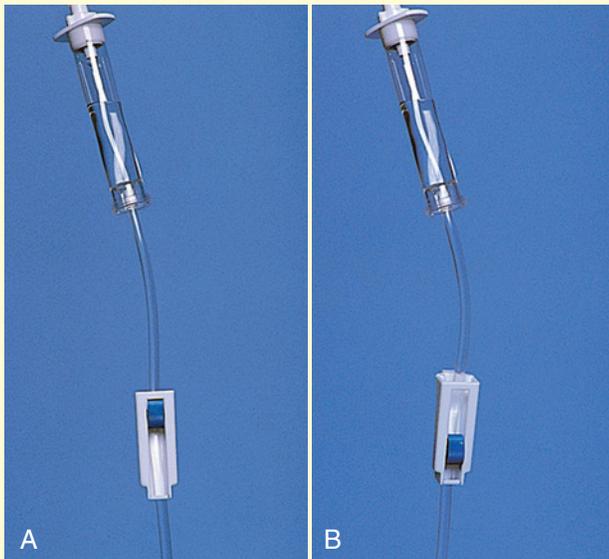
STEP	RATIONALE
1. Perform hand hygiene. Organize equipment on clean, clutter-free bedside stand or over-bed table.	Reduces transmission of infection and risk of accidents.
2. Change patient's gown to more easily removable gown with snaps at shoulder if available.	Use of a special IV gown makes gown removal easier and protects VAD site from trauma during gown changes.
3. Open sterile packages using sterile aseptic technique (see Chapter 29).	Maintains sterility of equipment and reduces spread of microorganisms.
4. *Option:* Prepare short extension tubing with needleless connector or stand-alone saline lock (check agency policy and procedures) to attach to VAD catheter hub.	Short extension tubing prevents traction on VAD. Many agencies use short extension tubing for continuous infusions and stand-alone saline locks (capped catheters). Continuous infusion attaches to needleless connector on short extension tubing. Saline locks provide IV access when continuous IV infusions are not needed.
a. Remove protective cap from needleless connector and attach syringe with 1 to 3 mL 0.9% sodium chloride (normal saline), maintaining sterility. Slowly inject enough saline to prime (fill) short extension tubing and connector, removing all air. Leave syringe attached to tubing (see illustration).	Replaces air with normal saline, preventing air from entering patient's vein later during VAD insertion.
b. Maintain sterility of end of connector by reapplying end caps, and set aside for attaching to catheter hub after successful venipuncture.	Prevents touch contamination, which allows microorganisms to enter infusion equipment and bloodstream.
5. ***For continuous infusion:*** Prepare IV tubing and solution	
a. Check IV solution, using six rights of medication administration (see Chapter 32). If using bar-code system, scan bar code on patient's wristband and then on IV fluid container. Be sure that prescribed additives such as potassium or vitamins are included and noted on bag label. Check solution for color, clarity, and expiration date. Check bag for leaks.	IV solutions are medications and need to be checked carefully to reduce risk of error. Bar-code systems reduce medication errors by verifying right patient, medication, dose, route, and time with the electronic health record (EHR) (FitzHenry et al., 2013).
	Do not use solutions that are discolored, contain particles, or are expired. Do not use leaky bags because they present an opportunity for infection (INS, 2011).

STEP 4a Prime short extension tubing, leaving syringe attached.

SKILL 42-1	INITIATING INTRAVENOUS THERAPY—cont'd

STEP	RATIONALE
b. Open infusion set, maintaining sterility of both ends of tubing. **NOTE:** EIDs sometimes have a special dedicated administration set; follow manufacturer instructions.	Prevents touch contamination, which allows microorganisms to enter infusion equipment and bloodstream.
c. Removing appropriate end caps, attach extension tubing with injection port to distal end of infusion set, maintaining sterility of the connection. Do not touch point of entry of connection. Leave end cap on distal end of extension tubing.	Distal end of extension tubing with injection port attaches to IV catheter hub after venipuncture, providing greater ease of access and ability to change easily between continuous and intermittent IV infusion. Prevents touch contamination, which allows microorganisms to enter infusion equipment and bloodstream.
d. Place roller clamp of IV tubing approximately 2 to 5 cm (1 to 2 inches) below drip chamber and move it to closed position (see illustrations).	Close proximity of roller clamp to drip chamber allows more accurate regulation of flow rate. Closing clamp prevents accidental spillage of IV fluid on patient, nurse, bed, or floor.
e. Remove protective sheath from IV tubing port on plastic IV solution bag or top of IV solution bottle while maintaining sterility (see illustration).	Provides access for insertion of infusion tubing into solution while preventing touch contamination.
f. *Insert infusion set into fluid bag or bottle:* Remove protective cap from tubing insertion spike, not touching spike, and insert it into port of IV bag, using a twisting motion (see illustration). Cleanse rubber stopper on glass-bottled solution with single-use antiseptic and insert spike into rubber stopper of IV bottle.	Prevents contamination of IV solution during insertion of spike. Flat surface on top of bottled solution may contain contaminants, whereas opening to plastic bag is recessed.

CLINICAL DECISION: *Do not touch spike (it is sterile). If contamination occurs (e.g., you accidentally touch outside of bag with the spike or drop spike), discard that IV tubing and obtain a new one.*

STEP	RATIONALE
g. Compress drip chamber and release, allowing it to fill one-half full with infusion fluid (see illustration).	Creates suction effect; fluid enters drip chamber, which prevents air from entering tubing.
h. Prime tubing by filling with IV solution: Remove protector cap on end of tubing if necessary (you can prime some tubing without removing cap) and slowly open roller clamp to allow fluid to travel from drip chamber through tubing to distal end. Maintain sterility of the end. Return roller clamp to closed position after tubing is filled with IV fluid. Replace protective cap on end of tubing if you removed it.	Priming replaces air in tubing with IV solution so air does not enter patient's vein. Slow fill of tubing decreases turbulence and chance of bubble formation. Closing clamp prevents continued flow of IV fluid. Cap on end of tubing maintains system sterility.


STEP 5d A, Roller clamp in open position. **B,** Roller clamp in off or closed position.

STEP 5e Remove protective covering from IV solution tubing port.

STEP 5f Insert tubing spike into IV container.

STEP	RATIONALE
i. Be certain that tubing is clear of air and air bubbles. To remove small air bubbles, firmly tap tubing where they are located (see illustration). Check entire length of tubing to ensure that all air bubbles are removed. If using multiple-port tubing, turn ports upside down and tap to fill and remove air.	Tapping causes air bubbles to rise up to drip chamber. Large air bubbles may act as emboli (Cook, 2013).

CLINICAL DECISION: *Add long extension tubing to IV tubing to provide more length, which enables patient to move much more freely while still keeping IV line stable.*

STEP	RATIONALE
j. If using optional long extension tubing (not short extension tubing in Step 4), remove protective cap and attach it to distal end of IV tubing, maintaining sterility. Then prime the long extension tubing.	Priming replaces air in tubing with IV solution so air does not enter patient's vascular system.
k. Insert primed tubing into EID with power off.	Facilitates starting infusion as soon as IV site is ready.

CLINICAL DECISION: *You can apply gloves before or after assessing veins. You must apply them before VAD insertion.*

STEP	RATIONALE
6. Perform hand hygiene and apply clean gloves. Wear eye protection and mask (check agency policy) if splash or spray of blood is possible.	Reduces transmission of microorganisms. Prevents spraying of blood on nurse's mucous membranes.

CLINICAL DECISION: *According to INS (2011), the use of visualization technologies (ultrasound) aids in vein identification and selection. Use an ultrasound device if veins are difficult to visualize or palpate.*

STEP	RATIONALE
7. Apply tourniquet to begin vein selection around arm above antecubital fossa or 10 to 15 cm (4 to 6 inches) above proposed insertion site (see illustration). Do not apply it too tightly to avoid injury, bruising the skin, or occluding arterial flow. Check for presence of radial pulse. *Option a:* You may apply tourniquet on top of thin layer of clothing such as a gown sleeve to protect fragile or hairy skin. *Option b:* Use BP cuff instead of tourniquet. Inflate it to a level just below patient's normal diastolic pressure (less than 50 mm Hg).	Tourniquet needs to be tight enough to decrease venous return but not occlude arterial flow. If patient has fragile veins, apply tourniquet loosely or not at all to prevent damage to veins or bruising. Avoid using antecubital fossa for IV insertion because a VAD at this site limits mobility. Use of BP cuff reduces trauma to skin and underlying tissues.
8. Select vein for VAD insertion. Veins on dorsal and ventral surfaces of upper extremities (e.g., cephalic, basilic, and median veins) are preferred in adults (see Figure 42-15). **a.** Use most distal site in nondominant arm if possible.	Ensures adequate vein that is easy to puncture and less likely to rupture. Patients with VAD placement in their dominant hand have decreased ability to perform activities of daily living (ADLs). Performing venipuncture distal to proximal increases availability of other sites for future IV therapy (INS, 2011).

STEP 5g Squeeze drip chamber to fill with fluid.

STEP 5i Remove air bubbles from tubing.

STEP 7 Tourniquet placed on arm for initial vein selection.

SKILL 42-1	INITIATING INTRAVENOUS THERAPY—cont'd

STEP	RATIONALE

b. Select a well-dilated vein. Methods to foster venous distention include:
  (1) Place extremity in dependent position.
  (2) Apply warmth to extremity for several minutes (e.g., with a warm washcloth).
	Increased volume of blood in vein at venipuncture site makes vein more visible.
	Gravity promotes venous dilation.
	Increases blood in vein by causing dilation.

CLINICAL DECISION: *Vigorous friction and multiple tapping of a vein, especially in older adults, causes hematoma and/or venous constriction. Choose appropriate dilation method.*

STEP	RATIONALE

c. Select vein large enough for a VAD. Note: Sometimes you need to remove gloves to palpate vein.
d. With your index finger, palpate vein by pressing downward. Note resilient, soft, bouncy feeling while releasing pressure (see illustration).
e. Avoid vein selection in:
  (1) Area with tenderness, pain, infection, or wound.
  (2) Extremity affected by previous stroke (cerebrovascular accident [CVA]), paralysis, mastectomy, or dialysis graft.
  (3) Site distal to previous venipuncture site, sclerosed or hardened veins, infiltrate site or phlebotic vessels, bruised areas, or areas of venous valves.
  (4) Fragile dorsal veins in older-adult patients and vessels in an extremity with compromised circulation.
f. Choose a site that does not interfere with patient's ADLs, use of mobility aids such as a cane, or planned procedures. Clip arm hair with scissors if necessary (explain to patient).
	Prevents interruption of venous flow while allowing adequate blood flow around catheter.
	Fingertip is more sensitive and better for assessing vein location and condition.
	
	May indicate inflamed vein or increase risk of infection.
	Increases risk of complications such as lymphedema or vessel damage.
	
	Such sites cause infiltration around newly placed VAD site and excessive vessel damage.
	
	Small, fragile veins have increased risk of infiltration, hematoma from vessel rupture, and phlebitis from vessel damage.
	Keeps patient as mobile and independent as possible.
	Hair impedes venipuncture or adherence of dressing.

CLINICAL DECISION: *If hair removal is needed, do not shave area with a razor. Shaving may cause micro-abrasions that increase risk of infection (INS, 2011).*

STEP	RATIONALE
9. Release tourniquet temporarily and carefully. *Option:* At this point in procedure you may apply a local anesthetic to the planned insertion site; wait several minutes for it to take effect (see product directions). Monitor for allergic reaction. **10.** Apply clean gloves if not done in Step 6. **11.** Place distal end of short infusion tubing (prepared in Step 4) or adaptor end of saline lock nearby on sterile gauze, avoiding touch contamination. **12.** If area of insertion needs cleaning, use soap and water first and dry. Use antiseptic swab or applicator to clean insertion site, using friction in a horizontal plane with first swab, in a vertical plane with second swab, and in a circular motion moving outward with third swab (see illustration). Allow to dry completely. Refrain from touching clean site unless using sterile technique.	Restores blood flow and prevents venospasm while preparing for venipuncture. Local anesthetic reduces insertion pain (Ganter-Ritz et al., 2012). Reduces transmission of microorganisms. Permits smooth, quick connection to VAD after accessing vein. Prevents microorganisms from entering infusion equipment and bloodstream. Mechanical friction penetrates antiseptic solution into cracks and fissures of the skin. Allowing antiseptic solution to air-dry completely reduces microbial counts and risk of phlebitis. Chlorhexidine 2% preparation is preferred (INS, 2011; O'Grady et al., 2011). If your fingers touch clean area, you have introduced microorganisms from your gloves, and you must clean it again (Alexander et al., 2014).

STEP 8d Palpate vein for resilience.

STEP 12 Cleanse site with chlorhexidine.

STEP	RATIONALE
13. Reapply tourniquet or BP cuff 10 to 12 cm (4 to 6 inches) above anticipated insertion site or keep BP cuff inflated <50 mm Hg until venipuncture completed. Check presence of distal pulse.	Diminished arterial flow prevents venous filling. The pressure of the tourniquet causes vein to fill and dilate.
14. Perform venipuncture. Anchor vein by placing thumb over it and stretching skin against direction of insertion 4 to 5 cm (1½ to 2 inches) distal to site (see illustration).	Stabilizes vein for needle insertion. Places VAD parallel to vein.
a. Warn patient of sharp, quick stick.	Prepares patient to avoid movement of extremity during venipuncture.
b. Insert VAD with bevel up at 10- to 30-degree angle slightly distal to actual site of venipuncture in direction of vein (see illustration).	Places needle at optimal angle to vein to reduce risk of puncturing posterior vein wall when entering vein. Superficial veins require smaller insertion angle. Deeper veins require greater angle.

CLINICAL DECISION: *Use each VAD only once for each insertion attempt. If you need to try again, use a new VAD for patient safety and protection from infection.*

---

15. Observe for blood return in flashback chamber of catheter, indicating that needle has entered vein (see illustration A). Lower catheter until almost flush with skin. Advance catheter approximately ¼ inch (0.6 cm) into vein and loosen stylet. Continue to hold skin taut and advance catheter into vein until hub is near venipuncture site (see illustration B). *Do not reinsert stylet once it is loosened.* Advance catheter while safety device automatically retracts stylet. (Techniques for retracting stylet vary with different VADs.) Follow manufacturer guidelines for specific safety catheter use. Place stylet directly into sharps container.	Increased venous pressure caused by tourniquet increases backflow of blood into catheter or tubing.
	Allows for full penetration of vein wall, placement of catheter in vein lumen, and advancement of catheter off stylet. Reduces risk of introduction of infectious microorganisms along catheter.
	Advancing entire stylet into vein may penetrate posterior vein wall, causing hematoma.
	Reinsertion of stylet can cause catheter shearing and potential catheter embolization (INS, 2011).
	Proper sharps disposal prevents needlestick injury (OSHA, 2012).

STEP 14 Stabilize vein below insertion site.

STEP 14b Puncture vein with catheter at a 10- to 30-degree angle. Catheter enters vein.

STEP 15 A, Look for blood return in flashback chamber. **B,** Advance catheter into vein until hub is near insertion site.

SKILL 42-1	INITIATING INTRAVENOUS THERAPY—cont'd

STEP	RATIONALE

CLINICAL DECISION: *Each nurse should make no more than two attempts at initiating IV access (INS, 2011).*
If you are not successful with two attempts, have another nurse attempt the insertion.

16. Stabilize catheter with nondominant hand and release tourniquet or BP cuff with other. Apply gentle but firm pressure with middle finger of nondominant hand 3 cm (1¼ inches) above insertion site. Keep catheter stable with index finger.	Permits venous flow. Pressure with finger on vein reduces backflow of blood and allows connection with short extension tubing or saline lock with minimal blood loss (INS, 2011).
17. Quickly connect distal end of primed short extension tubing from Step 11 or end of a prepared saline lock from Step 4 to catheter. Do not touch point of entry of connection. Secure connection.	Prompt connection of infusion set maintains patency of vein and prevents risk for exposure to blood. Maintains sterility.
18. If saline lock is attached, gently flush catheter with attached saline syringe to ensure that site is patent (see illustration). Observe for swelling at site while flushing. Then remove syringe.	Provides patient safety by not beginning infusion if site is not patent. Swelling during flush indicates infiltration, and site must be discontinued.
19. For continuous infusion, attach distal end of IV tubing to needleless connector on short extension tubing that is attached to catheter (see illustration). Turn on EID, program it, and begin infusion at correct rate (see Skill 42-2). If using gravity flow instead of EID, begin infusion by slowly opening roller clamp to regulate rate.	Initiates flow of fluid through IV catheter, preventing clotting of device.

CLINICAL DECISION: *Be sure to calculate rate (see Skill 42-2) and set EID correctly to infuse IV solution at prescribed rate.*

20. Observe insertion site for swelling.	Swelling indicates infiltration, which requires immediate catheter removal.
21. Secure catheter and apply sterile dressing over site (procedures differ; follow agency policy).	Prevents accidental dislodgement of catheter and protects site from infection.
a. *Manufactured catheter stabilization device:* Wipe selected area with single-use skin protectant and allow to dry completely (10-15 seconds). Apply sterile adhesive strip over catheter hub. Place retainer over tubing end just behind spin nut. Peel off half of liner; press to adhere to skin. Repeat on other side (see Figure 42-17). Then apply dressing.	A manufactured catheter stabilization device holds the catheter in place, improving patient outcomes by reducing risk of catheter dislodgement, phlebitis, and other complications (INS, 2011).

STEP 18 Flush catheter gently to ensure patency.

STEP 19 Connect IV tubing to short extension set that is attached to catheter.

STEP	RATIONALE
b. *Transparent dressing:* Continue to secure catheter with nondominant hand.	Prevents accidental dislodgement of catheter.
(1) Remove adherent backing. Apply one edge of dressing and gently smooth remaining dressing over IV site, leaving connection between IV tubing and catheter hub uncovered. Remove outer covering and smooth dressing gently over site (see illustration).	Occlusive dressing protects site from bacterial contamination. Connection between administration set and hub needs to be uncovered to facilitate changing tubing if necessary.
(2) After applying the transparent dressing, secure catheter by placing a 2.5-cm (1-inch) piece of transparent tape over extension tubing or administration set. Do not apply tape on top of transparent dressing.	Removal of tape from transparent dressing might cause accidental dislodgement of catheter.
	Tape on top of transparent dressing prevents moisture from being carried away from skin.
c. *Sterile gauze dressing:* If manufactured catheter stabilization device is not used, secure catheter by placing a narrow piece ($\frac{1}{2}$ inch) of sterile tape over catheter hub (see illustration). Place sterile tape only on hub, *never* over insertion site. Secure site for easy visualization. Avoid applying tape or gauze around arm.	Less frequently used than transparent dressing.
	Prevents accidental removal of catheter from vein. Prevents back-and-forth motion, which can irritate vein and introduce microorganisms on skin into vein. Sterile tape prevents site contamination.
	Wrapping anything around arm compresses veins or prevents visualization of insertion site.
(1) Place 2 × 2 gauze pad over insertion site and catheter hub. Secure all edges with tape (see illustration). Do not cover connection between IV tubing and catheter hub.	Secure dressing is less likely to allow entrance of microorganisms.
(2) *Option:* Fold 2 × 2 gauze pad in half and cover with a 2.5 cm (1 inch)–wide tape extending about an inch from each side. Place under tubing/catheter hub junction.	Tape on top of gauze makes it easier to access hub/tubing junction. Gauze pad elevates hub off skin to prevent pressure area.

STEP 21b(1) Apply transparent dressing.

STEP 21c Apply tape over catheter hub.

STEP 21c(1) Place 2 × 2–inch gauze over insertion site and catheter hub.

SKILL 42-1	INITIATING INTRAVENOUS THERAPY—cont'd

STEP	RATIONALE

CLINICAL DECISION: *Think carefully about where you place tape. Do not apply it over the catheter insertion site, over the connection between the tubing or port and the IV catheter hub, or on top of the transparent dressing.*

STEP	RATIONALE
22. Curl loop of tubing alongside arm and place second piece of tape directly over tubing to secure it (see illustration).	Securing loop of tubing reduces risk of dislodging catheter if IV tubing is pulled (i.e., loop comes apart before catheter dislodges).
23. For continuous infusion, check ordered rate of infusion programmed into EID and be sure that it is functioning properly. If using gravity-flow IV infusion, recheck flow rate to correct drops per minute (see Skill 42-2).	Manipulation of catheter during dressing application may alter flow rate. Check flow rate to maintain accurate administration of IV fluids. Flow can fluctuate; thus it must be checked at intervals for accuracy.
24. Label dressing per agency policy. Include date and time of IV insertion, VAD gauge and length, and your initials (see illustration).	Provides immediate access to data regarding when IV was inserted and when to rotate site.
25. Dispose of used stylet or other sharps in appropriate sharps container if not done previously. Discard supplies. Remove gloves and perform hand hygiene.	Reduces transmission of microorganisms, prevents accidental injuries, and follows guidelines for disposal of sharps (OSHA, 2012).
26. Teach patient how to move or turn without dislodging VAD.	Prevents accidental dislodgement of catheter.

EVALUATION

1. Observe patient every 1 to 2 hours.	Allows you to confirm integrity of IV site and system.
a. Check that correct amount of IV fluid has infused by observing fluid level in IV container.	Administration of prescribed amount of fluid maintains or restores fluid balance.
b. Check rate on EID or count drip rate (if gravity drip).	Accurate monitoring of rate further ensures administration of correct amount of fluid.
c. Check patency of VAD.	Flow rate slows or stops if catheter becomes partially occluded or obstructed.

CLINICAL DECISION: *If IV line is positional, fluid runs quickly, slowly, or stops, depending on position of patient's arm. Instruct patient to position arm to maintain flow; if this continues, consider restarting IV in another site.*

d. Observe patient during palpation of vessel for signs of discomfort.	Tenderness is an early sign of phlebitis.
e. Inspect insertion site, note skin color (e.g., redness, pallor). Inspect for presence of swelling, infiltration (see Table 42-13), and phlebitis (see Table 42-14). Palpate temperature of skin above dressing.	Redness, tenderness, and warmth indicate vein inflammation or phlebitis. Swelling above insertion site and cool temperature often indicate infiltration of fluid into tissues.
2. Change peripheral IV access per agency policy, per health care provider's orders, or immediately on suspected contamination or complication.	INS standards recommend VAD replacement and site rotation when clinically indicated rather than at set intervals (INS, 2011).
3. Observe patient to determine response to therapy (e.g., measure intake and output [I&O], daily weights, vital signs).	IV fluids and additives are administered to maintain or restore fluid and electrolyte balance. Early recognition of complications leads to prompt treatment.
4. Use **Teach Back** to determine patient's and family's understanding about IV therapy. State, "I want to be sure I explained the reason that you have this IV. Can you explain why you have the IV?" Revise your instruction now or develop plan for revised teaching if patient or family is not able to teach back correctly.	Evaluates what patient is able to explain or demonstrate.

STEP 22 Curl a loop of the short or long intravenous tubing alongside the arm. Secure tubing.

STEP 24 Label IV dressing.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Overload of IV solution, infiltration, phlebitis, local infection, and bleeding at venipuncture site
   - See Table 42-12.
2. Lack of effectiveness of IV therapy for ECV
   - Notify patient's health care provider, providing baseline and current heart rate and BP and length of time IV has been infusing; adjust infusion rate or type of IV solution as ordered.
   - Be prepared to draw blood for laboratory testing.

RECORDING AND REPORTING

- Document in nurses' notes or other designated location in an electronic health record (EHR) date and time of insertion; number and sites of attempts, precise description of insertion site (e.g., cephalic vein on dorsal surface of right lower arm, 2.5 cm above wrist); catheter gauge, type, length, and brand; type of dressing and catheter stabilization; flow rate; type of infusion, EID use, and your identity (INS, 2011). If using bar-code system, fluid type and time record automatically.
- Record patient's status, IV fluid, amount infused, and integrity and patency of system.
- Document your evaluation of patient learning.
- Report to oncoming nursing staff: type of fluid, flow rate, status of VAD, amount of fluid remaining in present container, expected time to hang subsequent IV container, and patient condition.
- Report to health care provider any adverse reactions.

HOME CARE CONSIDERATIONS

- Ensure that patient is able and willing to self-administer IV therapy or that a reliable family caregiver will provide IV therapy at home.
- Teach patient and family caregiver information needed to administer IV therapy safely (see Box 42-8). Consider their cultural norms (e.g., health beliefs and comfort with caregivers using touch) (Petroulias et al., 2013).

SKILL 42-2	REGULATING INTRAVENOUS FLOW RATE	

DELEGATION CONSIDERATIONS

The skill of regulating intravenous (IV) flow rate cannot be delegated to nursing assistive personnel (NAP). Instruct the NAP to inform you if:
- Patient indicates burning, bleeding, swelling, or coolness at catheter insertion site.
- Electronic infusion device (EID) alarm signals.
- Fluid container is almost empty.

EQUIPMENT
- EID, IV pump
- Watch with second hand
- Calculator or paper and pen/pencil
- Tape
- Label
- Clean gloves

STEP	RATIONALE
ASSESSMENT	
1. Review accuracy and completeness of health care provider's order for patient name, type, and amount of IV fluid, medication additives, infusion time, and purpose of infusion. Follow six rights of medication administration (see Chapter 32).	Ensures administration of correct IV fluid at proper rate. IV fluids are medications. The six rights prevent medication administration error.
2. Perform hand hygiene and apply clean gloves.	Prevents transmission of microorganisms.
3. Observe for patency of IV tubing and vascular access device (VAD).	For fluid to infuse at proper rate, IV line and VAD must be free of kinks, knots, and clots.
4. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy. Compare identifiers with information on the patient's MAR or medical record.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
5. Inspect IV site and verify with patient how existing IV feels (e.g., determine if any tenderness, pain, or burning exists).	Tenderness, pain, or burning may be early indication of phlebitis. Includes patient in own care.
6. Assess patient's knowledge of how positioning of IV site affects flow rate.	Fosters patient participation in maintaining most effective position of arm with IV equipment.
7. Assess patient risk for fluid and electrolyte imbalance, given type of IV fluid (e.g., neonate, cardiac or kidney disease)	Helps prioritize nursing assessments.

SKILL 42-2	REGULATING INTRAVENOUS FLOW RATE—cont'd

STEP	RATIONALE

PLANNING

1. Gather paper and pencil or calculator to calculate flow rate.

   Use accurate mathematical calculations to obtain correct rate for patient safety.

2. Check order to see how long each liter of fluid should infuse. If hourly rate (mL/hr) is not provided in order, calculate it by dividing volume by hours. For example:

   Provides even infusion of fluid over prescribed hourly rate. A volume of $1\ L = 1000\ mL$.

$$mL/hr = \frac{Total\ infusion\ volume\ (mL)}{Hours\ of\ infusion}$$

1000 mL/8 hr = 125 mL/hr

or if 3 L is ordered for 24 hours,

3000 mL/24 hr = 125 mL/hr

CLINICAL DECISION: *It is common for health care providers to write an abbreviated IV order such as "D_5W with 20 mEq KCl 125 mL/hr continuous." This order implies that IV infusion should be maintained at this rate until an order has been written for IV infusion to be discontinued. Occasionally an IV order calls for 1 L "TKO" (to keep open) or "KVO (keep vein open)," either of which means at a slow rate to keep vein open. Clarify with the provider if any part of the order is unclear.*

---

3. If KVO (or TKO) rate is ordered, check agency policy regarding flow rate. KVO often falls in the range of 10 to 25 mL/hr.

   KVO rate prevents catheter clotting, thus preserving venous access while infusing a minimal amount of fluid.

4. Use hourly rate to program electronic infusion device (EID) (see Implementation) or, if gravity-flow infusion, use to calculate minute flow rate (gtt/min).

   EID automatically delivers correct minute flow rate. Gravity infusion requires nurse calculation.

5. Calculate minute flow rate for gravity-flow infusion:

   Use microdrip tubing when infusing small or very precise volumes. Use macrodrip tubing to infuse fluid more rapidly.

   a. Determine drop factor (calibration) in drops per milliliter (gtt/mL) of infusion set currently in use:
   Microdrip: 60 gtt/mL
   Macrodrip: 10 or 15 gtt/mL; see label on administration set packaging.

   Drop factor for macrodrip tubing varies with manufacturer.

   b. Select one of the following formulas to calculate minute flow rate (drops/min) based on drop factor of infusion set:

   Formulas compute correct flow rate over a minute.

   (1) mL/hr/60 min = mL/min
   Drop factor × mL/min = gtt/min
   Or
   (2) mL/hr × drop factor/60 min = gtt/min
   Using formula (2) above, calculate minute flow rate for an IV solution that should infuse at 125 mL/hr:
   Microdrip:
   125 mL/hr × 60 gtt/mL = 7500 gtt/hr
   7500 gtt ÷ 60 minutes = 125 gtt/min

   When using microdrip, mL/hr always equals gtt/min.

   Macrodrip:
   125 mL/hr × 15 gtt/mL = 1875 gtt/hr
   1875 gtt ÷ 60 minutes = 31-32 gtt/min

   Multiply hourly rate (mL/hr) by drop factor and divide product by 60 to convert hours to minutes.

IMPLEMENTATION

1. Using an EID (infusion pump or smart pump):

   Smart pumps with medication safety software are designed for administration of IV fluid that contains medications.

   a. Consult manufacturer directions for setup of infusion. Use tubing compatible with EID.

   Special infusion tubing is required for most EIDs. It is designed to prevent free flow of fluid when tubing is removed from device. Check agency equipment and associated policies and procedures.

STEP	RATIONALE
b. Close roller clamp on primed IV tubing and insert tubing into chamber of EID control mechanism or pump module per manufacturer directions (see illustration). Roller clamp on IV tubing goes between EID and patient.	Most electronic infusion pumps use positive pressure to infuse. They move fluid through IV tubing by compressing and milking tubing.
c. Turn on EID power; test alarm; select required volume per hour, volume to be infused (VTBI), and any other information required. Close control chamber door if not already done and press run/start button. If smart pump alarms immediately and shuts down, your settings were outside unit parameters. Recalculate infusion rate and set EID again.	Program EID per manufacturer instructions for patient safety. Smart pumps require additional information such as patient unit and medication. They contain a computer that matches pump setting against a drug dose database (Harding, 2013). If your setting does not match database, pump alarms and automatically shuts down for patient safety.
d. Open roller clamp completely while EID is in use.	Ensures that EID regulates infusion rate.
e. Check intermittently (hourly for adults, more frequently for pediatric patients) to see that correct amount of IV fluid has infused by observing fluid level in IV container.	EIDs do not replace frequent, accurate nursing evaluation. They may continue to infuse IV fluids even after an infiltration or other complication.
f. Assess patency of system if EID alarm signals.	Alarm indicates problem in system. An empty solution container, kinked tubing, air in tubing, closed clamp, infiltration, clotted catheter, and/or low battery all trigger EID alarm.
2. Using gravity flow:	
a. Ensure that IV container is 36 inches above IV site for adults.	Pressure caused by gravity is necessary to overcome venous pressure and resistance from tubing and catheter.
b. Slowly open roller clamp on tubing until you can see drops in drip chamber. Hold a watch with second hand at same level as drip chamber and count drip rate for 1 minute (see illustration). Adjust roller clamp to increase or decrease drip rate until you obtain desired number of drops per minute.	Regulate to prescribed rate of fluid infusion.
c. Monitor drip rate at least hourly.	Many factors influence drip rate; frequent monitoring ensures IV fluid administration as prescribed.
3. Attach piece of tape or label to IV fluid container with date and time of container change (check agency policy). If using polyvinylchloride (PVC) container, mark only on label and not container.	Provides reference to determine next time for container change, especially with KVO rate. Ink may leak into IV fluid through PVC container.
4. Instruct patient to avoid raising arm with IV line because it can affect flow rate; to avoid touching control clamp or other equipment; and about purpose of EID alarms.	Provides information so patient does not alter infusion rate. Ask patient to instruct family if appropriate.
5. Remove and discard gloves, perform hand hygiene.	Reduces transmission of microorganisms.

STEP 1b Insert IV tubing into chamber of control mechanism of electronic infusion device.

STEP 2b Nurse counting drip rate on gravity-flow infusion.

STEP 3b Open regulator clamp to fill volume-control device.

SKILL 42-2	REGULATING INTRAVENOUS FLOW RATE—cont'd

STEP	RATIONALE

EVALUATION

1. Monitor IV infusion at least every hour, noting volume of IV fluid infused and rate.	Ensures that correct volume infuses over prescribed time period.
2. Observe patient for signs of overhydration or dehydration to determine response to therapy and restoration of fluid balance.	Signs and symptoms of new overhydration or continued dehydration warrant changing rate of fluid infused. Contact health care provider for new infusion rate order.
3. Evaluate for signs of infiltration, inflammation at site, kink or knot in infusion tubing, or occluded VAD.	Prevents or identifies conditions that decrease or stop flow rate.
4. Use *Teach Back* to determine patient's and family's understanding about arm position. State, "I want to be sure I explained how your arm position can affect the IV flow. Can you show me a correct arm position?" Revise your instructions now or develop a plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient is able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Sudden infusion of large fluid volume of solution. Patient has symptoms of dyspnea, crackles in lungs, and increased urinary output, indicating fluid overload.
  • Temporarily slow infusion rate to 10 gtt/min; notify health care provider.
  • Place patient in high-Fowler's position.
  • See Table 42-12.
2. IV fluid container empties with subsequent loss of VAD patency.
  • Discontinue present IV infusion and start new IV line in other extremity or proximal to previous insertion site.
3. IV fluid infuses slower than prescribed.
  • Check for positional change that might affect rate, EID malfunction (or insufficient height of IV fluid container with gravity flow), kinking or obstruction of tubing, infiltration, or other complications at VAD site.
  • Consult health care provider for new order to provide necessary fluid volume.

RECORDING AND REPORTING

  • Record rate of infusion in milliliters per hour (or drops per minute with gravity flow) in designated location in patient's medical record.
  • Document use of EID.
  • Immediately record any new IV fluid rate.
  • At change of shift or when leaving on break, report rate and volume left of infusion to nurse in charge or next nurse assigned to care for patient.
  • Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

  • Ensure that patient or family caregiver is able and willing to operate infusion pump and administer IV therapy. Assess for any visual or physical limitations with ability to connect and disconnect infusion therapy and problem solve infusion pump malfunction (Alexander et al., 2014).
  • Home care nurse should be in the home during initiation of infusion therapy to ensure correct pump settings for solution, rate, time, and alarms. The nurse ensures that EID functions properly before use and that patient's electrical outlets are properly grounded.
  • Provide a 24-hour access telephone number for patient to call for assistance.

SKILL 42-3	MAINTENANCE OF INTRAVENOUS SYSTEM

DELEGATION CONSIDERATIONS

The skills of changing an intravenous (IV) fluid container and tubing cannot be delegated to nursing assistive personnel (NAP). Instruct the NAP to:

- Watch for appropriate position of patient to avoid kinking of intravenous IV tubing and injury at insertion site.
- Report when the IV fluid container is nearly empty.
- Report any leakage that occurs from or around the IV site.
- Report observations of changes in patient's temperature or signs and symptoms of IV-related complications such as pain or tenderness around IV site.

EQUIPMENT

Changing an IV fluid container and tubing (continuous infusion)

- Clean gloves
- Correct type and volume of IV solution
- Infusion tubing
- Tape or tubing label
- Pen
- Filter (size appropriate to solution) and extension tubing (if necessary)
- Manufactured catheter stabilization device if available
- Handheld bar-code scanner if using bar-code system

Changing an IV fluid container and tubing (intermittent infusion or saline lock)

- Correct type and volume of IV solution
- Infusion tubing
- Tape or tubing label
- Pen
- Prefilled 5-mL syringe with flush agent (preservative-free sterile 0.9% sodium chloride (normal saline) for adults) (INS, 2011).
- Sterile 2 × 2 gauze pads (optional)
- Clean gloves
- Antiseptic swab (chlorhexidine 2% preferred [INS, 2011])
- Handheld bar-code scanner if using bar-code system

Discontinuing peripheral IV access

- Clean gloves
- Sterile 2 × 2 or 4 × 4 gauze pad
- Antiseptic swab (chlorhexidine 2% preferred [INS, 2011])
- Tape

STEP	RATIONALE

ASSESSMENT

1. Changing IV fluid container:

   a. Review accuracy and completeness of health care provider's order for patient name, type and amount of IV fluid, medication additives, infusion time, and purpose of infusion. Follow six rights of medication administration (see Chapter 32). If order is written for KVO (keep vein open) or TKO (to keep open), note date and time of last fluid container change and refer to agency policy to determine need for IV fluid container change.

Provides patient safety by preventing medication errors.

Agency policy determines how often IV fluid container change is required for KVO infusion rate.

   b. Determine compatibility of all IV fluids and additives by consulting approved online database, drug reference book, or pharmacist.

Incompatibilities cause physical and chemical changes with adverse patient outcomes.

2. Changing IV tubing:

   a. Assess current tubing for puncture, contamination, or occlusion, which requires immediate tubing change.

Compromised tubing allows fluid leakage, bacterial contamination, and entry of pathogens into patient's bloodstream.

Whole blood, blood component products, or incompatible mixtures can occlude or partially occlude tubing because viscous solutions adhere to walls of tubing, decreasing size of lumen.

   b. Note date and time of last IV tubing change. Agency policy indicates frequency of routine change for IV administration sets and saline/heparin locks.

INS recommends changing continuous IV tubing no more often than 96-hour intervals unless tubing becomes compromised. Change primary intermittent tubing set every 24 hours (INS, 2011).

3. Discontinuing peripheral IV access: Review accuracy and completeness of health care provider's order for discontinuing IV therapy.

Order required for discontinuing IV therapy.

4. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy. Compare identifiers with information on patient's MAR or medical record. If using bar-code system, scan bar code on patient's wristband and then on IV fluid container.

Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016). Bar-code systems reduce medication errors by verifying right patient, medication, dose, and time with EHR (FitzHenry et al., 2013).

5. Determine patient's/family member's understanding of need for IV therapy or reason for discontinuing it.

Reveals need for patient teaching.

SKILL 42-3	MAINTENANCE OF INTRAVENOUS SYSTEM—cont'd

STEP	RATIONALE

PLANNING

1. Collect appropriate equipment, perform hand hygiene, and arrange equipment at patient's bedside.

For changing IV fluid container: Have next solution prepared at least 1 hour before needed. If prepared in pharmacy, ensure that it has been delivered to patient care unit. Check that solution is correct and properly labeled. Allow solution to warm to room temperature if refrigerated. Follow six rights of medication administration and verify solution expiration date. Observe for precipitate, discoloration, and leakage.

Keeps procedure organized and provides patient safety. Hand hygiene reduces transmission of microorganisms.

Adequate planning for changing solution reduces risk of clot formation at catheter tip caused by lack of flow from empty IV container. Checking that solution is correct prevents medication error (Alexander et al., 2014).

2. Coordinate tubing changes with IV fluid container changes if possible.

Promotes patient safety by reducing number of times IV system is open.

3. Explain to patient/family member procedure, its purpose, and what is expected of patient.

Promotes patient cooperation and decreases anxiety.

For discontinuing peripheral IV access: Explain that patient must hold extremity still; that he or she may feel burning sensation when you remove catheter; and that procedure will take about 5 minutes.

IMPLEMENTATION

1. Changing IV fluid container:

  a. Determine patency of current vascular access device (VAD) site: Look for swelling, coolness to touch, or tenderness around VAD site. With EID use, VAD should be patent if site is not infiltrated and EID functions without alarm signals. If not using EID, carefully adjust roller clamp to see an increase in flow rate and then regulate back to prescribed rate.

New IV access site is necessary if infiltration or phlebitis is present, IV tubing is compromised, or VAD site is not patent.

EID alarm signals when system is occluded.

In absence of EID, adjusting roller clamp increases flow rate if there is no obstruction.

CLINICAL DECISION: *Lowering IV container below level of IV site for presence of blood return (retrograde) is an unreliable indicator of patency.*

  b. Prepare to change solution when approximately 50 mL of fluid remains in container. Be sure that drip chamber is at least half full.

Prevents air from entering tubing and vein from clotting from lack of flow.

  c. Prepare new IV fluid container for changing. If using plastic bag, hang on IV pole and remove protective cover from IV tubing port. If using glass bottle, remove metal cap and disks.

Permits quick, smooth, and organized change from old to new IV fluid container.

  d. Close roller clamp to stop flow of existing infusion. Remove tubing from EID. Then remove old IV fluid container from IV pole and hold it with tubing port pointing upward.

Prevents solution remaining in drip chamber from emptying while changing IV fluid container.

Port held upward prevents IV fluid from spilling.

  e. Quickly remove spike from old solution container (see illustration) and, without touching tip, insert it into new container (see illustration).

Reduces risk of solution in drip chamber running dry and maintains sterility.

STEP 1e   A, Quickly remove spike from old solution container. **B,** Without touching tip, insert spike into new container.

STEP	RATIONALE

CLINICAL DECISION: *If you contaminate the spike, discard that IV tubing and use a new one.*

f. Hang new fluid container on IV pole.	Gravity helps delivery of fluid into drip chamber.
g. Check for air in tubing. If bubbles form, remove them by closing roller clamp below them, stretching tubing downward, and tapping tubing with finger (bubbles rise in fluid to drip chamber) (see illustration). For larger amount of air, swab the port below the air with alcohol and allow to dry; insert needleless syringe into port and aspirate air into syringe.	Reduces risk of air descending the tubing. Use of air-eliminating filter also reduces this risk.
h. Make sure that drip chamber is one-third to one-half full. If it is too full, pinch off tubing below it, invert container, squeeze drip chamber (see illustration) to push fluid into container, release tubing, and hang container.	Reduces risk of air entering tubing. If chamber is completely filled, you cannot observe drips.
i. Insert tubing into EID and restart pump. If no EID, regulate flow to prescribed rate with roller clamp.	Delivers IV fluid as ordered.
j. Attach piece of tape or label to IV fluid container with date and time of container change (check agency policy). If using polyvinylchloride (PVC) container, mark only on label and not container.	Provides reference to determine next time for container change, especially with KVO rate. Ink may leak into IV fluid through PVC container.
2. Changing IV tubing:	
a. Open new infusion set and connect add-on pieces (e.g., filter, extension tubing). Keep protective coverings over infusion spike and distal connector for VAD. Secure all connections.	Protective covers maintain sterility of IV system. Securing connections reduces risk of contamination, infection, and hemorrhage.
b. Apply clean gloves.	Reduces transmission of microorganisms (OSHA, 2012).
c. If catheter hub is not accessible, remove IV dressing as directed in Skill 42-4. Do not remove catheter-securing device, transparent dressing, or tape that secures catheter hub to skin.	Catheter hub must be accessible to provide smooth transition when removing old and inserting new tubing.

STEP 1g Nurse taps tubing to cause air bubbles to rise up to drip chamber.

STEP 1h Remove excess fluid from drip chamber.

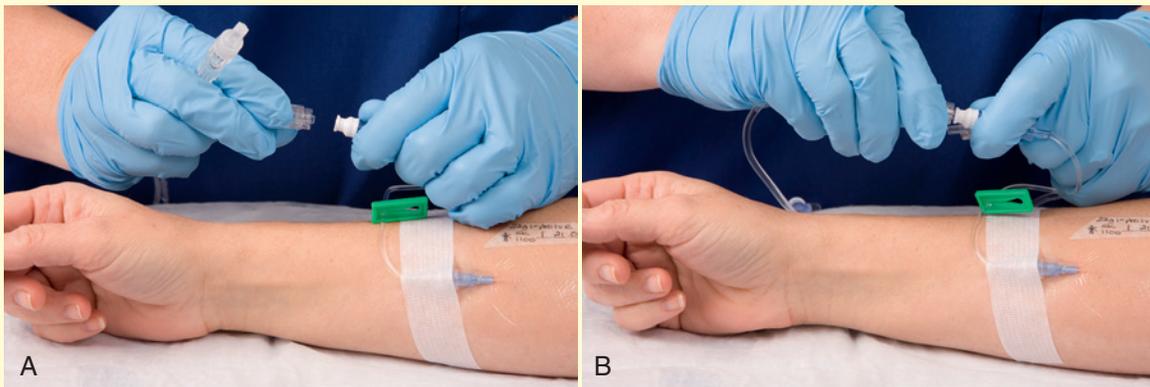
SKILL 42-3	MAINTENANCE OF INTRAVENOUS SYSTEM—cont'd

STEP	RATIONALE
d. *Prepare tubing, using existing continuous IV infusion:*	
(1) Close roller clamp on new IV tubing.	Prevents spillage of fluid after spiking container.
(2) Slow rate of infusion through old tubing to KVO rate, using EID or roller clamp if no EID.	Prevents complete infusion of fluid remaining in tubing, thus decreasing risk of VAD clotting.
(3) Compress and fill drip chamber of old tubing.	Ensures that drip chamber contains enough fluid to maintain IV patency while changing tubing.
(4) Invert IV fluid container and remove old tubing. Keep spike sterile and upright. *Optional:* Tape old drip chamber to IV pole without contaminating spike.	Allows fluid to continue to flow through IV catheter while new tubing is prepared.
(5) Place insertion spike of new tubing into IV fluid container. Hang container on IV pole, compress and release drip chamber on new tubing, and fill drip chamber one-third to one-half full.	Permits flow of fluid from solution into new infusion tubing.

CLINICAL DECISION: *If you contaminate the spike, discard that IV tubing and use a new one.*

STEP	RATIONALE
(6) Slowly open roller clamp, remove protective cap from adapter (if necessary), and flush new tubing with solution. Close roller clamp when full. Replace cap. Place capped end of adapter near patient's IV site.	Priming slowly instead of allowing a wide-open flow reduces formation of air in tubing. Removes air from tubing and replaces it with fluid. Positions equipment for quick, smooth connection of new tubing.
(7) Stop EID if used and close roller clamp on old tubing.	Prevents spillage of fluid as tubing is removed from catheter.
e. *Prepare tubing, using existing saline lock:*	
(1) If loop or short extension tubing is needed, use sterile technique to connect new injection cap to new loop or tubing.	Sterile technique prevents transmission of infection.
(2) Swab injection cap with antiseptic swab and let dry. Insert syringe with 1 to 3 mL saline solution and inject through injection cap into loop of extension tubing (see illustration). Place capped end of tubing near patient's IV site.	Maintains patency of VAD.

STEP 2e(2) Flush injection port slowly.

STEP	RATIONALE
f. *Reestablish infusion:*	
(1) Remove manufactured catheter stabilization device or tape from tubing. Gently disconnect old tubing from catheter hub (see illustration A) and quickly insert adapter of new tubing into catheter hub, being sure that it is secure, thus maintaining sterility of point of entry of connection (see illustration B).	Allows smooth transition from old to new tubing, minimizing time that system is open to infection. Careful technique prevents VAD dislodgement or vein trauma during tubing change and transmission of microorganisms.
(2) *For continuous infusion:* Open roller clamp on new tubing, allowing solution to run rapidly for 30 to 60 seconds; then regulate drip rate using EID or roller clamp if gravity drip.	Brief rapid flow ensures catheter patency and prevents occlusion. Regulation restores infusion rate to deliver IV fluid as prescribed.
(3) Attach piece of tape or label with date and time of tubing change onto tubing below drip chamber.	Provides reference to determine next time for tubing change.
(4) Apply new manufactured catheter stabilization device or tape if used (see Skill 42-1, Step 21). Form loop of tubing and secure it to patient's arm with strip of tape.	Avoids accidental pulling against site and stabilizes catheter.
g. Remove and discard old IV tubing. If necessary, apply new dressing (see Skill 42-4). Remove and dispose of gloves. Perform hand hygiene.	Reduces transmission of microorganisms.
3. Discontinuing peripheral IV access:	
a. Perform hand hygiene. Apply clean gloves.	Reduces transmission of microorganisms.
b. Turn off EID and close roller clamp or, if no EID, close roller clamp that controls rate.	Prevents spillage of IV fluid.
c. Remove IV site dressing and manufactured catheter stabilization device (see Skill 42-4). Remove any tape that secures catheter. Do not use scissors.	Exposes catheter with minimal discomfort. Scissors might accidentally damage catheter or injure patient (INS, 2011).
d. Hold catheter hub and clean site with antiseptic swab. Allow to dry completely.	Removes secretions around skin puncture site.
e. Place sterile gauze over venipuncture site and apply light pressure while withdrawing catheter, using slow, steady motion. Keep hub parallel to skin (see illustration). Do not raise or lift catheter before it is completely out of vein. Inspect end of catheter, being sure it is intact after removal.	Dry pad causes less irritation to puncture site. Removal technique avoids trauma to vein or hematoma formation. Inspection determines if catheter tip is intact. Tip of catheter can break off and embolize, which is an emergency situation.


STEP 2f(1) A, Disconnect old intravenous tubing. **B,** Connect Luer-Lok adapter of new IV tubing.

STEP 3e Remove IV catheter slowly, keeping catheter parallel to vein.

SKILL 42-3	MAINTENANCE OF INTRAVENOUS SYSTEM—cont'd

STEP	RATIONALE
f. Keep gauze in place and apply continuous pressure to site for 2 to 3 minutes and assess bleeding.	Controls bleeding and hematoma formation. Pressure should be applied until hemostasis occurs (INS, 2011).

CLINICAL DECISION: *If patient receives anticoagulants or platelet inhibitors (e.g., low-dose aspirin, war-farin sodium [Coumadin], heparin) or has a low platelet count, apply steady pressure longer (for 5 to 10 minutes) and assess bleeding.*

STEP	RATIONALE
g. Apply sterile folded gauze dressing over insertion site and secure with tape.	Maintains pressure to prevent bleeding and reduces bacterial entry into puncture site.
h. Discard used supplies, remove gloves, and perform hand hygiene.	Reduces transmission of microorganisms.

EVALUATION

1. *For changing IV fluid container and/or tubing:*

a. Evaluate IV flow rate hourly; observe connections for leaking and patency of system.	Ensures proper fluid administration.
b. Observe patient for signs of overhydration or dehydration to determine response to therapy and restoration of fluid balance.	Signs and symptoms of overhydration or continued dehydration warrant changing rate of fluid infused. Contact health care provider for new infusion rate order.

2. *For discontinuing peripheral IV access:*

a. Observe site for bleeding soon after procedure and assess for redness, tenderness, drainage, or swelling daily.	Detects bleeding after catheter removal. Detects local infection or postinfusion phlebitis (INS, 2011). Postinfusion phlebitis may occur 48 to 96 hours after catheter removal.
b. Use **Teach Back** to determine patient's and family's understanding about discontinuing IV therapy. State, "I want to be sure I explained what may happen to your arm after removing the IV. Can you tell me what to look for and tell the RN?" Revise your instruction now or develop plan for revised teaching if patient or family is not able to teach back correctly.	Evaluates what patient or family is able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Flow rate is incorrect; patient receives too little or too much fluid.
- Readjust infusion rate to ordered rate.
- Evaluate patient for adverse effects; notify health care provider if apparent.
- Determine and correct cause of incorrect flow rate (e.g., positional change that might affect rate, EID malfunction [or poor height of IV container with gravity flow], kinking or obstruction of tubing, infiltration or other complications of VAD site).
- Notify health care provider if patient's anticipated infusion is 100 to 200 mL less than or greater than expected (check agency policy).

2. Catheter tip is missing after withdrawal.
- Apply tourniquet high on extremity to restrict mobility of catheter embolus.
- Immediately notify health care provider.

3. See Table 42-12 for infiltration, phlebitis, and local infection.

RECORDING AND REPORTING

- Record amount and type of fluid infused, amount and type of fluid started, and tubing change on patient's medical record according to agency policy. If using bar-code system, fluid type and time record automatically in an electronic health record (EHR).
- Record time that peripheral IV access was discontinued on patient's record according to agency policy. Include site assessment information and status of catheter, including gauge, length, and catheter tip integrity.
- Document your evaluation of patient learning.

HOME CARE CONSIDERATIONS

- Ensure that patient is able and willing to self-manage IV therapy (including changing IV containers) or that reliable family caregiver is at home to provide IV care.
- Instruct patient or family caregiver in procedure for performing an IV solution and tubing change. Consider their cultural norms (e.g., health beliefs and comfort with caregivers using touch) (Petroulias et al., 2013).
- Instruct patient or caregiver to notify health care provider if bleeding or drainage is noted at insertion site or if pain or tenderness occurs up to 4 days after catheter removal.

SKILL 42-4	CHANGING A PERIPHERAL INTRAVENOUS DRESSING

DELEGATION CONSIDERATIONS

The skill of changing a peripheral intravenous (IV) dressing cannot be delegated to nursing assistive personnel (NAP). Delegation to licensed practical nurses (LPNs) varies by state Nurse Practice Act. Instruct the NAP to inform you if:
- Patient indicates moistness or loosening of an IV dressing.

EQUIPMENT
- Antiseptic swabs (chlorhexidine 2% preferred [INS, 2011])
- Adhesive remover *(optional)*
- Skin protectant swab
- Clean gloves
- Strips of nonallergenic tape
- Manufactured catheter stabilization device if available
- Dressing: Sterile transparent dressing (preferred) or sterile 2 × 2- or 4 × 4-inch gauze pad

STEP	RATIONALE

ASSESSMENT

1. Determine agency policy regarding peripheral IV dressing changes. Transparent dressings usually remain in place until IV site is changed unless dressing becomes wet, soiled, or loose.

Dressing change increases risk of catheter displacement and is performed only if dressing is compromised.

2. Perform hand hygiene. Observe present dressing for moisture and intactness. Determine whether moisture is from site leakage or external source.

Moisture is a medium for bacterial growth and renders dressing contaminated. Loose dressing increases risk for bacterial contamination of venipuncture site or displacement of vascular access device (VAD).

3. Observe IV system for proper functioning or complications. Apply clean gloves if dressing is moist. Palpate VAD site through intact dressing, assessing for pain or burning.

Unexplained decrease in flow rate requires investigating VAD placement and patency. Pain is associated with both phlebitis and infiltration.

4. Identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.

Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).

5. Assess patient's understanding of need for continued IV infusion.

Determines need for patient teaching.

PLANNING

1. Explain procedure and purpose to patient and family. Explain that patient must hold affected extremity still and how long procedure will take.

Decreases anxiety, promotes cooperation, and gives patient time frame around which to plan personal activities.

2. Collect equipment, perform hand hygiene and arrange equipment at bedside.

Ensures organized procedure.

IMPLEMENTATION

1. Apply clean gloves.

Reduces transmission of microorganisms.

2. Remove transparent dressing by pulling up one corner and pulling dressing laterally while holding catheter hub and tubing with nondominant hand (see illustration). Leave tape or catheter stabilization device that secures IV catheter in place. *For gauze dressing:* Stabilize catheter hub while removing old dressing one layer at a time. Be cautious if catheter tubing becomes tangled between two layers of dressing.

Prevents accidental displacement of VAD.

3. Observe insertion site for signs and symptoms of infiltration, phlebitis (see Tables 42-12 to 42-14), and local infection (inflammation and exudate). Discontinue infusion if complication exists (see Skill 42-3).

Presence of infiltration, phlebitis, or local infection requires removal of VAD and new IV start in other extremity or proximal to previous insertion site if continued therapy is necessary.

4. If IV is infusing properly, gently remove any tape or stabilization device that secures catheter. Stabilize catheter with one hand. Use adhesive remover to clean skin and remove adhesive residue if needed.

Exposes venipuncture site. Stabilization prevents accidental displacement of catheter. Adhesive residue decreases ability of new tape to adhere securely to skin.

STEP 2 Remove transparent dressing while pulling it laterally.

SKILL 42-4	CHANGING A PERIPHERAL INTRAVENOUS DRESSING—cont'd

STEP	RATIONALE

CLINICAL DECISION: *Keep one finger stabilizing VAD at all times until dressing is applied. This requires careful advance planning regarding placing and opening supplies and how to work with one hand. If patient is restless or uncooperative, ask another nurse to help with dressing change.*

STEP	RATIONALE
5. While stabilizing VAD, clean insertion site with antiseptic swab using friction in a horizontal plane and then a vertical plane, followed by a circular motion moving from insertion site outward (see illustration). Allow antiseptic to dry completely.	Friction penetrates antiseptic into epidermal layer of skin. Antimicrobial solutions should be allowed to air-dry completely to reduce microbial counts effectively (Alexander et al, 2014; INS, 2011).
6. *Optional:* Apply skin protectant solution (e.g., skin preparation, no-sting barrier film) to area where you will apply tape or dressing. Allow to dry.	Coats skin with protective solution to maintain skin integrity, prevents irritation from adhesive, and promotes adherence of dressing.
7. Secure catheter with new stabilization device or tape (see Skill 42-1, Step 21) and apply sterile dressing over site (procedures differ; follow agency policy).	Prevents accidental dislodgement of catheter and protects site from infection (INS, 2011; Vizcarra et al, 2014).
a. *Transparent dressing:* Apply as directed in Skill 42-1, Step 21b.	Occlusive dressing protects site from bacterial contamination (Bernatchez, 2014).
b. *Gauze dressing:* Apply as directed in Skill 42-1, Step 21c.	Less frequently used than transparent dressing.

CLINICAL DECISION: *Think carefully about where you place tape. Do not apply it over catheter insertion site, over connection between tubing or port and IV catheter hub, or on top of transparent dressing.*

STEP	RATIONALE
8. Remove and discard gloves.	Reduces transmission of microorganisms.
9. *Optional:* Apply protective device over area if patient may pick at or bump dressing (see illustration).	Site protection devices include vented plastic or stretch netting coverings and mitts for hands.
	Designed to reduce risk of phlebitis, infiltration, or catheter displacement from mechanical motion.
10. Anchor IV tubing with additional pieces of tape if necessary.	Prevents accidental displacement of IV catheter.
11. Label dressing per agency policy. Label information should include date and time of original IV insertion and VAD gauge and length.	Labeling with IV insertion date and VAD length facilitates appropriate site rotation and safe discontinuation of IV access.
12. Discard equipment and perform hand hygiene.	Reduces transmission of microorganisms.

EVALUATION

1. Observe new dressing to be sure that it is applied, taped, and labeled properly.	Validates quality of completed dressing change.
2. Ensure that flow rate is accurate.	Validates that IV line is patent and functioning correctly. Manipulation of catheter and tubing may affect rate of infusion.
3. Use ***Teach Back*** to determine patient's and family's understanding about dressing change. State, "I want to be sure I explained why I changed your IV dressing. Can you explain why I changed the dressing?" Revise your instruction now or develop plan for revised teaching if patient or family is not able to teach back correctly.	Evaluates what patient or family is able to explain or demonstrate.

STEP 5 Cleanse peripheral insertion site with antiseptic swab.

STEP 9 IV House protective device. (Courtesy IV House, St Louis, MO)

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. VAD is accidentally dislodged or removed.
- Start new IV line in other extremity or proximal to previous insertion site if continued therapy is necessary.

2. IV site develops infiltration, phlebitis, and local infection.
- See Table 42-12.

RECORDING AND REPORTING

- Record time that peripheral dressing was changed, reason for change, type of dressing material used, patency of system, and description of venipuncture site.
- Document your evaluation of patient learning.
- Report to charge nurse or oncoming nursing shift that dressing was changed and any significant information about integrity of system.
- Report any complications to health care provider and document them.

KEY POINTS

- Body fluids containing water, Na$^+$, and other electrolytes are distributed between ECF and ICF compartments.
- A dynamic interplay of fluid and electrolyte intake and absorption, distribution, and output determines fluid and electrolyte balance.
- Fluid moves between blood vessels and interstitial fluid by filtration; water moves between ECF and ICF by osmosis.
- ECV deficit and excess are abnormal *volumes* of isotonic fluid, manifested as sudden changes in body weight and changes in markers of vascular and interstitial volume.
- Osmolality imbalances are abnormal *concentrations* of body fluids, manifested as altered serum Na$^+$ levels and decreased level of consciousness.
- Interplay of acid production, acid buffering, and acid excretion determines acid-base balance.
- Acid-base imbalances are excesses or deficits of carbonic or metabolic acids, manifested as changes in level of consciousness and abnormalities of PaCO$_2$, HCO$_3^-$, and pH.
- Patients who are very young or very old, whose I&O of fluid and/or electrolytes are not equal, or who have various chronic diseases or trauma are at high risk for fluid, electrolyte, and acid-base imbalances.
- Treatment for ECV excess is Na$^+$ restriction and fluid restriction if severe; treatment for hyponatremia usually is water restriction. Prevention and treatment of ECV deficit, hypernatremia, and electrolyte deficits involve oral or parenteral administration of appropriate fluid.
- Initiation and maintenance of IV therapy require clinical decision making, skill, and organized procedures to maintain sterility and patency of the system and periodic updating of procedures on the basis of current research evidence.
- Nurses monitor vigilantly for complications of IV therapy, which include fluid overload, infiltration, phlebitis, local infection, and bleeding at the infusion site.
- Administration of blood or blood products requires a specific procedure for correctly identifying patient and blood product and responding to transfusion reactions quickly.
- Patient and family teaching is important for preventing fluid, electrolyte, and acid-base imbalances and effective restorative care.

CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

Mrs. Hilda Beck, age 72, fell at home because she became light-headed after vomiting and diarrhea that lasted over 24 hours. Even though she was nauseated, she drank some water because she knew she needed fluid. She was admitted for oral and intravenous (IV) fluid therapy.

1. What was problematic about Mrs. Beck's oral fluid replacement at home when she had vomiting and diarrhea?

2. Mrs. Beck's intravenous (IV) fluid order is 1000 mL 0.9% sodium chloride to run over 5 hours. Calculate the mL/hr that you should program into her infusion pump.

3. Mrs. Beck says, "When I get diarrhea, I should drink sodium-containing fluid when I'm thirsty." She needs what additional teaching?

ⓔ *Answers to Clinical Application Questions can be found on the Evolve website.*

REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. An intravenous (IV) fluid is infusing more slowly than ordered. The infusion pump is set correctly. Which factors could cause this slowing? (Select all that apply.)
   1. Infiltration at vascular access device (VAD) site
   2. Patient lying on tubing
   3. Roller clamp wide open
   4. Tubing kinked in bedrails
   5. Circulatory overload

2. Which patients does a nurse plan to teach regarding water restriction?
   1. A 23-year-old with extracellular fluid volume (ECV) deficit
   2. A 34-year-old with hyponatremia
   3. A 47-year-old with hypercalcemia
   4. A 69-year-old with metabolic acidosis

3. A nurse assesses pain and redness at a vascular access device (VAD) site. Which action is taken first?
   1. Apply a warm, moist compress
   2. Monitor the patient's blood pressure

3. Aspirate the infusing fluid from the VAD
4. Stop the infusion and discontinue the intravenous infusion

4. When delegating input and output (I&O) measurement to nursing assistive personnel, a nurse instructs them to record what information for ice chips?
   1. The total volume
   2. Two-thirds of the volume
   3. One-half of the volume
   4. One-quarter of the volume

5. A nurse assesses four patients. Which patient has greatest risk for hypomagnesemia?
   1. A 72-year-old with chronic alcoholism
   2. A 79-year-old with bone cancer
   3. A 41-year-old with hypernatremia
   4. A 46-year-old with respiratory acidosis

6. Which assessment does a nurse interpret as a transfusion reaction?
   1. Crackles in dependent lobes of lungs
   2. High fever, severe hypotension
   3. Anxiety, itching, confusion
   4. Chills, tachycardia, and flushing

7. What assessment does a nurse make before hanging an intravenous (IV) fluid that contains potassium?
   1. Urine output
   2. Arterial blood gases
   3. Fullness of neck veins
   4. Level of consciousness

8. The health care provider's order is 500 mL 0.9% NaCl intravenously over 4 hours. Which rate does a nurse program into the infusion pump?
   1. 125 mL/hr
   2. 167 mL/hr
   3. 200 mL/hr
   4. 1000 mL/hr

9. An older-adult patient is receiving intravenous (IV) 0.9% NaCl. A nurse detects new onset of crackles in the lung bases. What is the priority action?
   1. Notify a health care provider
   2. Record in medical record
   3. Decrease the IV flow rate
   4. Discontinue the IV site

10. Place the following steps for discontinuing intravenous (IV) access in the correct order:
    1. Perform hand hygiene and apply gloves.
    2. Explain procedure to patient.
    3. Remove IV site dressing and tape.
    4. Use two identifiers to ensure correct patient.
    5. Stop the infusion and clamp the tubing.
    6. Carefully check the health care provider's order.
    7. Clean the site, withdraw the catheter, and apply pressure.

11. A patient has severe hypercalcemia. What are the priority nursing interventions? (Select all that apply.)
    1. Fall prevention interventions
    2. Teaching regarding sodium restriction
    3. Encouraging increased fluid intake
    4. Monitoring for constipation
    5. Explaining how to take daily weights

12. A patient has hypokalemia with stable cardiac function. What are the priority nursing interventions? (Select all that apply.)
    1. Fall prevention interventions
    2. Teaching regarding sodium restriction
    3. Encouraging increased fluid intake
    4. Monitoring for constipation
    5. Explaining how to take daily weights

13. A patient is admitted to the hospital with severe dyspnea and wheezing. Arterial blood gas levels on admission are pH 7.26; $PaCO_2$, 55 mm Hg; PaO_2, 68 mm Hg; and HCO_3^-, 24. The nurse interprets these laboratory values to indicate:
    1. Metabolic acidosis.
    2. Metabolic alkalosis.
    3. Respiratory acidosis.
    4. Respiratory alkalosis.

14. Which assessment does a nurse use as a clinical marker of vascular volume in a patient at high risk of extracellular fluid volume (ECV) deficit?
    1. Dryness of mucous membranes
    2. Presence or absence of edema
    3. Fullness of neck veins when supine
    4. Fullness of neck veins when upright

15. A patient is hyperventilating from acute pain and hypoxia. Interventions to manage his pain and oxygenation will decrease his risk of which acid-base imbalance?
    1. Metabolic acidosis
    2. Metabolic alkalosis
    3. Respiratory acidosis
    4. Respiratory alkalosis

Answers: 1. 1, 2, 4; **2.** 2, 3; **3.** 4; **5.** 1; **6.** 4; **7.** 1; **8.** 1; **9.** 3; **10.** 6, 4, 2, 1, 5, 3, 7; **11.** 1, 3, 4; **12.** 1, 4; **13.** 3; **14.** 3; **15.** 4.

Sleep

Proper rest and sleep are as important to health as good nutrition and adequate exercise. Physical and emotional health depends on the ability to fulfill these basic human needs. Individuals need different amounts of sleep and rest. Without proper amounts, the ability to concentrate, make judgments, and participate in daily activities decreases; and irritability increases.

Identifying and treating patients' sleep pattern disturbances are important goals. To help patients you need to understand the nature of sleep, the factors influencing it, and patients' sleep habits. Patients require individualized approaches on the basis of their personal habits, patterns of sleep, and the particular problem influencing sleep. Nursing interventions are often effective in resolving short- and long-term sleep disturbances.

Sleep provides healing and restoration (Huether et al., 2012). Achieving the best possible sleep quality is important for the promotion of good health and recovery from illness. Ill patients often require more sleep and rest than healthy patients. However, the nature of illness often prevents some patients from getting adequate rest and sleep. The environment of a hospital or long-term care facility and the activities of health care personnel often make sleep difficult. Some patients have preexisting sleep disturbances; others develop sleep problems as a result of an illness or hospitalization.

SCIENTIFIC KNOWLEDGE BASE

Physiology of Sleep

Sleep is a cyclical physiological process that alternates with longer periods of wakefulness. The sleep-wake cycle influences and regulates physiological function and behavioral responses.

Circadian Rhythms. People experience cyclical rhythms as part of their everyday lives. The most familiar rhythm is the 24-hour, day-night cycle known as the diurnal or circadian rhythm (derived from Latin: *circa,* "about," and *dies,* "day"). The suprachiasmatic nucleus (SCN) nerve cells in the hypothalamus control the rhythm of the sleep-wake cycle and coordinate this cycle with other circadian rhythms (Huether et al., 2012). Circadian rhythms influence the pattern of major biological and behavioral functions. The predictable changing of body temperature, heart rate, blood pressure, hormone secretion, sensory acuity, and mood depend on the maintenance of the 24-hour circadian cycle (Kryger et al., 2011).

Factors such as light, temperature, social activities, and work routines affect circadian rhythms and daily sleep-wake cycles. All people have biological clocks that synchronize their sleep cycles. This explains why some people fall asleep at 8 PM, whereas others go to bed at

midnight or early in the morning. Different people also function best at different times of the day.

Hospitals or extended care facilities usually do not adapt care to an individual's sleep-wake cycle preferences. Typical hospital routines interrupt sleep or prevent patients from falling asleep at their usual time. Poor quality of sleep results when a person's sleep-wake cycle changes. Reversals in the sleep-wake cycle, such as when a person who is normally awake during the day falls asleep during the day, often indicate a serious illness.

The biological rhythm of sleep frequently becomes synchronized with other body functions. For example, changes in body temperature correlate with sleep patterns. Normally body temperature peaks in the afternoon, decreases gradually, and drops sharply after a person falls asleep. When the sleep-wake cycle becomes disrupted (e.g., by working rotating shifts), other physiological functions usually change as well. For example, a new nurse who starts working the night shift experiences a decreased appetite and loses weight. Anxiety, restlessness, irritability, and impaired judgment are other common symptoms of sleep cycle disturbances. Failure to maintain an individual's usual sleep-wake cycle negatively influences the patient's overall health.

Sleep Regulation. Sleep involves a sequence of physiological states maintained by highly integrated central nervous system (CNS) activity. It is associated with changes in the peripheral nervous, endocrine, cardiovascular, respiratory, and muscular systems (Huether et al., 2012). Specific physiological responses and patterns of brain activity identify each sequence. Instruments such as the electroencephalogram (EEG), which measures electrical activity in the cerebral cortex; the electromyogram (EMG), which measures muscle tone; and the electrooculogram (EOG), which measures eye movements provide information about some structural physiological aspects of sleep.

The major sleep center in the body is the hypothalamus. It secretes hypocretins (orexins) that promote wakefulness and rapid eye movement (REM) sleep. Prostaglandin D_2, L-tryptophan, and growth factors control sleep (Huether et al., 2012).

Researchers believe that the ascending reticular activating system (RAS) located in the upper brainstem contains special cells that maintain alertness and wakefulness. The RAS receives visual, auditory, pain, and tactile sensory stimuli. Activity from the cerebral cortex (e.g., emotions or thought processes) also stimulates the RAS. Arousal, wakefulness, and maintenance of consciousness result from neurons in the RAS releasing catecholamines such as norepinephrine (Kryger et al., 2011).

The homeostatic process (Process S), which primarily regulates the length and depth of sleep; and the circadian rhythms (Process C: "biological time clocks"), which influence the internal organization of sleep and the timing and duration of sleep-wake cycles, operate simultaneously to regulate sleep and wakefulness (Daroff et al., 2012). Time of wake up is defined by the intersection of Process S and Process C (Figure 43-1).

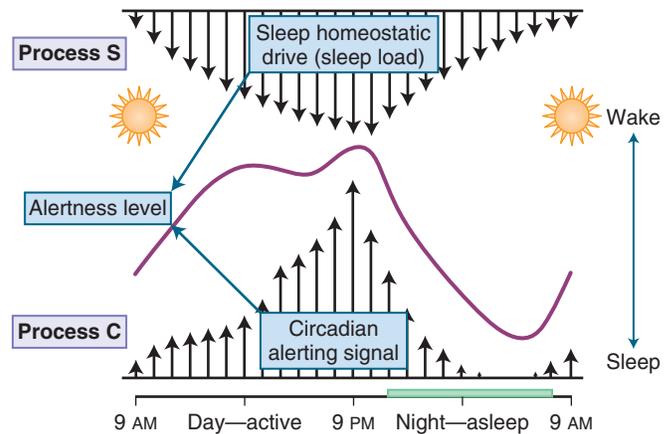
Stages of Sleep. Current theory suggests that sleep is an active multiphase process. Different brain-wave, muscle, and eye activity is associated with different stages of sleep (Chase, 2013). Normal sleep involves two phases: **nonrapid eye movement (NREM) sleep** and **rapid eye movement (REM) sleep** (Box 43-1). During NREM a sleeper progresses through four stages during a typical 90-minute sleep cycle. The quality of sleep from stage 1 through stage 4 becomes increasingly deep. Lighter sleep is characteristic of stages 1 and 2, during which a person is more easily aroused. Stages 3 and 4 involve a deeper sleep, called *slow-wave sleep*. REM sleep is the phase at the end of each sleep


FIGURE 43-1 Two-process model of sleep regulation shows the time course of the homeostatic process *(Process S)* and the circadian process *(Process C)*. Process S rises during waking and declines during sleep. The intersection of Process S and Process C defines the time of wake-up. (From Daroff RB et al: *Bradley's neurology in clinical practice,* ed 6, Philadelphia, 2012, Saunders.)

cycle. Different factors promote or interfere with various stages of the sleep cycle.

Sleep Cycle. The normal sleep pattern for an adult begins with a presleep period during which the person is aware only of a gradually developing sleepiness. This period normally lasts 10 to 30 minutes; however, if a person has difficulty falling asleep, it lasts an hour or more.

Once asleep, the person usually passes through four or five complete sleep cycles per night, each consisting of four stages of NREM sleep and a period of REM sleep (Huether et al., 2012). Each cycle lasts approximately 90 to 100 minutes. The cyclical pattern usually progresses from stage 1 through stage 4 of NREM, followed by a reversal from stages 4 to 3 to 2, ending with a period of REM sleep (Figure 43-2). A person usually reaches REM sleep about 90 minutes into the sleep cycle. Seventy-five to eighty percent of sleep time is spent in NREM sleep.

With each successive cycle stages 3 and 4 shorten, and the period of REM lengthens. REM sleep lasts up to 60 minutes during the last sleep cycle. Not all people progress consistently through the stages of sleep. For example, a sleeper moves back and forth for short intervals between NREM stages 2, 3, and 4 before entering REM stage. The amount of time spent in each stage varies over the life span. Newborns and children spend more time in deep sleep. Sleep becomes more fragmented with aging, and a person spends more time in lighter stages (National Sleep Foundation, 2014a). Shifts from stage to stage of sleep tend to accompany body movements. Shifts to light sleep or wakefulness tend to occur suddenly, whereas shifts to deep sleep tend to be gradual (Kryger et al., 2011). The number of sleep cycles depends on the total amount of time that the person spends sleeping.

Functions of Sleep

The primary function of sleep is unclear (Gilsenan, 2012). It contributes to physiological and psychological restoration. NREM sleep contributes to body tissue restoration (Huether et al., 2012). During NREM sleep biological functions slow. A healthy adult's normal heart rate throughout the day averages 70 to 80 beats/min or less if the individual is in excellent physical condition. However, during sleep the heart rate falls to 60 beats/min or less, which benefits cardiac function.

BOX 43-1 Stages of the Sleep Cycle

Stage 1: NREM
- Stage lasts a few minutes.
- It includes lightest level of sleep.
- Decreased physiological activity begins with gradual fall in vital signs and metabolism.
- Sensory stimuli such as noise easily arouse person.
- When awakened, person feels as though daydreaming has occurred.

Stage 2: NREM
- Stage lasts 10 to 20 minutes.
- It is a period of sound sleep.
- Relaxation progresses.
- Body functions continue to slow.
- Arousal remains relatively easy.

Stage 3: NREM
- Stage lasts 15 to 30 minutes.
- It involves initial stages of deep sleep.
- Muscles are completely relaxed.
- Vital signs decline but remain regular.
- Sleeper is difficult to arouse and rarely moves.

Stage 4: NREM
- Stage lasts approximately 15 to 30 minutes.
- It is the deepest stage of sleep.
- If sleep loss has occurred, sleeper spends considerable part of night in this stage.
- Vital signs are significantly lower than during waking hours.
- Sleepwalking and enuresis (bed-wetting) sometimes occur.
- It is very difficult to arouse sleeper.

REM Sleep
- Stage usually begins about 90 minutes after sleep has begun.
- Duration increases with each sleep cycle and averages 20 minutes.
- Vivid, full-color dreaming occurs; less vivid dreaming occurs in other stages.
- Stage is typified by rapidly moving eyes, fluctuating heart and respiratory rates, increased or fluctuating blood pressure, loss of skeletal muscle tone, and increase of gastric secretions.
- It is very difficult to arouse sleeper.

NREM, Nonrapid eye movement; *REM,* rapid eye movement.

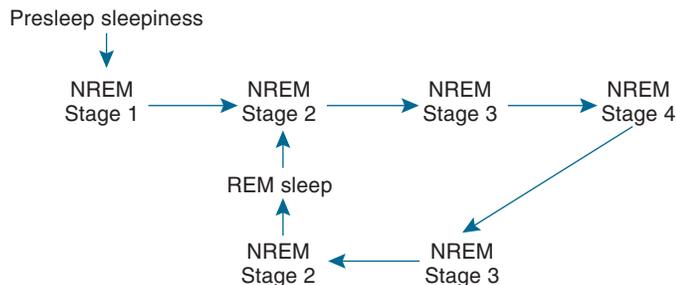
Presleep sleepiness


FIGURE 43-2 Stages of adult sleep cycle. *NREM,* Nonrapid eye movement; *REM,* rapid eye movement.

Other biological functions decreased during sleep are respirations, blood pressure, and muscle tone (Huether et al., 2012).

The body needs sleep to routinely restore biological processes. During deep slow-wave (NREM stage 4) sleep, the body releases human growth hormone for the repair and renewal of epithelial and specialized cells such as brain cells (Huether et al., 2012). Protein synthesis and cell division for renewal of tissues such as the skin, bone marrow, gastric mucosa, or brain occur during rest and sleep. NREM sleep is especially important in children, who experience more stage 4 sleep.

Another theory about the purpose of sleep is that the body conserves energy during sleep. The skeletal muscles relax progressively, and the absence of muscular contraction preserves chemical energy for cellular processes. Lowering of the basal metabolic rate further conserves body energy supply (Redeker and McEnany, 2011).

REM sleep is necessary for brain tissue restoration and appears to be important for cognitive restoration and memory (Conte and Ficca, 2013). It is associated with changes in cerebral blood flow, increased cortical activity, increased oxygen consumption, and epinephrine release. This association helps with memory storage and learning (Huether et al., 2012).

The benefits of sleep on behavior often go unnoticed until a person develops a problem resulting from sleep deprivation. A loss of REM sleep leads to feelings of confusion and suspicion. Various body functions (e.g., mood, motor performance, memory, and equilibrium) are altered when prolonged sleep loss occurs (National Sleep Foundation, 2014e). Changes in the natural and cellular immune function also occur with moderate-to-severe sleep deprivation. The annual direct cost of sleep-related problems in this country is 16 billion dollars. An additional 50 to 100 billion dollars are spent on indirect costs related to accidents, litigation, property damage, hospitalization, and death (University of Maryland Medical Center Sleep Disorders Center, 2015).

Dreams. Although dreams occur during both NREM and REM sleep, the dreams of REM sleep are more vivid and elaborate; and some believe that they are functionally important to learning, memory processing, and adaptation to stress (Kryger et al., 2011). REM dreams progress in content throughout the night from dreams about current events to emotional dreams of childhood or the past. Personality influences the quality of dreams (e.g., a creative person has elaborate and complex dreams, whereas a depressed person dreams of helplessness).

Most people dream about immediate concerns such as an argument with a spouse or worries over work. Sometimes a person is unaware of fears represented in bizarre dreams. Clinical psychologists try to analyze the symbolic nature of dreams as part of a patient's psychotherapy. The ability to describe a dream and interpret its significance sometimes helps resolve personal concerns or fears.

Another theory suggests that dreams erase certain fantasies or nonsensical memories. Because most people forget their dreams, few have dream recall or do not believe they dream at all. To remember a dream, a person has to consciously think about it on awakening. People who recall dreams vividly usually awake just after a period of REM sleep.

Physical Illness

Any illness that causes pain, physical discomfort, or mood problems such as anxiety or depression often results in sleep problems. People with such alterations frequently have trouble falling or staying asleep. Illnesses also force patients to sleep in unfamiliar positions. For example, it is difficult for a patient with an arm or leg in traction to rest comfortably.

Respiratory disease often interferes with sleep. Patients with chronic lung disease such as emphysema are short of breath and frequently cannot sleep without two or three pillows to raise their heads. Asthma, bronchitis, and allergic rhinitis alter the rhythm of breathing and disturb sleep. A person with a common cold has nasal congestion, sinus

drainage, and a sore throat, which impair breathing and the ability to relax.

Connections among heart disease, sleep, and sleep disorders exist. Sleep-related breathing disorders are linked to increased incidence of nocturnal angina (chest pain), increased heart rate, electrocardiogram changes, high blood pressure, and risk of heart diseases and stroke (Huether et al., 2012). Hypertension often causes early-morning awakening and fatigue. Research also identifies an increased risk of sudden cardiac death in the first hours after awakening. Sleep disruptions and frequent arousals occur in people with heart failure as a result of the apnea, hypercapnia, and hypoxemia that develops as the disease progresses (Kryger et al., 2011). Hypothyroidism decreases stage 4 sleep, whereas hyperthyroidism causes people to take more time to fall asleep.

Nocturia, or urination during the night, disrupts sleep and the sleep cycle. After repeated awakenings to urinate, returning to sleep is difficult, and the sleep cycle is not complete. Although this condition is most common in older people with reduced bladder tone or people with cardiac disease, diabetes, urethritis, or prostatic disease, it also occurs in a significant number of younger people (Van Kerrebroeck, 2011).

Many people experience restless legs syndrome (RLS), which occurs before sleep onset. More common in women, older people, and those with iron deficiency anemia, RLS symptoms include recurrent, rhythmical movements of the feet and legs. Patients feel an itching sensation deep in the muscles. Relief comes only from moving the legs, which prevents relaxation and subsequent sleep. RLS is sometimes a relatively benign condition, depending on how severely sleep is disrupted. Primary RLS is a CNS disorder. Researchers associate secondary RLS with lower levels of iron, pregnancy, renal failure, stress, diet, Parkinson's disease, or a side effect of drugs (Chasens and Umlauf, 2012).

People with peptic ulcer disease often awaken in the middle of the night. Studies showing a relationship between gastric acid secretion and stages of sleep are conflicting. One consistent finding is that people with duodenal ulcers fail to suppress acid secretion in the first 2 hours of sleep (Kryger et al., 2011). Many patients experience gastroesophageal reflux as a result of the acid production, which disrupts sleep (Kryger et al., 2011).

Sleep Disorders

Sleep disorders are conditions that, if untreated, generally cause disturbed nighttime sleep that results in one of three problems: insomnia, abnormal movements or sensation during sleep or when waking up at night, or excessive daytime sleepiness (EDS) (Kryger et al., 2011). Many adults in the United States have significant sleep problems from inadequacies in either the quantity or quality of their nighttime sleep and experience hypersomnolence on a daily basis (National Sleep Foundation, 2014e). The American Academy of Sleep Medicine developed the International Classification of Sleep Disorders version 2 (ICSD-2), which classifies sleep disorders into eight major categories (Box 43-2).

Insomnia disorders are related to difficulty falling asleep, frequently awaking from sleep, short periods of sleep, or sleep that is nonrestorative (Kryger et al., 2011). Individuals with sleep-related breathing disorders have changes in respirations during sleep. Hypersomnias are sleep disturbances that result in daytime sleepiness and are not caused by disturbed sleep or alterations in circadian rhythms (Kryger et al., 2011). The circadian rhythm sleep disorders are caused by a misalignment between the timing of sleep and individual desires or the societal norm. The parasomnias are undesirable behaviors that occur usually during sleep. Sleep and wake disturbances are associated with many medical and psychiatric sleep disorders, including psychiatric, neurological, or other medical disorders. In sleep-related movement disorders the person experiences simple stereotyped movements

---

BOX 43-2 Classification of Select Sleep Disorders

Insomnias
- Adjustment sleep disorder (acute insomnia)
- Inadequate sleep hygiene
- Behavioral insomnia of childhood
- Insomnia caused by medical condition

Sleep-Related Breathing Disorder
Central Sleep Apnea Syndromes
- Primary central sleep apnea
- Central sleep apnea caused by medical condition
- Obstructive sleep apnea syndromes

Hypersomnias Not Caused by a Sleep-Related Breathing Disorder
- Narcolepsy (four specified types)
- Menstrual-related hypersomnia
- Hypersomnia caused by a medical condition

Parasomnias
Disorders of Arousal
- Sleepwalking
- Sleep terrors

Parasomnias Usually Associated with REM Sleep
- Nightmare disorder
- REM sleep-behavior disorder

Other Parasomnias
- Sleep-related hallucinations
- Sleep-related eating disorder
- Sleep-related enuresis (bed-wetting)

Circadian Rhythm Sleep Disorders
Primary Circadian Rhythm Sleep Disorders
- Delayed–sleep phase type
- Advanced–sleep phase type

Behaviorally Induced Circadian Rhythm Sleep Disorders
- Jet lag type
- Shift work type
- Drug or substance use

Sleep-Related Movement Disorders
- Restless legs syndrome
- Periodic limb movements
- Sleep-related bruxism (teeth grinding)

Isolated Symptoms, Apparently Normal Variants, and Unresolved Issues
- Long sleeper
- Short sleeper
- Sleep talking

Other Sleep Disorders
- Physiological (organic) sleep disorders
- Environmental sleep disorder

Data from American Academy of Sleep Medicine: International classes of diseases and international classification of sleep disorders. In Kryger HM et al: *Principles and practice of sleep medicine,* ed 5, St Louis, 2011, Saunders.
REM, Rapid eye movement.

that disturb sleep. The category of isolated symptoms, apparently normal variants, and unresolved issues includes sleep-related symptoms that fall between normal and abnormal sleep. The "other" sleep disorders category contains sleep problems that do not fit into other categories.

Sleep laboratory studies diagnose a sleep disorder. A **polysomnogram** involves the use of EEG, EMG, and EOG to monitor stages of sleep and wakefulness during nighttime sleep. The Multiple Sleep Latency Test (MSLT) provides objective information about sleepiness and selected aspects of sleep structure by measuring eye movements, muscle-tone changes, and brain electrical activity during at least four napping opportunities spread throughout the day. The MSLT takes 8 to 10 hours to complete. Patients wear an Actigraph device on the wrist to measure sleep-wake patterns over an extended period of time. Actigraphy data provide information about sleep time, sleep efficiency, number and duration of awakenings, and levels of activity and rest.

Insomnia. **Insomnia** is a symptom that patients experience when they have chronic difficulty falling asleep, frequent awakenings from sleep, and/or a short sleep or nonrestorative sleep (Kryger et al., 2011). It is the most common sleep-related complaint. People with insomnia experience EDS and insufficient sleep quantity and quality. However, frequently a patient gets more sleep than he or she realizes. Insomnia often signals an underlying physical or psychological disorder. It occurs more frequently in and is the most common sleep problem for women.

People experience transient insomnia as a result of situational stresses such as family, work, or school problems; jet lag; illness; or loss of a loved one. Insomnia sometimes recurs, but between episodes a patient is able to sleep well. However, a temporary case of insomnia caused by a stressful situation can lead to chronic difficulty in getting enough sleep, perhaps because of the worry and anxiety that develop about getting it.

Insomnia is often associated with poor **sleep hygiene,** or practices that a patient associates with sleep. If the condition continues, the fear of not being able to sleep is enough to cause wakefulness. During the day people with chronic insomnia feel sleepy, fatigued, depressed, and anxious. Treatment is symptomatic, including improved sleep-hygiene measures, biofeedback, cognitive techniques, and relaxation techniques. Behavioral and cognitive therapies have few adverse effects and show evidence of sustained improvement in sleep over time (Babson et al., 2010).

Sleep Apnea. **Sleep apnea** is a disorder characterized by the lack of airflow through the nose and mouth for periods of 10 seconds or longer during sleep. There are three types of sleep apnea: central, obstructive, and mixed apnea. The most common form is obstructive sleep apnea (OSA). Research estimates that 2% to 4% of the adults in the United States meet the diagnostic criteria for OSA (Adult Obstructive Sleep Apnea Task Force, 2009). The two major risk factors for OSA are obesity and hypertension. Smoking, heart failure, type II diabetes, alcohol, and a positive family history of OSA also greatly increase the risk of developing the problem (Adult Obstructive Sleep Apnea Task Force, 2009). It occurs in up to 2% of middle-age women and up to 4% of middle-age men, with occurrence higher in the older-adult population and African-Americans (Malhotra and Desai, 2010).

OSA occurs when muscles or structures of the oral cavity or throat relax during sleep. The upper airway becomes partially or completely blocked, diminishing nasal airflow (hypopnea) or stopping it (apnea) for as long as 30 seconds (Kryger et al., 2011). The person still attempts to breathe because chest and abdominal movement continue, which often results in loud snoring and snorting sounds. When breathing is partially or completely diminished, each successive diaphragmatic movement becomes stronger until the obstruction is relieved. Structural abnormalities such as a deviated septum, nasal polyps, certain jaw configurations, larger neck circumference, or enlarged tonsils predispose a patient to OSA (Pinto and Caple, 2010). The effort to breathe during sleep results in arousals from deep sleep often to the stage 2 cycle. In severe cases hundreds of hypopnea/apnea episodes occur every hour, resulting in severe interference with deep sleep.

Excessive daytime sleepiness (EDS) and fatigue are the most common complaints of people with OSA. People with severe OSA often report taking daytime naps and experience a disruption in their daily activities because of sleepiness (Adult Obstructive Sleep Apnea Task Force, 2009). Feelings of sleepiness are usually most intense on waking, right before going to sleep, and about 12 hours after the mid-sleep period. EDS often results in impaired waking function, poor work or school performance, accidents while driving or using equipment, and behavioral or emotional problems. In general, OSA has the potential to contribute to high blood pressure and increased risk for heart attack and stroke (National Sleep Foundation, 2014c).

OSA causes a serious decline in arterial oxygen saturation level. Patients are at risk for cardiac dysrhythmias, right heart failure, pulmonary hypertension, angina attacks, stroke, and hypertension.

Central sleep apnea (CSA) involves dysfunction in the respiratory control center of the brain. The impulse to breathe fails temporarily, and nasal airflow and chest wall movement cease. The oxygen saturation of the blood falls. The condition is common in patients with brainstem injury, muscular dystrophy, and encephalitis. Less than 10% of sleep apnea is predominantly central in origin. People with CSA tend to awaken during sleep and therefore complain of insomnia and EDS. Mild and intermittent snoring is also present.

Patients with sleep apnea rarely achieve deep sleep. In addition to complaints of EDS, sleep attacks, fatigue, morning headaches, irritability, depression, difficulty concentrating, and decreased sex drive are common (Kryger et al., 2011). OSA affects quality-of-life issues such as marital relationships and interactions within and outside the family and often is an embarrassment to a patient (Adult Obstructive Sleep Apnea Task Force, 2009). Treatment includes therapy for underlying cardiac or respiratory complications and emotional problems that occur as a result of the symptoms of this disorder.

Narcolepsy. **Narcolepsy** is a dysfunction of mechanisms that regulate sleep and wake states. Excessive daytime sleepiness is the most common complaint associated with this disorder. During the day a person suddenly feels an overwhelming wave of sleepiness and falls asleep; REM sleep occurs within 15 minutes of falling asleep. **Cataplexy,** or sudden muscle weakness during intense emotions such as anger, sadness, or laughter, occurs at any time during the day. If the cataplectic attack is severe, a patient loses voluntary muscle control and falls to the floor. A person with narcolepsy often has vivid dreams that occur as he or she is falling asleep. These dreams are difficult to distinguish from reality. Sleep paralysis, or the feeling of being unable to move or talk just before waking or falling asleep, is another symptom. Some studies show a genetic link for narcolepsy (Ahmed and Thorpy, 2010).

A person with narcolepsy falls asleep uncontrollably at inappropriate times. When individuals do not understand this disorder, a sleep attack is easily mistaken for laziness, lack of interest in activities, or drunkenness. Typically the symptoms first begin to appear in adolescence and are often confused with the EDS that commonly occurs in teens. Narcoleptic patients are treated with stimulants or wakefulness-promoting agents such as sodium oxybate, modafinil (Provigil) or armodafinil (Nuvigil) that only partially increase wakefulness and reduce sleep attacks. Patients also receive antidepressant medications that suppress cataplexy and the other REM-related symptoms. Brief

daytime naps no longer than 20 minutes help reduce subjective feelings of sleepiness. Other management methods that help are following a regular exercise program, practicing good sleep habits, avoiding shifts in sleep, strategically timing daytime naps if possible, eating light meals high in protein, practicing deep breathing, chewing gum, and taking vitamins (Kryger et al., 2011). Patients with narcolepsy need to avoid factors that increase drowsiness (e.g., alcohol; heavy meals; exhausting activities; long-distance driving; and long periods of sitting in hot, stuffy rooms).

Sleep Deprivation. **Sleep deprivation** is a problem many patients experience as a result of dyssomnia. Causes include symptoms (e.g., fever, difficulty breathing, or pain) caused by illnesses, emotional stress, medications, environmental disturbances (e.g., frequent nursing care), and variability in the timing of sleep because of shift work. Physicians and nurses are particularly prone to sleep deprivation as a result of long work schedules and rotating shifts. Chronic sleep deprivation is associated with development of cardiovascular disease, weight gain, type II diabetes, poor memory, depression, and digestive problems (Redeker and McEnany, 2011).

Hospitalization, especially in intensive care units (ICUs), makes patients particularly vulnerable to the extrinsic and circadian sleep disorders that cause the "ICU syndrome of sleep deprivation" (Fontana and Pittiglio, 2010). Constant environmental stimuli within the ICU such as strange noises from equipment, the frequent monitoring and care given by nurses, and ever-present lights confuse patients. Repeated environmental stimuli and the patient's poor physical status lead to sleep deprivation (Fontana and Pittiglio, 2010).

A person's response to sleep deprivation is highly variable. Patients experience a variety of physiological and psychological symptoms (Box 43-3). The severity of symptoms is often related to the duration of sleep deprivation.

Parasomnias. The parasomnias are sleep problems that are more common in children than adults. Some have hypothesized that sudden infant death syndrome (SIDS) is thought to be related to apnea, hypoxia, and cardiac arrhythmias caused by abnormalities in the autonomic nervous system that are manifested during sleep (Kryger et al., 2011). Because of an association between the prone position and the occurrence of SIDS, the American Academy of Pediatrics recommends that parents place apparently healthy infants in the supine position during sleep (Koren et al., 2010).

Parasomnias that occur among older children include somnambulism (sleepwalking), night terrors, nightmares, nocturnal enuresis (bed-wetting), body rocking, and bruxism (teeth grinding). When adults have these problems, it often indicates more serious disorders. Specific treatment varies. However, in all cases it is important to support patients and maintain their safety.

BOX 43-3   Sleep-Deprivation Symptoms

Physiological Symptoms
- Ptosis, blurred vision
- Fine-motor clumsiness
- Decreased reflexes
- Slowed response time
- Decreased reasoning and judgment
- Decreased auditory and visual alertness
- Cardiac arrhythmias

Psychological Symptoms
- Confused and disoriented
- Increased sensitivity to pain
- Irritable, withdrawn, apathetic
- Agitated
- Hyperactive
- Decreased motivation
- Excessive sleepiness

NURSING KNOWLEDGE BASE

Sleep and Rest

When people are at **rest,** they usually feel mentally relaxed, free from anxiety, and physically calm. Rest does not imply inactivity, although everyone often thinks of it as settling down in a comfortable chair or lying in bed. When people are at rest, they are in a state of mental, physical, and spiritual activity that leaves them feeling refreshed, rejuvenated, and ready to resume the activities of the day. People have their own habits for obtaining rest and can find ways to adjust to new environments or conditions that affect the ability to rest. They rest by reading a book, practicing a relaxation exercise, listening to music, taking a long walk, or sitting quietly.

Illness and unfamiliar health care routines easily affect the usual rest and sleep patterns of people entering a hospital or other health care facility. Nurses frequently care for patients who are on bed rest to reduce physical and psychological demands on the body in a variety of health care settings. However, these people do not necessarily feel rested. Some still have emotional worries that prevent complete relaxation. For example, concern over physical limitations or a fear of being unable to return to their usual lifestyle causes such patients to feel stressed and unable to relax. You must always be aware of a patient's need for rest. A lack of rest for long periods causes illness or worsening of existing illness.

Normal Sleep Requirements and Patterns

Sleep duration and quality vary among people of all age-groups. For example, one person feels adequately rested with 4 hours of sleep, whereas another requires 10 hours. Nurses play an important role in identifying treatable sleep-deprivation problems.

Neonates. The neonate up to the age of 3 months averages about 16 hours of sleep a day, sleeping almost constantly during the first week. The sleep cycle is generally 40 to 50 minutes with wakening occurring after one to two sleep cycles. Approximately 50% of this sleep is REM sleep, which stimulates the higher brain centers. This is essential for development because the neonate is not awake long enough for significant external stimulation.

Infants. Infants usually develop a nighttime pattern of sleep by 3 months of age. The infant normally takes several naps during the day but usually sleeps an average of 8 to 10 hours during the night for a total daily sleep time of 15 hours. About 30% of sleep time is in the REM cycle. Awakening commonly occurs early in the morning, although it is not unusual for an infant to wake up during the night.

Toddlers. By the age of 2 children usually sleep through the night and take daily naps. Total sleep averages 12 hours a day. After 3 years of age children often give up daytime naps (Hockenberry and Wilson, 2015). It is common for toddlers to awaken during the night. The percentage of REM sleep continues to fall. During this period toddlers may be unwilling to go to bed at night because they need autonomy or fear separation from their parents.

Preschoolers. On average a preschooler sleeps about 12 hours a night (about 20% is REM). By the age of 5 he or she rarely takes daytime naps except in cultures in which a siesta is the custom (Hockenberry and Wilson, 2015). The preschooler usually has difficulty relaxing or quieting down after long, active days and has bedtime fears, awakens during the night, or has nightmares. Partial awakening followed by normal return to sleep is frequent (Hockenberry and

Wilson, 2015). In the awake period the child exhibits brief crying, walking around, unintelligible speech, sleepwalking, or bed-wetting.

School-Age Children. The amount of sleep needed varies during the school years. A 6-year-old averages 11 to 12 hours of sleep nightly, whereas an 11-year-old sleeps about 9 to 10 hours (Hockenberry and Wilson, 2015). The 6- or 7-year-old usually goes to bed with some encouragement or by doing quiet activities. The older child often resists sleeping because he or she is unaware of fatigue or has a need to be independent.

Adolescents. On average the majority of teenagers get about 7 hours or less of sleep per night (National Sleep Foundation, 2014d). The typical adolescent is subject to a number of changes such as school demands, after-school social activities, and part-time jobs, which reduce the time spent sleeping (Wiggins and Freeman, 2014). Adolescents typically have electronic devices such as televisions, computers, smartphones, or video games in their rooms, which further contribute to sleep disruption, poor sleep quality, and decreased amount of sleep (National Sleep Foundation, 2014d). Shortened sleep time often results in EDS, which frequently leads to reduced performance in school, vulnerability to accidents, behavior and mood problems, and increased use of alcohol (Wiggins and Freeman, 2014).

Young Adults. Most young adults average 6 to 8½ hours of sleep a night. Approximately 20% of sleep time is REM sleep, which remains consistent throughout life. It is common for the stresses of jobs, family relationships, and social activities to frequently lead to insomnia and the use of sleep medication. Daytime sleepiness contributes to an increased number of accidents, decreased productivity, and interpersonal problems in this age-group.

Pregnancy increases the need for sleep and rest. However, a majority of pregnant women describe variations in sleep habits (Redeker and McEnany, 2011). Increases in estrogen and progesterone during pregnancy affect sleep. Estrogen has been shown to decrease REM sleep (Redeker and McEnany, 2011). First-trimester sleep disturbances include a reduction in overall sleep time and quality. Daytime drowsiness, insomnia, and nighttime awakenings also increase because of frequent nocturnal voiding. These disturbances level off in the second trimester (Redeker and McEnany, 2011). Insomnia, periodic limb movements, RLS, and sleep-disordered breathing are common problems during the third trimester of pregnancy (Kryger et al., 2011).

Middle Adults. During middle adulthood the total time spent sleeping at night begins to decline. The amount of stage 4 sleep begins to fall, a decline that continues with advancing age. Insomnia is particularly common, probably because of the changes and stresses of middle age. Anxiety, depression, or certain physical illnesses cause sleep disturbances. Women experiencing menopausal symptoms often experience insomnia.

Older Adults. Complaints of sleeping difficulties increase with age. Older adults experience weakening, desynchronized circadian rhythms that alter the sleep-wake cycle (Neikrug and Ancoli-Israel, 2010). Episodes of REM sleep tend to shorten. Stages 3 and 4 NREM sleep progressively decrease; some older adults have almost no stage 4, or deep sleep. An older adult awakens more often during the night, and it takes more time for him or her to fall asleep. The tendency to nap seems to increase progressively with age because of the frequent awakenings experienced at night.

The presence of chronic illness often results in sleep disturbances for the older adult. For example, an older adult with arthritis frequently has difficulty sleeping because of painful joints. Changes in sleep pattern are often caused by changes in the CNS that affect the regulation of sleep. Many older adults with insomnia have co-morbid psychiatric illness or medical conditions, take medications that disrupt sleep patterns, or use drugs or alcohol (Fiorentino and Martin, 2010). Sensory impairment reduces an older person's sensitivity to time cues that maintain circadian rhythms.

Factors Influencing Sleep

A number of factors affect the quantity and quality of sleep. Often a single factor is not the only cause for a sleep problem. Physiological, psychological, and environmental factors frequently alter the quality and quantity of sleep.

Drugs and Substances. Sleepiness, insomnia, and fatigue often result as a direct effect of commonly prescribed medications (Box 43-4). These medications alter sleep and weaken daytime alertness, which is problematic (Kryger et al., 2011). Medications prescribed for sleep often cause more problems than benefits. Older adults take a variety of drugs to control or treat chronic illness, and the combined effects of their drugs often seriously disrupt sleep. Some substances such as L-tryptophan, a natural protein found in foods such as milk, cheese, and meats, promote sleep.

Lifestyle. A person's daily routine influences sleep patterns. An individual working a rotating shift (e.g., 2 weeks of days followed by a

---

BOX 43-4   Drugs and Their Effects on Sleep

Hypnotics
- Interfere with reaching deeper sleep stages
- Provide only temporary (1-week) increase in quantity of sleep
- Eventually cause "hangover" during day; excess drowsiness, confusion, decreased energy
- Sometimes worsen sleep apnea in older adults

Antidepressants and Stimulants
- Suppress REM sleep
- Decrease total sleep time

Alcohol
- Speeds onset of sleep
- Reduces REM sleep
- Awakens person during night and causes difficulty returning to sleep

Caffeine
- Prevents person from falling asleep
- Causes person to awaken during night
- Interferes with REM sleep

Diuretics
- Nighttime awakenings caused by nocturia

Beta-Adrenergic Blockers
- Cause nightmares
- Cause insomnia
- Cause awakening from sleep

Benzodiazepines
- Alter REM sleep
- Increase sleep time
- Increase daytime sleepiness

Nicotine
- Decreases total sleep time
- Decreases REM sleep time
- Causes awakening from sleep
- Causes difficulty staying asleep

Opiates
- Suppress REM sleep
- Cause increased daytime drowsiness

Anticonvulsants
- Decrease REM sleep time
- Cause daytime drowsiness

REM, Rapid eye movement.

week of nights) often has difficulty adjusting to the altered sleep schedule. For example, the body's internal clock is set at 11 PM, but the work schedule forces sleep at 9 AM instead. The individual is able to sleep only 3 or 4 hours because his or her body clock perceives that it is time to be awake and active. Difficulties maintaining alertness during work time result in decreased and even hazardous performance. After several weeks of working a night shift, a person's biological clock usually does adjust. Other alterations in routines that disrupt sleep patterns include performing unaccustomed heavy work, engaging in late-night social activities, and changing evening mealtime.

Usual Sleep Patterns. In the past century the amount of sleep obtained nightly by U.S. citizens has decreased, causing many Americans to be sleep deprived and experience excessive sleepiness during the day. Sleepiness becomes pathological when it occurs at times when individuals need or want to be awake. People who experience temporary sleep deprivation as a result of an active social evening or lengthened work schedule usually feel sleepy the next day. However, they are able to overcome these feelings even though they have difficulty performing tasks and remaining attentive. Chronic lack of sleep is much more serious and causes serious alterations in the ability to perform daily functions. Sleepiness tends to be most difficult to overcome during sedentary (inactive) tasks such as driving.

Emotional Stress. Worry over personal problems or a situation frequently disrupts sleep. Emotional stress causes a person to be tense and often leads to frustration when sleep does not occur. Stress also causes a person to try too hard to fall asleep, to awaken frequently during the sleep cycle, or to oversleep. Continued stress causes poor sleep habits.

Older patients frequently experience losses that lead to emotional stress such as retirement, physical impairment, or the death of a loved one. Older adults and other individuals who experience depressive mood problems experience delays in falling asleep, earlier appearance of REM sleep, frequent or early waking, feelings of sleeping poorly, and daytime sleepiness (National Sleep Foundation, 2014c).

Environment. The physical environment in which a person sleeps significantly influences the ability to fall and remain asleep. Good ventilation is essential for restful sleep. The size, firmness, and position of the bed affect the quality of sleep. If a person usually sleeps with another individual, sleeping alone often causes wakefulness. On the other hand, sleeping with a restless or snoring bed partner disrupts sleep.

In hospitals and other inpatient facilities, noise creates a problem for patients. Noise in hospitals is usually new or strange and often loud. Thus patients wake easily. This problem is greatest the first night of hospitalization, when patients often experience increased total wake time, increased awakenings, and decreased REM sleep and total sleep time. People-induced noises (e.g., nursing activities) are sources of increased sound levels. ICUs are sources of high noise levels because of staff, monitor alarms, and equipment. Close proximity of patients, noise from confused and ill patients, ringing alarm systems and telephones, and disturbances caused by emergencies make the environment unpleasant. Noise causes increased agitation; delayed healing; impaired immune function; and increased blood pressure, heart rate, and stress (Dennis et al., 2010).

Light levels affect the ability to fall asleep. Some patients prefer a dark room, whereas others such as children or older adults prefer keeping a soft light on during sleep. Patients also have trouble sleeping because of the room temperature. A room that is too warm or too cold often causes a patient to become restless.

Exercise and Fatigue. A person who is moderately fatigued usually achieves restful sleep, especially if the fatigue is the result of enjoyable work or exercise. Exercising 2 hours or more before bedtime allows the body to cool down and maintain a state of fatigue that promotes relaxation. However, excess fatigue resulting from exhausting or stressful work makes falling asleep difficult. This is often seen in grade-school children and adolescents who keep stressful, long schedules because of school, social activities, and work.

Food and Caloric Intake. Following good eating habits is important for proper sleep. Eating a large, heavy, and/or spicy meal at night often results in indigestion that interferes with sleep. Caffeine, alcohol, and nicotine consumed in the evening produce insomnia. Coffee, tea, cola, and chocolate contain caffeine and xanthines that cause sleeplessness. Thus drastically reducing or avoiding these substances can improve sleep. Some food allergies cause insomnia. A milk allergy sometimes causes nighttime waking and crying or colic in infants.

Weight loss or gain influences sleep patterns. Weight gain contributes to OSA because of increased size of the soft tissue structures in the upper airway (Kryger et al., 2011). Weight loss causes insomnia and decreased amounts of sleep (Ross et al., 2011). Certain sleep disorders are the result of the semi-starvation diets popular in a weight-conscious society.

CRITICAL THINKING

Successful critical thinking requires a synthesis of knowledge, including information gathered from patients, experience, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require you to anticipate the information necessary, analyze the data, and make decisions regarding patient care. You adapt critical thinking to the changing needs of the patient. During assessment consider all elements to make appropriate nursing diagnoses (Figure 43-3).

In the case of sleep, integrate knowledge from nursing and disciplines such as pharmacology and psychology. Personal experience with a sleep problem and experience with patients prepares you to know effective forms of sleep therapies. You use critical thinking attitudes such as perseverance, confidence, and discipline to complete a comprehensive assessment and develop a plan of care to provide successful management of the sleep problem. Professional standards such as the *Nursing Scope and Standards of Practice* (American Nurses Association, 2010), *Clinical Guidelines for the Treatment of Primary Insomnia* (National Guideline Clearinghouse, 2014), and "Excessive Sleepiness" in *Evidence-based Geriatrics Nursing Protocols for Best Practice* (Chasens and Umlauf., 2012) provide valuable guidelines to assess and address the needs of patients with sleep disorders.

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in the care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care.

◆ Assessment

During the assessment process thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care.

Through the Patient's Eyes. Sleep is a subjective experience. Only the patient is able to report whether or not it is sufficient and

Knowledge
- Sleep cycle physiology
- Pathophysiology and clinical signs of sleep disturbances
- Factors that potentially affect a person's ability to sleep
- Pharmacological agents' effects on sleep
- A normal sleep pattern
- Cultural variations in sleep patterns

Experience
- Caring for patients with chronic sleep problems
- Caring for patients experiencing acute sleep disturbances in a health care setting
- Personal experience with acute or chronic sleep disruption

ASSESSMENT
- Determine the patient's usual and current sleep pattern
- Review factors affecting the patient's sleep
- Assess the patient's response to sleep disturbance
- Assess the patient's developmental level
- Explore the patient's approaches to improve sleep in the home

Standards
- Apply intellectual standards (e.g., clarity, accuracy, completeness) when gathering a sleep history
- Apply *Standards of Clinical Practice* for promoting sleep in a specific health care setting
- Apply standards from National Guideline Clearinghouse and other evidence-based sources

Attitudes
- Display perseverance in exploring causes and possible solutions to long-term sleep problems
- Use creativity in assessment to reveal a more thorough picture of the patient's sleep problem
- Explore the patient's thoughts about possible causes of the problem

FIGURE 43-3 Critical thinking model for sleep assessment.

restful. If the patient is satisfied with the quantity and quality of sleep received, you consider it normal, and the nursing history that you will collect is brief. If a patient admits to or suspects a sleep problem, you will need a detailed history and assessment. If a patient has an obvious sleep problem, consider asking if his or her sleep partner can be approached for further assessment data.

A poor night's sleep for a patient often starts a vicious cycle of anticipatory anxiety. The patient fears that sleep will again be disturbed while trying harder and harder to sleep. Use a skilled and caring approach to assess the patient's sleep needs. A caring nurse individualizes care for each patient. Always ask patients what they expect regarding sleep. This includes asking about the interventions that they currently use and how successful they are. It is important to understand patients' expectations regarding their sleep pattern. When they ask for help because of sleep disturbances, they typically expect a nurse to respond promptly to help them improve the quantity and quality of their sleep.

Sleep Assessment. Most people are able to provide a reasonably accurate estimate of their sleep patterns, particularly if any changes

have occurred. Aim your assessment at first understanding the characteristics of the patient's sleep problem and usual sleep habits so you incorporate ways for promoting sleep into nursing care. For example, if the nursing history reveals that a patient always reads before falling asleep, it makes sense to offer reading material at bedtime.

Sources for Sleep Assessment. Usually patients are the best resource for describing sleep problems and how they are a change from their usual sleep and waking patterns. Often the patient knows the cause for sleep problems such as a noisy environment or worry over a relationship.

In addition, bed partners are able to provide information about patients' sleep patterns that help reveal the nature of certain sleep disorders. For example, partners of patients with sleep apnea often complain that the patient's snoring disturbs their sleep. Ask bed partners (if the patient agrees) whether patients have breathing pauses during sleep and how frequently the apneic attacks occur. Some partners mention becoming fearful when patients apparently stop breathing for periods.

When caring for children, seek information about sleep patterns from parents or guardians because they are usually a reliable source of information. Hunger, excessive warmth, and separation anxiety often contribute to an infant's difficulty going to sleep or frequent awakenings during the night. Parents of infants need to keep a 24-hour log of their infant's waking and sleeping behavior for several days to determine the cause of the problem. They also need to describe the infant's eating pattern and sleeping environment because these influence sleeping behavior. Older children often are able to relate fears or worries that inhibit their ability to fall asleep. If children frequently awaken in the middle of bad dreams, parents are able to identify the problem but perhaps do not understand the meaning of the dreams. Ask parents to describe the typical behavior patterns that foster or impair sleep. For example, excessive stimulation from active play or visiting friends predictably impairs sleep. With chronic sleep problems, parents need to relate the duration of the problem, its progression, and children's responses.

Tools for Sleep Assessment. Two effective subjective measures of sleep are the Epworth Sleepiness Scale and the Pittsburgh Sleep Quality Index. The Epworth Sleepiness Scale evaluates the severity of EDS (Chasens and Umlauf, 2012). The Pittsburgh Sleep Quality Index assesses sleep quality and patterns (Redeker and McEnany, 2011). Another effective, brief method for assessing sleep quality is the use of a visual analog scale. Draw a straight horizontal line 100 mm (4 inches) long. Opposing statements such as "best night's sleep" and "worst night's sleep" are at opposite ends of the line. Ask patients to place a mark on the horizontal line at the point corresponding to their perceptions of the previous night's sleep. Measuring the distances of the mark along the line in millimeters offers a numerical value for satisfaction with sleep. Use the scale repeatedly to show change over time. Such a scale is useful to assess an individual patient, not to compare patients.

Another brief subjective method to assess sleep is a numeric scale with a 0-to-10 sleep rating. Ask individuals to separately rate the quantity and quality of their sleep on the scale. Instruct them to indicate with a number between 0 and 10 their sleep quantity and then their quality of sleep, with 0 being the worst sleep and 10 being the best.

Sleep History. When suspecting a patient has a sleep problem, assess the quality and characteristics of sleep in greater depth by asking the patient to describe the problem. This includes recent changes in sleep pattern, sleep symptoms experienced during waking hours, use of sleep and other prescribed or over-the-counter medications, diet

BOX 43-5 Nursing Assessment Questions

Nature of the Problem
- Describe for me the type of sleep problem you're having.
- Why do you think you're not getting enough sleep?
- Describe a recent night's sleep. How is this sleep different from your usual sleep?

Signs and Symptoms
- Do you have difficulty falling asleep, staying asleep, or waking up?
- Have you been told that you snore loudly?
- Do you have headaches when awakening?

Onset and Duration of Signs and Symptoms
- When did you notice the problem?
- What do you do to relieve the symptom?
- How long has this problem lasted?

Severity
- How long does it take you to fall asleep?
- How often during the week do you have trouble falling asleep?
- How many hours of sleep a night did you get this week?
- How does this compare to your usual amount of sleep?
- What do you do when you awaken during the night or too early in the morning?

Predisposing Factors
- What do you do just before you go to bed?
- Have you recently had any changes at work or at home?
- How is your mood? Have you noticed any changes recently?
- Which medications or recreational drugs do you take on a regular basis?
- Are you taking any new prescriptions or over-the-counter medications?
- Do you eat food (spicy or greasy foods) or drink substances (alcohol or caffeinated beverages) that affect your sleep?
- Do you have a physical illness that affects your sleep?
- Does anyone in your family have a history of sleep problems?

Effect on Patient
- How has the loss of sleep affected you?
- Do you feel excessively sleepy or irritable or have trouble concentrating during waking hours?
- Do you have trouble staying awake? Have you fallen asleep at the wrong times (e.g., while driving, sitting quietly in a meeting)?

BOX 43-6 Questions to Ask to Assess for Specific Sleep Disorders

Insomnia
- How easily do you fall asleep?
- Do you fall asleep and have difficulty staying asleep? How many times do you awaken?
- What time do you awaken in the morning? What causes you to awaken early?
- What do you do to prepare for sleep? To improve your sleep?
- What do you think about as you try to fall asleep?
- How often do you have trouble sleeping?

Sleep Apnea
- Do you snore loudly? Does anyone else in your family snore loudly?
- Has anyone ever told you that you often stop breathing for short periods during sleep? (Spouse or bed partner/roommate may report this.)
- Do you experience headaches after awakening?
- Do you have difficulty staying awake during the day?

Narcolepsy
- Do you fall asleep at the wrong times? (Friends or relatives may report this.)
- Do you have episodes of losing muscle control or falling to the floor?
- Have you ever had the feeling of being unable to move or talk just before waking or falling asleep?
- Do you have vivid, lifelike dreams when going to sleep or awakening?

and intake of substances such as caffeine or alcohol that influence sleep, and recent life events that have affected the patient's mental and emotional status.

Description of Sleeping Problems. Conduct a more detailed history when a patient has a persistent or what appears to be a serious sleep problem. Open-ended questions help a patient describe a problem more fully. A general description of the problem followed by more focused questions usually reveals specific characteristics that are useful in planning therapies. To begin, you need to understand the nature of the sleep problem, its signs and symptoms, its onset and duration, its severity, any predisposing factors or causes, and the overall effect on the patient. Ask specific questions related to the sleep problem (Box 43-5).

Proper questioning helps to determine the type of sleep disturbance and the nature of the problem. Box 43-6 gives examples of additional questions for you to ask a patient when you suspect specific sleep disorders. The questions help to select specific sleep therapies and the best time for implementation.

As an adjunct to the sleep history, have the patient and bed partner keep a sleep-wake log for 1 to 4 weeks. The patient completes the sleep-wake log daily to provide information on day-to-day variations in sleep-wake patterns over extended periods. Entries in the log often include 24-hour information about various waking and sleeping health behaviors such as physical activities, mealtimes, type and amount of intake (alcohol and caffeine), time and length of daytime naps, evening and bedtime routines, the time the patient tries to fall asleep, nighttime awakenings, and the time of morning awakening. A partner helps record the estimated times the patient falls asleep or awakens. Although the log is helpful, the patient needs to be motivated to participate in its completion.

Usual Sleep Pattern. Normal sleep is difficult to define because individuals vary in their perception of adequate quantity and quality of sleep. However, it is important to have patients describe their usual sleep pattern to determine the significance of the changes caused by a sleep disorder. Knowing a patient's usual, preferred sleep pattern allows you to try to match sleeping conditions in a health care setting with those in the home. Ask the following questions to determine a patient's sleep pattern:

1. What time do you usually get in bed each night?
2. How much time does it usually take to fall asleep? Do you do anything special to help you fall asleep?
3. How many times do you wake up during the night? Why?
4. What time do you typically wake up in the morning?
5. On average, how many hours do you sleep each night?

Compare patient data with their pattern before the sleep problem or with the predominant pattern usually found for other patients of the same age. On the basis of this comparison, you begin to assess for identifiable patterns such as insomnia.

Patients with sleep problems frequently show patterns drastically different from their usual one, or sometimes the change is relatively minor. Hospitalized patients usually need or want more sleep as a result of illness. However, some require less sleep because they are less

active. Some patients who are ill think that it is important to try to sleep more than usual, eventually making sleeping difficult.

Physical and Psychological Illness. Determine whether the patient has any preexisting health problems that interfere with sleep. A history of psychiatric problems also makes a difference. For example, a patient who is living with bipolar disorder sleeps more when depressed than when manic. A patient who is depressed often experiences an inadequate amount of fragmented sleep. Chronic diseases such as chronic obstructive pulmonary disease and painful disorders such as arthritis interfere with sleep. Also assess the patient's medication history, including a description of over-the-counter and prescribed drugs. If a patient takes medications to aid sleep, gather information about the type and amount of medication and frequency used. Also assess the patient's daily caffeine intake.

If the patient has recently had surgery, expect him or her to experience some sleep disturbance. Patients usually awaken frequently during the first night after surgery and receive little deep or REM sleep. Depending on the type of surgery, it takes several days to months for a normal sleep cycle to return.

Current Life Events. In your assessment learn if the patient is experiencing any changes in lifestyle that disrupt sleep. A person's occupation often offers a clue to the nature of the sleep problem. Changes in job responsibilities, rotating shifts, or long hours contribute to a sleep disturbance. Questions about social activities, recent travel, or mealtime schedules help clarify the assessment.

Emotional and Mental Status. A patient's emotions and mental status affect the ability to sleep. For example, if a patient is experiencing anxiety, emotional stress related to illness, or situational crises such as loss of job or a loved one, he or she often experiences insomnia. When a sleep disturbance is related to an emotional problem, the key is to treat the primary problem; its resolution often improves sleep (Chasens and Umlauf, 2012). Patients with mental illnesses may need mild sedation for adequate rest. Assess the effectiveness of any medication and its effect on daytime function.

Bedtime Routines. Ask patients what they do to prepare for sleep. For example, some patients drink a glass of milk, take a sleeping pill, eat a snack, or watch television. Assess habits that are beneficial compared with those that disturb sleep. For example, watching television promotes sleep for one person, whereas it stimulates another to stay awake. Sometimes pointing out that a particular habit is interfering with sleep helps patients find ways to change or eliminate habits that are disrupting sleep.

Pay special attention to a child's bedtime rituals. For example, the parents need to report whether it is necessary to read a bedtime story, rock the child to sleep, or engage in quiet play. Some young children need a special blanket or stuffed animal when going to sleep.

Bedtime Environment. During assessment ask the patient to describe preferred bedroom conditions, including preferences for lighting in the room, music or television in the background, or needing to have the door open versus closed. Include questions about the presence of electronic devices in the bedroom (e.g., phones, televisions), all of which have small lights that remain on or have a light that blinks when the battery is low. Patients are often surprised how many of these devices are in the sleeping environment.

In addition, some children need the company of a parent to fall asleep. In a health care environment environmental distractions such as a roommate's television, an electronic monitor in the hallway, a noisy nurses' station, or another patient who cries out at night often interfere with sleep. Identify those factors to reduce or control the environment.

Behaviors of Sleep Deprivation. Some patients are unaware of how their sleep problems are affecting their behavior. Observe for

---

BOX 43-7   Nursing Diagnostic Process

Insomnia

Assessment Activities	Defining Characteristics
Ask patient to explain nature of sleep problem.	Patient reports difficulty falling asleep, taking up to 1 hour. Patient reports waking up two to three times nightly with difficulty returning to sleep.
Observe patient's behavior and ask spouse if patient is experiencing behavior changes.	Patient admits to not feeling well rested. Spouse describes times when patient was lethargic and irritable.
Determine if patient has had recent lifestyle changes.	Spouse reports that patient recently lost job and is concerned about finding new position.

---

behaviors such as irritability, disorientation (similar to a drunken state), frequent yawning, and slurred speech. If sleep deprivation has lasted a long time, psychotic behavior such as delusions and paranoia sometimes develop. For example, a patient reports seeing strange objects or colors in the room, or he or she acts afraid when the nurse enters the room.

◆ **Nursing Diagnosis**

Review your assessment data, looking for clusters that include defining characteristics for a sleep pattern disturbance or other health problem. If you identify a sleep problem, specify the condition such as insomnia or sleep deprivation. By specifying the sleep disturbance diagnosis, you are able to design more effective interventions. For example, you choose different therapies for patients with insomnia who are unable to fall asleep than for those with sleep deprivation. Box 43-7 demonstrates how to use nursing assessment activities to identify and cluster defining characteristics to make an accurate nursing diagnosis.

Assessment also identifies the related factor or probable cause of a sleep disturbance such as a noisy environment or a high intake of caffeinated beverages in the evening. These causes become the focus of interventions for minimizing or eliminating a problem-focused diagnosis. For example, if a patient is experiencing insomnia as a result of a noisy health care environment, offer some basic recommendations for helping sleep such as controlling the noise of hospital equipment, reducing interruptions, or keeping doors closed. If the insomnia is related to worry over a threatened marital separation, introduce coping strategies and create an environment for sleep. If you incorrectly define the probable cause or related factors, the patient does not benefit from care.

Sleep problems affect patients in other ways. For example, you find that a patient with sleep apnea has problems with a spouse who is tired and frustrated over the patient's snoring. In addition, the spouse is concerned that the patient is breathing improperly and thus is in danger. The nursing diagnosis of *Compromised Family Coping* indicates that you need to provide support to the patient and spouse so they understand sleep apnea and obtain the medical treatment needed. Examples of nursing diagnoses for patients with sleep problems include the following:

- *Anxiety*
- *Ineffective Breathing Pattern*
- *Acute Confusion*
- *Ineffective Coping*

- *Insomnia*
- *Fatigue*
- *Disturbed Sleep Pattern*
- *Sleep Deprivation*
- *Readiness for Enhanced Sleep*

◆ Planning

Goals and Outcomes. During planning you again synthesize information from multiple resources to develop an individualized plan of care (Figure 43-4) (see the Nursing Care Plan). Professional standards are especially important to consider in developing a care plan. These standards often offer evidence-based guidelines for effective nursing interventions. For example, the *Evidence-based Geriatrics Nursing Protocols for Best Practice,* titled "Excessive Sleepiness" (Chasens and Umlauf, 2012), recommends individualized nursing interventions that maintain and support an older adult's normal sleep pattern and bedtime ritual. It is important for a plan of care for sleep promotion to include strategies appropriate to the patient's sleep routines, living environment, and lifestyle.

As you plan care for a patient with sleep disturbances, creation of a concept map is another method for developing holistic patient-centered care (Figure 43-5). Create the map after identifying relevant nursing diagnoses from the assessment database. In this example the nursing diagnoses are linked to the patient's medical diagnosis of depression and situational stress. The concept map shows the relationships among the nursing diagnoses *Insomnia, Stress Overload, Sedentary Lifestyle,* and *Readiness for Enhanced Sleep.* This approach to planning care helps the nurse recognize relationships among planned interventions. For this patient, interventions and successful outcomes for one nursing diagnosis affect the resolution of another.

When developing goals and outcomes, it is important for a nurse and patient to collaborate. As a result, you are more likely to set realistic goals and measurable outcomes with your patients. An effective plan includes outcomes established over a realistic time frame that focus on the goal of improving the quantity and quality of sleep in the home. Often family members are very helpful in contributing to the plan. A sleep-promotion plan frequently requires many weeks to accomplish. The following is an example of a goal with patient outcomes:

Goal: The patient will control environmental sources disrupting sleep within 1 month.

Outcomes:
- Patient identifies factors in the immediate home environment that disrupt sleep in 2 weeks.
- Patient reports having a discussion with family members about environmental barriers to sleep in 2 weeks.
- Patient reports changes made in the bedroom to promote sleep within 4 weeks.
- Patient reports having fewer than two awakenings per night within 4 weeks.

Setting Priorities. Work with patients to establish priority outcomes and interventions. Frequently sleep disturbances are the result of other health problems. For example, when physical symptoms are interfering with sleep, managing the symptoms is your first priority. After symptoms are relieved, focus on sleep therapies. Patients are a helpful resource in determining which interventions hold priority. For example, once patients understand the factors that disrupt sleep, they make choices about the types of changes they would like to make in their lifestyle or sleeping environment.

Teamwork and Collaboration. Partner closely with the patient and sleep partner to ensure that any therapies such as a change in the sleep schedule or changes to the bedroom environment are realistic and achievable. In a health care setting plan treatments or routines so the patient is able to rest. For example, in the ICU use available electronic monitors to track trends in vital signs without waking a patient each hour. Other staff members need to be aware of the care plan so they can cluster activities at certain times to reduce awakenings. In a nursing home the focus of the plan involves better planning of rest periods around the activities of the other residents. Roommates often have very different schedules.

When patients have chronic sleep problems, the initial referral for a patient is often to a comprehensive sleep center for assessment of the problem. The nature of the sleep disturbance then determines whether referrals to additional health care providers are necessary. For example, if a sleep problem is related to a situational crisis or emotional problem, refer the patient to a mental health clinical nurse specialist or clinical psychologist for counseling. If the nurse works in an inpatient setting and the patient needs a referral for continued care after discharge, offering information about the sleep problem is useful to the home care nurse. The success of sleep therapy depends on an approach that fits the patient's lifestyle and the nature of the sleep disorder.

◆ Implementation

Nursing interventions designed to improve the quality of a person's rest and sleep are largely focused on health promotion. Patients need adequate sleep and rest to maintain active and productive lifestyles. During times of illness rest and sleep promotion are important for recovery. Nursing care in an acute, restorative, or continuing care

Knowledge
- Role other health professionals provide for sleep therapy
- Evidence and practice-based sleep therapies
- Adult learning principles to apply when teaching the patient and family

Experience
- Previous patient responses to planned nursing interventions for promoting sleep
- Previous experience in adapting sleep therapies to personal needs

PLANNING
- Select nursing interventions that will promote sleep in the home/health care setting
- Involve sleep partner as needed in the selection of interventions
- Consult with health professionals as needed

Standards
- Individualize sleep therapies to the patient's lifestyle and preferences
- Apply intellectual standards (e.g., relevance, completeness, and significance) when choosing sleep therapies

Attitudes
- Display confidence when selecting interventions for the patient
- Be disciplined in planning therapies; it may take time to achieve desired results
- Be creative when adapting sleep therapies to the patient's daily schedule

FIGURE 43-4 Critical thinking model for sleep planning.

⊚ NURSING CARE PLAN

Insomnia

ASSESSMENT

Julie Arnold, a 43-year-old attorney, is the first patient of the morning at the neighborhood health clinic where you work. When you ask her how she's doing, she tells you that she's having difficulty sleeping. Her physician has diagnosed that she's suffering from depression. Julie is married and has two school-age children. She also tells you that she is caring for her mother, who is staying with them currently after she was discharged from the hospital following an exacerbation of her heart failure. Julie's assessment includes a thorough sleep history and a discussion of how the sleep problem has affected her life. You also conduct a physical examination.

Assessment Activities	Findings/Defining Characteristics*
Ask Julie to explain the nature of her sleep problem.	Julie explains that she **wakes up once or twice a night.** She states, "I feel tired when I wake up, and I have trouble concentrating at work in the afternoon." She also reports that she has less patience with her children at home and no energy in the evenings.
Ask Julie if there have been any recent changes in her life.	Julie says that she is feeling pressured at work to complete an important case that she started 2 weeks ago and because of this she is working longer hours. She also reports that, because of her heavy work schedule, she has stopped her routine of walking 1 to 2 miles daily. She reports that she has no time for any exercise when she gets home because **she needs to take care of her mother and the children.**
Ask Julie to describe her bedtime routine.	Julie responds that she is **going to bed** between 12 AM and 1 AM, which is **2 hours later than her usual bedtime. It takes her an hour to fall asleep.** She says that she used to get 7 to 8 hours of sleep a night and now **it is more like 5 to 6 hours.** She drinks two to three cups of coffee after dinner while she is working on her case before bedtime.
Assess Julie for physical signs of sleep problems.	During the examination you note that Julie has dark circles under her eyes; she shifts her position in the chair multiple times and yawns frequently. She admits to **fatigue.**

***Defining characteristics** are shown in bold type.

NURSING DIAGNOSIS: Insomnia related to psychological stress from job pressures

PLANNING

Goals	Expected Outcomes (NOC)†
	Sleep
Patient will achieve an improved sense of adequate sleep within 4 weeks.	Patient reports waking up less frequently during the night and feeling rested within 4 weeks.
	Patient verbalizes adherence to a regular bedtime routine within 4 weeks.
Patient will achieve a more normal sleep pattern within 4 weeks.	Patient falls asleep within 30 minutes of going to bed within 4 weeks.
	Patient reports sleeping 7 hours nightly within 4 weeks.

†Outcome classification labels from Moorhead S et al: *Nursing outcomes classification (NOC),* ed 5, St Louis, 2013, Mosby.

INTERVENTIONS (NIC)‡	RATIONALE
Sleep Enhancement	
Encourage patient to establish a bedtime routine and a regular sleep pattern.	Maintaining a consistent schedule helps induce sleep (National Guideline Clearinghouse, 2014).
Instruct patient to avoid caffeine and nicotine before bedtime.	Caffeine and nicotine are stimulants and cause difficulty falling asleep.
Help patient identify ways to eliminate stressful concerns about work before bedtime (e.g., taking time before actual sleep to read a light novel).	Excess worry and intense activities before bedtime stimulate patient and prevent sleep (Redeker and McEnany, 2011).
Adjust environment; have patient control noise, temperature, and light in the bedroom.	Develop an environment conducive to sleep (Flynn Makic et al., 2014).
Exercise Promotion	
Encourage patient to begin walking routinely during the day but not 2 to 3 hours before bedtime.	Regular exercise increases activity levels and improves sleep quality. Exercise just before bedtime is a stimulant that prevents sleep (Redeker and McEnany, 2011).
Relaxation Therapy	
Teach patient how to perform muscle relaxation before bedtime; include demonstration.	Relaxation therapy helps reduce anxiety, which interferes with sleep (National Guideline Clearinghouse, 2014; National Sleep Foundation 2014b).

‡Intervention classification labels from Bulechek GM, et al: *Nursing interventions classification (NIC),* ed 6, St Louis, 2013, Mosby.

EVALUATION

Nursing Actions	Patient Response/Finding	Achievement of Outcome
Ask Julie if she is able to fall asleep and stay asleep.	Julie responds, "It usually takes 15 to 20 minutes to fall asleep; last week, on two separate nights, I only woke up once each night."	Julie reports that she falls asleep within 30 minutes and wakes up less frequently during the night.
Ask Julie to describe her waking behaviors at work and home during the day.	Julie responds that she has completed her case at work and feels less pressure. She has restarted her walking routine and is better able to cope with her children. She is able to concentrate at work more.	Julie reports feeling more rested.
Observe Julie's waking nonverbal expressions and behavior.	Julie sits in the chair without shifting position. She does not yawn during the conversation. The dark circles under her eyes are almost gone.	Julie reports that she is sleeping an average of 7 hours a night.

CONCEPT MAP

Nursing diagnosis: Insomnia
- Takes an hour to fall asleep
- Goes to bed 2 hours later than usual
- Reports feeling fatigued

▼

Interventions
- Have patient keep a sleep log for a week
- Teach patient sleep hygiene measures
- Teach patient relaxation techniques to use to induce sleep
- Encourage patient to drink a cup of chamomile tea or warm milk at bedtime

Nursing diagnosis: Sedentary lifestyle
- Has stopped her routine of walking daily
- Has no time to walk because of longer work hours

▼

Interventions
- Help patient develop a plan for exercise
- Instruct patient to keep an exercise log
- Encourage patient to have children assist with her mother so she can walk at night
- Provide positive reinforcement for increased exercise

Primary health problem: Depression, situational stress
Priority assessments: Sleep history, usual bedtime routine, stress levels, physiological manifestations of stress

Nursing diagnosis: Stress overload
- Working longer hours on an important case at work
- Caring for mother in her home
- Has less patience with her children
- Reports difficulty sleeping and feelings of fatigue

▼

Interventions
- Help patient identify situations that produce anxiety and stress
- Encourage patient to set a schedule with her family so they can provide support and assistance with her mother
- Use active listening when talking to patient
- Encourage patient to verbalize her feelings
- Encourage patient to participate in family activities

Nursing diagnosis: Fatigue
- States feels tired when she wakes up
- Has trouble concentrating at work in the afternoon
- Has dark circles under eyes
- Yawns frequently

▼

Interventions
- Instruct patient to contact health care provider if fatigue persists after sleep improves
- Encourage short naps if possible
- Plan rest periods to balance with activities

——— Link between medical diagnosis and nursing diagnosis   - - - - - Link between nursing diagnoses

FIGURE 43-5 Concept map for Julie Arnold.

setting differs from that provided in a patient's home. The primary differences are in the environment and the nurse's ability to support normal rest and sleep habits. A patient's age also influences the types of therapies that are most effective. Box 43-8 provides principles for promoting sleep in older patients.

Health Promotion. In community health and home settings help patients develop behaviors conducive to rest and relaxation. To develop good sleep habits at home, patients and their bed partners need to learn techniques that promote sleep and conditions that interfere with

it (Kryger et al., 2011) (Box 43-9). Parents also learn how to promote good sleep habits for their children. Patients benefit most from instructions based on information about their homes and lifestyles such as which type of activities promote sleep in a night-shift worker or how to make the home environment more conducive to sleep. They will more likely apply information that is useful and valued.

Environmental Controls. All patients require a sleeping environment with a comfortable room temperature and proper ventilation, minimal sources of noise, a comfortable bed, and proper lighting (National Heart, Lung, and Blood Institute, 2011). Children and adults

BOX 43-8 FOCUS ON OLDER ADULTS

Promoting Sleep

Sleep-Wake Pattern
- Maintain a regular bedtime and wake-up schedule (Rybarczyk et al., 2013).
- Eliminate naps unless they are a routine part of the schedule.
- If naps are taken, limit to 20 minutes or less twice a day (Touhy and Jett, 2014).
- Go to bed when sleepy.
- Use warm bath and relaxation techniques (Touhy and Jett, 2014).
- If unable to sleep in 15 to 30 minutes, get out of bed.
- Avoid stimulating activities such as exercise or watching television before bedtime (Chasens and Umlauf, 2012).

Environment
- Sleep where you sleep best.
- Keep noise to minimum; use soft music to mask it if necessary.
- Use night-light and keep path to bathroom free of obstacles.
- Set room temperature to preference; use socks to promote warmth.
- Listen to relaxing music (Touhy and Jett, 2014).
- Increase exposure to bright light during the day (Chasens and Umlauf, 2012).

Medications
- Use sedatives and hypnotics with caution as last resort and then only short term if absolutely necessary (Kryger et al., 2011).
- Adjust medications being taken for other conditions and assess for drug interactions that may cause insomnia or excessive daytime sleepiness.

Diet
- Limit alcohol, caffeine, and nicotine in late afternoon and evening (Touhy and Jett, 2014).
- Consume carbohydrates or milk as a light snack before bedtime (Touhy and Jett, 2014).
- Decrease fluids 2 to 4 hours before sleep (Touhy and Jett, 2014).

Physiological/Illness Factors
- Elevate head of bed and provide extra pillows as preferred (Townsend-Roccichelli et al., 2010).
- Use analgesics 30 minutes before bed to ease aches and pains.
- Use therapeutics to control symptoms of chronic conditions as prescribed (Chasens and Umlauf, 2012).

BOX 43-9 PATIENT TEACHING

Sleep-Hygiene Habits

Objective
- Patient will follow proper sleep-hygiene habits at home.

Teaching Strategies
- Instruct patient to try to exercise daily, preferably in the morning or afternoon, and to avoid vigorous exercise in the evening within 2 hours of bedtime.
- Caution patient against sleeping long hours during weekends or holidays to prevent disturbance of normal sleep-wake cycle.
- Explain that, if possible, patients should not use the bedroom for intensive studying, snacking, television watching, or other nonsleep activity besides sex.
- Encourage patients to try to avoid worrisome thinking when going to bed and to use relaxation exercises.
- If patient does not fall asleep within 30 minutes of going to bed, advise him or her to get out of bed and do some quiet activity until feeling sleepy enough to go back to bed.
- Recommend that patient limit caffeine to morning coffee and limit alcohol intake (more than one to two drinks a day interrupts sleep cycle).
- Ask patient to examine environment. Instruct that use of earplugs and eyeshades may be helpful.
- Instruct patient to avoid heavy meals 3 hours before bedtime; a light snack may help.

Evaluation
- Have patient complete sleep-wake log for 1 week and compare it with previous sleep-wake log.
- Ask patient to periodically complete visual analog or sleep-rating scale for perceptions of quality of sleep.

vary more in regard to comfortable room temperature. Instruct parents to place the infant on a firm mattress that is covered by a fitted sheet that meets current safety standards; to clothe the baby in a sleeper for warmth; to not place pillows, quilts, toys, or anything in the crib; and to position the crib away from open windows or drafts (AAP, 2012). Older adults often require extra blankets or covers.

Eliminate distracting noise so the bedroom is as quiet as possible. In the home the television, telephone, or intermittent chiming of a clock often disrupts a patient's sleep. Involve the family in identifying approaches for reducing noise in the home, especially if there are several family members, all with different sleep schedules. It is also important to remember that some patients sleep with familiar inside noises such as the hum of a fan. Commercial products that produce a soothing noise such as ocean waves or rainfall create a soothing environment for sleep.

A bed and mattress need to provide support and comfortable firmness. Bed boards placed under mattresses add support. Sometimes extra pillows are important to help a person position comfortably in bed. The position of the bed in the room also makes a difference for some patients.

Patients vary in regard to the amount of light that they prefer at night. Infants and older adults sleep best in softly lit rooms. Light should not shine directly on their eyes. Small table lamps prevent total darkness. For older adults light reduces the chance of confusion and prevents falls when walking to the bathroom. If streetlights shine through windows or when patients nap during the day, heavy shades, drapes, or slatted blinds are helpful.

Promoting Bedtime Routines. Bedtime routines relax patients in preparation for sleep (Bulechek et al., 2013). It is always important for people to go to sleep when they feel tired or sleepy. Going to bed while fully awake and thinking about other things often causes insomnia and interferes with the bed as a stimulus for sleep. Newborns and infants sleep through so much of the day that a specific routine is hardly necessary. However, quiet activities such as holding them snugly in blankets, singing or talking softly, and gentle rocking help them fall asleep.

A bedtime routine (e.g., same hour for bedtime, snack, or quiet activity) used consistently helps young children avoid delaying sleep. Parents need to reinforce patterns of preparing for bedtime. Quiet activities such as reading stories, coloring, allowing children to sit in a parent's lap while listening to music or listening to a prayer are routines that are often associated with preparing for bed.

Adults need to avoid excessive mental stimulation just before bedtime. Reading a light novel, watching an enjoyable television program, or listening to music helps a person relax. Relaxation exercises such as slow, deep breathing for 1 or 2 minutes relieve tension and prepare the body for rest (see Chapter 44). Guided imagery and praying also promote sleep for some patients.

At home discourage patients from trying to finish office work or resolve family problems before bedtime. The bedroom is not a place to work, and patients need to always associate it with sleep. Working toward a consistent time for sleep and awakening helps most patients gain a healthy sleep pattern and strengthens the rhythm of the sleep-wake cycle.

Promoting Safety. For any patient prone to confusion or falls, safety is critical. A small night-light helps a patient orient to the room environment before going to the bathroom. Beds set lower to the floor can lessen the chance of a person falling when first standing. Instruct patients to remove clutter and throw rugs from the path used to walk from the bed to the bathroom. If a patient needs help to ambulate from a bed to the bathroom, place a small bell at the bedside to call family members. Sleepwalkers are unaware of their surroundings and are slow to react, increasing the risk of falls. Do not startle sleepwalkers but instead gently wake them and lead them back to bed.

Infants' beds need to be safe. To reduce the chance of suffocation, do not place pillows, stuffed toys, or the ends of loose blankets in cribs (AAP, 2012). Loose-fitting plastic mattress covers are dangerous because infants pull them over their faces and suffocate. Parents need to place an infant on his or her back to prevent suffocation (Meadows-Oliver and Hendrie, 2013).

Promoting Comfort. People fall asleep only after feeling comfortable and relaxed (Bulechek et al., 2013). Minor irritants often keep patients awake. Soft cotton nightclothes keep infants or small children warm and comfortable. Instruct patients to wear loose-fitting nightwear. An extra blanket is sometimes all that is necessary to prevent a person from feeling chilled and being unable to fall asleep. Patients need to void before retiring so they are not kept awake by a full bladder.

Establishing Periods of Rest and Sleep. In the home it helps to encourage patients to stay physically active during the day so they are more likely to sleep at night. Increasing daytime activity lessens problems falling asleep. In a home setting you frequently care for patients with chronic debilitating disease. The nursing care plan includes having patients set aside afternoons for rest to promote optimal health. Help adjust medication schedules, instruct patients to regularly void before rest periods, and suggest silencing the telephone ringer so rest periods are uninterrupted.

Stress Reduction. The inability to sleep because of emotional stress also makes a person feel irritable and tense. When patients are emotionally upset, encourage them to try not to force sleep. Otherwise insomnia frequently develops, and soon bedtime is associated with the inability to relax. Encourage a patient who has difficulty falling asleep to get up and pursue a relaxing activity such as sewing or reading rather than staying in bed and thinking about sleep.

Preschoolers have bedtime fears (fear of the dark or strange noises), awaken during the night, or have nightmares. After nightmares the parent enters the child's room immediately and talks to him or her briefly about fears to provide a cooling-down period. One approach is

to comfort children and leave them in their own beds so their fears are not used as excuses to delay bedtime. Keeping a light on in the room also helps some children. Cultural tradition causes families to approach sleep practices differently (Box 43-10). Always respect those that differ from traditional recommendations.

Bedtime Snacks. Some people enjoy bedtime snacks, whereas others cannot sleep after eating. A dairy product such as warm milk or cocoa that contains L-tryptophan is often helpful in promoting sleep. A full meal before bedtime often causes gastrointestinal upset or reflux and interferes with the ability to fall asleep.

Warn patients against drinking or eating foods with caffeine before bedtime. Coffee, tea, colas, and chocolate act as stimulants, causing a person to stay awake or to awaken throughout the night. Caffeinated foods and liquids and alcohol act as diuretics and cause a person to awaken in the night to void (National Heart, Lung, and Blood Institute, 2011).

⊕ BOX 43-10   CULTURAL ASPECTS OF CARE

Co-sleeping

Practices and patterns of sleep and rest vary among cultures. Culture and biology influence the development of sleep problems in children. Sleep patterns, bedtime routines, sleep aids, and sleep arrangements are components of cultural practices related to the use of space and interaction distances (Giger, 2013). Traditionally experts recommend having infants and children sleep in their own beds. Co-sleeping, in which infants and children sleep with their parents, is a culturally preferred habit; and the practice varies among cultures (Jain et al., 2011). It is more common in nonindustrialized countries. Reasons for co-sleeping practices are breastfeeding, comfort, tradition, better or more sleep, and environmental for warmth and protection for an infant (i.e., against the cold) (Ward, 2014). This practice is also common in the United States with some Asian, Hispanic, and African-American families (Jain et al., 2011). Health care providers in the United States discourage it because of safety issues, even though research does not show that the practice is unsafe. American culture promotes independence in childhood. One belief is that co-sleeping does not promote this independence; thus health care providers discourage it (Getter and McKenna, 2010). Research results related to co-sleeping and the incidence of sudden infant death syndrome (SIDS) are mixed (Blair et al., 2014). Sofa sharing is not a safe practice. Bed should not be shared if the infant was born preterm or the parents use alcohol or drugs or smoke (Blair et al., 2014). As a nurse be culturally sensitive when discussing co-sleeping practices with parents and developing sleeping plans for children.

Implications for Patient-Centered Care
- Complete a thorough sleep assessment of the child and family.
- Discuss the risks of co-sleeping with parents. During the discussion remain culturally sensitive and respectful of the parents' views (Jain et al., 2011).
- Co-sleeping has been linked to increased risk of SIDS under certain conditions such as parental smoking and alcohol or drug use (Getter and McKenna, 2010).
- Instruct parents who practice co-sleeping to avoid using alcohol or drugs that impair arousal. Decreased arousal prevents the parents from waking if the child is having problems (Ward, 2014).
- Co-sleeping should occur on a firm mattress (never on a water bed, sofa, or couch) (Ward, 2014).
- Encourage parents to use light sleeping clothes, keep room temperature comfortable, and not bundle the child tightly or in too many clothes.

Infants require special measures to minimize nighttime awakenings for feeding. It is common for children to need middle-of-the-night bottle-feeding or breastfeeding. Hockenberry and Wilson (2015) recommend offering the last feeding as late as possible. Tell parents not to give infants bottles in bed.

QSEN QSEN: BUILDING COMPETENCY IN EVIDENCE-BASED PRACTICE At her annual checkup, Julie Arnold tells you that she continues to have trouble falling asleep so she drinks 1 to 2 glasses of wine before bedtime to make her sleepy. On the basis of the current evidence, what is your best response?

ⓔ *Answers to QSEN Activities can be found on the Evolve website.*

Pharmacological Approaches. Melatonin is a neurohormone produced in the brain that helps control circadian rhythms and promote sleep (Kryger et al., 2011). It is a popular nutritional supplement that is found to be helpful in improving sleep efficiency and decreasing nighttime awakenings. The recommended dose is 0.3 to 1 mg taken 2 hours before bedtime. Older adults who have decreased levels of melatonin find it beneficial as a sleep aid (Kryger et al., 2011). Short-term use of melatonin has been found to be safe, with mild side effects of nausea, headache, and dizziness being infrequent (Redeker and McEnany, 2011). Ramelteon (Rozerem), a melatonin receptor agonist, is well tolerated and appears to be effective in improving sleep by improving the circadian rhythm and shortening time-to-sleep onset (National Guideline Clearinghouse, 2014; Redeker and McEnany, 2011). It is safe for long- and short-term use, particularly in older adults.

Several other herbal products help in sleep. Valerian is effective in mild insomnia and RLS. It affects the release of neurotransmitters and produces very mild sedation (Redeker and McEnany, 2011). Kava helps promote sleep in patients with anxiety. It should be used cautiously because of its potential toxic effects on the liver (Larzelere et al., 2010). Chamomile, an herbal tea, has a mild sedative effect that may be beneficial in promoting sleep (Redeker and McEnany, 2011). Caution patients about the dosage and use of herbal compounds because the U.S. Food and Drug Administration (FDA) does not regulate them. Herbal compounds may interact with prescribed medication, and patients need to avoid using these together (Meiner, 2015).

The use of nonprescription sleeping medications is not advisable. Patients need to learn the risks of such drugs. Over the long term these drugs lead to further sleep disruption, even when they initially seemed effective. Caution older adults about using over-the-counter antihistamines because of their long duration of action, which can cause confusion, constipation, urinary retention, and increased risk of falls (Redeker and McEnany, 2011). Help patients use behavioral and proper sleep-hygiene measures to establish sleep patterns that do not require the use of drugs.

Acute Care. Patients in acute care settings have their normal rest and sleep routine disrupted, which generally leads to sleep problems. In this setting nursing interventions focus on controlling factors in the environment that disrupt sleep, relieving physiological or psychological disruptions to sleep, and providing for uninterrupted rest and sleep periods for patients. "Excessive Sleepiness" in the *Evidence-based Geriatric Nursing Protocols for Best Practice* is based on the principle that nurses need to individualize an effective strategy on the basis of patient needs and that sleep medications are a last-resort intervention (Chasens and Umlauf, 2012).

BOX 43-11 EVIDENCE-BASED PRACTICE

Sleep Hygiene in Hospitalized Patients

PICO Question: Does the use of a sleep-hygiene protocol versus routine care in hospitalized patients improve sleep?

Evidence Summary

Sleep disruption commonly occurs in hospitalized patients because of disruption of normal routines, anxiety and stress, noise, pain, medical treatments, and environmental factors (Faraklas et al., 2013; Flynn Makic et al., 2014). Sleep deprivation impacts physical and psychological healing and often causes delirium (Brand, 2014; Faraklas et al., 2013). Implementation of nurse-driven sleep-hygiene protocols has been shown to be effective in improving sleep in hospitalized patients (Brand, 2014; Faraklas et al., 2013; Flynn Makic et al., 2014). Effective strategies in the protocols focused on education of staff nurses on protocol and interventions to decrease environmental stimuli and limit patient disruptions (Brand, 2014: Faraklas et al., 2013). After implementation of sleep-hygiene protocols, noise levels decreased on the nursing unit (Brand, 2014). Patients also reported that they were able to fall asleep more quickly and had fewer sleep disruptions (Faraklas et al., 2013).

Application to Nursing Practice

- Work with nurses on the unit to develop a sleep-hygiene protocol (Brand, 2014; Faraklas et al., 2013).
- Cluster nursing activities to provide uninterrupted periods of sleep (Murphy et al., 2013).
- Ask patients about sleep-hygiene measures used at home and work to use these in the hospital (Faraklas et al., 2013).
- Provide programs for staff on the effects of noise and noise-reduction strategies (Brand, 2014).
- Reduce lighting, telephone volumes, and staff conversations in the halls during quiet time and nighttime (Flynn Makic et al., 2014).
- Use sleep-hygiene measures with patients such as personal hygiene, adjusting room temperature, and relaxation methods.

Environmental Controls. In a hospital the nurse controls the environment in several ways (Box 43-11). Close the curtains between patients in semiprivate rooms. Dim lights on a hospital nursing unit at night. One of the biggest problems for patients in the hospital is noise. Important ways to reduce noise are to conduct conversations and reports in a private area away from patient rooms and keep necessary conversations to a minimum, especially at night (Flynn Makic et al., 2014). Additional ways to control noise in the hospital are listed in Box 43-12.

Promoting Comfort. Compared with beds at home, hospital beds are often harder and of a different height, length, or width. Keeping them clean and dry and in a comfortable position helps patients relax. Some patients suffer painful illnesses requiring special comfort measures such as the application of dry or moist heat, the use of supportive dressings or splints, and the use of pillows to assist in proper positioning before retiring (Figure 43-6).

Establishing Periods of Rest and Sleep. In a hospital or extended care setting it is difficult to provide patients with the time needed to rest and sleep. The most effective treatment for sleep disturbances is elimination or correction of factors that disrupt the sleep pattern. You need to plan care to avoid waking patients for nonessential tasks. Do this by scheduling assessments, treatments, procedures, and routines for times when patients are awake. For example, if a patient's physical condition has been stable, avoid waking him or her to check vital signs.

BOX 43-12 Control of Noise in the Hospital

- Close doors to patients' room when possible.
- Keep doors to work areas on unit closed when in use.
- Reduce volume of nearby telephone and paging equipment.
- Wear rubber-soled shoes. Avoid clogs.
- Turn off bedside oxygen and other equipment that is not in use.
- Turn down alarms and beeps on bedside monitoring equipment.
- Turn off room television and radio unless patient prefers soft music.
- Avoid abrupt loud noise such as flushing a toilet or moving a bed.
- Keep necessary conversations at low levels, particularly at night.
- Conduct conversations and reports in a private area away from patient rooms.
- Designate a time period during the day for "quiet time" for patients.

FIGURE 43-6 Positioning patient for sleep.

Allowing patients to determine the timing and methods of delivery of basic care measures promotes rest. Do not give baths and routine hygiene measures during the night for nursing convenience. Draw blood samples at a time when the patient is awake. Unless maintaining the therapeutic blood level of a drug is essential, give medications during waking hours. Work with the radiology department and other support services to schedule diagnostic studies and therapies at intervals that allow patients time for rest. Always try to provide the patient with 2 to 3 hours of uninterrupted sleep during the night.

When the patient's condition demands more frequent monitoring, plan activities to allow extended rest periods. A nurse instructs assistive personnel in the coordination of patient care to reduce patient disturbances. This means planning activities so the patient has as long as an hour or more to rest quietly rather than having a nurse or other personnel return to the room every few minutes. For example, if a patient needs frequent dressing changes, is receiving intravenous therapy, and has drainage tubes from several sites, do not make a separate trip into the room to check each problem. Instead use a single visit to perform all three tasks. Become the patient's advocate for promoting optimal sleep. This means becoming a gatekeeper by postponing or rescheduling visits by family or by questioning the frequency of certain procedures.

Promoting Safety. Patients with OSA are at risk for complications while in the hospital. Surgery and anesthesia disrupt normal sleep patterns. After surgery patients reach deep levels of REM sleep. This deep sleep causes muscle relaxation that leads to OSA. Patients with OSA who are given opioid analgesics after surgery have an increased risk of developing airway obstruction because the medications suppress normal arousal mechanisms (Redeker and McEnany, 2011). These patients often need ventilator support in the postoperative period because of the increased risk of respiratory complications. Monitor the patient's airway, respiratory rate and depth, and breath sounds frequently after surgery.

Recommend lifestyle changes to patients with OSA that include sleep hygiene, alcohol moderation, smoking cessation, and a weight-loss program (Freedman, 2010). Teach the patient to elevate the head of the bed and use a side or prone position for sleep. Use pillows to prevent a supine position (Pinto and Caple, 2010).

One of the most effective therapies is use of a nasal continuous positive airway pressure (CPAP) device at night, which requires a patient to wear a mask over the nose. A mask delivers room air at a high pressure. The air pressure prevents airway collapse. The CPAP device is portable and effective particularly for OSA. Another treatment option is the use of an oral appliance. These appliances advance the mandible or tongue to relieve pharyngeal obstruction (Wickwire and Collop, 2010). In cases of severe sleep apnea the tonsils, uvula, or parts of the soft palate are removed surgically. The success of surgical procedures to correct OSA varies.

Stress Reduction. Patients who are hospitalized for extensive diagnostic testing often have difficulty resting or sleeping because of uncertainty about the state of their health. Giving patients control over their health care minimizes uncertainty and anxiety. Providing information about the purpose of procedures and routines and answering questions gives patients the peace of mind needed to rest or fall asleep. A nurse on the night shift needs to take time to sit and talk with patients unable to sleep. This helps to determine the factors keeping patients awake. Back rubs also help patients relax more thoroughly. If a sedative is indicated, confer with the patient's health care provider to be sure that the lowest dose is used initially. Discontinuing a sedative as soon as possible prevents a dependence that seriously disrupts the normal sleep cycle. Older adults' metabolism of drugs is slow, making them more vulnerable to the side effects of sedatives, hypnotics, antianxiety drugs, or analgesics.

Restorative or Continuing Care. The nursing interventions implemented in the acute care setting are also used in the restorative or continuing care environment. Controlling the environment, especially noise; establishing periods of rest and sleep; and promoting comfort are important considerations. Nursing interventions related to stress reduction and controlling physiological disturbances are also implemented in these settings. Helping a patient achieve restful sleep in this environment sometimes takes time.

Promoting Comfort. Providing for personal hygiene improves a patient's sense of comfort. A warm bath or shower before bedtime is relaxing. Offer patients restricted to bed the opportunity to void and wash their face and hands. Toothbrushing and care of dentures also help to prepare patients for sleep. Position patients to support their dependent body parts and protect pressure points. Offer a back or hand massage to aid in muscle relaxation just before a patient goes to sleep (Harris and Richards, 2010) (see Chapter 44).

Controlling Physiological Disturbances. As a nurse you learn to control symptoms of physical illness that disrupt sleep. For example, a patient with respiratory abnormalities sleeps with two pillows or in a semi-sitting position to ease the effort to breathe. He or she benefits

from taking prescribed bronchodilators before sleep to prevent airway obstruction. A patient with a hiatal hernia also needs special care. After meals he or she often experiences a burning sensation as a result of gastric reflux. To prevent sleep disturbances have the patient eat a small meal several hours before bedtime and sleep in a semi-sitting position. Patients with pain, nausea, or other recurrent symptoms receive any symptom-relieving medication timed so the drug takes effect at bedtime. Remove or change any irritants against the patient's skin such as moist dressings or drainage tubes.

Pharmacological Approaches. The liberal use of drugs to manage insomnia is quite common in American culture. CNS stimulants such as amphetamines, caffeine, nicotine, terbutaline, theophylline, and modafinil need to be used sparingly and under medical management (Burchum and Rosenthal, 2016). In addition, withdrawal from CNS depressants such as alcohol, barbiturates, tricyclic antidepressants (amitriptyline, imipramine, and doxepin), and triazolam causes insomnia. Consult with pharmacist and health care provider about managing doses.

Medications that induce sleep are called **hypnotics**. **Sedatives** are medications that produce a calming or soothing effect (Burchum and Rosenthal, 2016). A patient who takes sleep medications needs to know about their proper use and their risks and possible side effects. Long-term use of antianxiety, sedative, or hypnotic agents disrupts sleep and leads to more serious problems. The FDA requires that the product labels of all sleep medications contain safety information related to the potential adverse effects of severe allergic reactions; severe facial swelling; and complex sleep behaviors such as sleep-driving, making phone calls, and preparing and eating food while asleep (USFDA, 2015).

Benzodiazepines and benzodiazepine-like drugs are common classifications of drugs used to treat sleep problems. The benzodiazepine-like drugs have become the treatment of choice for insomnia because of improved efficacy and safety of use (Burchum and Rosenthal, 2016). Experts recommend a low dose of a short-acting medication such as zolpidem (Ambien) for short-term use (no longer than 2 to 3 weeks) (Burchum and Rosenthal, 2016). These drugs cause fewer problems with dependence and abuse and fewer rebound insomnia and hangover effects than benzodiazepines.

The benzodiazepines cause relaxation, antianxiety, and hypnotic effects by facilitating the action of neurons in the CNS that suppress responsiveness to stimulation, thereby decreasing levels of arousal (Burchum and Rosenthal, 2016). Short-acting benzodiazepines (e.g., oxazepam, lorazepam, or temazepam) at the lowest possible dose for short-term treatment of insomnia are recommended. Initial doses are small; and increments are added gradually, on the basis of patient response, for a limited time. Warn patients not to take more than the prescribed dose, especially if the medication seems to become less effective after initial use. The use of benzodiazepines in older adults is potentially dangerous because of the tendency of the drugs to remain active in the body for a longer time. As a result, they also cause respiratory depression; next-day sedation; amnesia; rebound insomnia; and impaired motor functioning and coordination, which leads to increased risk of falls (Burchum and Rosenthal, 2016). If older patients who were recently continent, ambulatory, and alert become incontinent or confused and/or demonstrate impaired mobility, the use of benzodiazepines needs to be considered as a possible cause.

Administer benzodiazepines cautiously to children under 12 years of age. These medications are contraindicated in infants less than 6 months. Pregnant patients need to avoid them because their use is associated with risk of congenital anomalies. Nursing mothers do not receive the drugs because they are excreted in breast milk. Raise these issues with patients' health care providers.

Knowledge
- Characteristics of desirable sleep pattern
- Behaviors reflecting adequate sleep

Experience
- Previous patient responses to planned nursing interventions for promoting sleep
- Previous experience in adapting sleep therapies to personal needs

EVALUATION
- Evaluate signs and symptoms of the patient's sleep disturbance
- Review the patient's sleep pattern
- Ask the patient's sleep partner to report the patient's response to sleep therapies
- Ask the patient if expectations of care are being met

Standards
- Use established expected outcomes to evaluate the patient's response to care (e.g., improved duration of sleep, fewer awakenings)

Attitudes
- Demonstrate humility if an intervention is unsuccessful; rethink your approach
- Display perseverance in staying with a plan or in trying new approaches in the case of chronic sleep problems

FIGURE 43-7 Critical thinking model for sleep evaluation.

Regular use of any sleep medication often leads to tolerance and withdrawal. Rebound insomnia is a problem after stopping a medication. Immediately administering a sleeping medication when a hospitalized patient complains of being unable to sleep does the patient more harm than good. Consider alternative approaches to promote sleep. Routine monitoring of patient response to sleep medications is important.

◆ Evaluation

Through the Patient's Eyes. With regard to problems with sleep, the patient is the source for evaluating if expectations are met. Each patient has a unique need for sleep and rest. He or she is the only one who knows if sleep problems are improved and which interventions or therapies are most successful in promoting sleep (Figure 43-7). It is important to ask the patient if his or her sleep needs have been met. For example, ask the patient, "Are you feeling more rested?"; "Can you tell me if you believe that we've done all we can to help improve your sleep?" or "Which interventions have been most effective in helping you sleep?" If expectations have not been met, you need to spend more time trying to understand the patient's needs and preferences. Working closely with the patient and bed partner enables you to redefine expectations that can be met realistically within the limits of the patient's condition and treatment.

Patient Outcomes. To evaluate the effectiveness of nursing interventions, make comparisons with baseline assessment data to evaluate if sleep has improved. Determine whether expected outcomes have been met. Use evaluative measures shortly after a therapy has been tried (e.g., observing whether a patient falls asleep after reducing noise and darkening a room). Use other evaluative measures after a patient

wakes from sleep (e.g., asking him or her to describe the number of awakenings during the previous night). The patient and bed partner usually provide accurate evaluative information. Over longer periods use assessment tools such as the visual analog or sleep-rating scale to determine whether sleep has progressively improved or changed.

Also evaluate the level of understanding that patients or family members gain after receiving instruction in sleep habits. You measure compliance with these practices during a home visit, when you are able to observe the environment. When expected outcomes are not met, revise the nursing measures or expected outcomes on the basis of the patient's needs or preferences. When outcomes are not met, ask questions such as:

- Are you able to fall asleep within 20 minutes of getting in bed?
- Describe how well you sleep when you exercise.
- Does the use of quiet music at bedtime help you to relax?
- Do you feel rested when you wake up?

If a nurse has successfully developed a good relationship with a patient and a therapeutic plan of care, subtle behaviors often indicate the level of the patient's satisfaction. Note the absence of signs of sleep problems such as lethargy, frequent yawning, or position changes in the patient. You are effective in promoting rest and sleep if the patient's goals and expectations are met.

KEY POINTS

- Sleep provides physiological and psychological restoration.
- The 24-hour sleep-wake cycle is a circadian rhythm that influences physiological function and behavior.
- The control and regulation of sleep depends on a balance among regulators within the CNS.
- During a typical night's sleep a person passes through four to five complete sleep cycles. Each sleep cycle contains three NREM stages of sleep and a period of REM sleep.
- The most common type of sleep disorder is insomnia.
- The hectic pace of a person's lifestyle, emotional and psychological stress, and alcohol ingestion frequently disrupt the sleep pattern.
- If a patient's sleep is adequate, assess his or her usual bedtime, normal bedtime ritual, preferred environment for sleeping, and usual preferred rising time.
- When a patient has a sleep problem, conduct a complete sleep history. Identifying nursing diagnoses for sleep problems depends on identifying factors that impair sleep.
- When planning interventions to promote sleep, consider the usual characteristics of the patient's home environment and normal lifestyle.
- A regular bedtime routine of relaxing activities prepares a person physically and mentally for sleep.
- An environment with a darkened room, reduced noise, comfortable bed, and good ventilation promotes sleep.
- Important nursing interventions for promoting sleep in the hospitalized patient are establishing periods for uninterrupted sleep and rest and controlling noise levels.
- Pain or other disease symptom control is essential to promoting the ability to sleep.
- Long-term use of sleeping pills often leads to difficulty initiating and maintaining sleep.

CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

Julie returns to the neighborhood health clinic for a follow-up visit. She tells you that, since she started her sleep-hygiene plan, she feels more rested. She tells you that she is concerned because her husband says that she has started snoring loudly when she's sleeping.

1. On the basis of Julie's husband's report of her snoring, which additional assessment data should you gather from her?
2. Julie tells you that her 76-year-old mother is having trouble sleeping after being in the hospital. Julie asks you about a prescription for a sleeping pill for her mother. What is your best response?
3. Julie and David tell you that they are concerned about their 14-year-old daughter. She just started high school and is having sleep problems. List at least three interventions for Julie and David to use to improve their teenage daughter's sleep patterns.

REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. The nurse is developing a plan for a patient who was diagnosed with narcolepsy. Which interventions should the nurse include on the plan? (Select all that apply.)
   1. Take brief, 20-minute naps no more than twice a day.
   2. Drink a glass of wine with dinner.
   3. Eat the large meal at lunch rather than dinner.
   4. Establish a regular exercise program.
   5. Teach the patient about the side effects of modafinil (Provigil).
2. The nurse incorporates which priority nursing intervention into a plan of care to promote sleep for a hospitalized patient?
   1. Have patient follow hospital routines.
   2. Avoid waking patient for nonessential tasks.
   3. Give prescribed sleeping medications at dinner.
   4. Turn television on low to late-night programming.
3. A 72-year-old patient asks the nurse about using an over-the-counter antihistamine as a sleeping pill to help her get to sleep. What is the nurse's best response?
   1. "Antihistamines are better than prescription medications because these can cause a lot of problems."
   2. "Antihistamines should not be used because they can cause confusion and increase your risk of falls."
   3. "Antihistamines are effective sleep aids because they do not have many side effects."
   4. "Over-the-counter medications when combined with sleep-hygiene measures are a good plan for sleep."
4. The nurse is providing health teaching for a patient using herbal compounds such as kava for sleep. Which points need to be included? (Select all that apply.)
   1. Can cause urinary retention
   2. Should not be used indefinitely
   3. May have toxic effects on the liver
   4. May cause diarrhea and anxiety
   5. Are not regulated by the U.S. Food and Drug Administration (FDA)
5. The patient reports episodes of sleepwalking to the nurse. Through understanding of the sleep cycle, the nurse recognizes that sleepwalking occurs during which sleep phase?
   1. Rapid eye movement (REM) sleep
   2. Stage 1 nonrapid eye movement (NREM) sleep
   3. Stage 4 NREM sleep
   4. Transition period from NREM to REM sleep
6. The nurse is administering a benzodiazepine sleep aid to an older adult. What should be the priority assessment for the patient?

  1. Incontinence
  2. Nausea and vomiting
  3. Bradycardia
  4. Respiratory depression
7. The nurse is contacting the health care provider about a patient's sleep problem. Place the steps of the SBAR (*s*ituation, *b*ackground, *a*ssessment, *r*ecommendation) in the correct order.
  1. Mrs. Dodd, 46 years old, was admitted 3 days ago following a motor vehicle accident. She is in balanced skeletal traction for a fractured left femur. She is having difficulty falling asleep.
  2. "Dr. Smithson, this is Pam, the nurse caring for Mrs. Dodd. I'm calling because Mrs. Dodd is having difficulty sleeping."
  3. "I'm calling to ask if you would order a hypnotic such as zolpidem (Ambien) to use on a prn basis."
  4. Mrs. Dodd is taking her pain medication every 4 hours as ordered and rates her pain as 2 out of 10. Last night she was still awake at 0100. She states that she is comfortable but just can't fall asleep. Her vital signs are BP 124/76, P 78, R 12 and T 37.1°C (98.8°F).
8. Which statement made by a mother being discharged to home with her newborn infant indicates that she understands the discharge teaching related to best sleep practices?
  1. "I'll give the baby a bottle to help her fall asleep."
  2. "We'll place the baby on her back to sleep."
  3. "We put the baby's stuffed animals in the crib to make her feel safe."
  4. "I know the baby will not need to be fed until morning."
9. The nurse is developing a plan of care for a patient experiencing obstructive sleep apnea (OSA). Which intervention is appropriate to include on the plan?
  1. Instruct the patient to sleep in a supine position.
  2. Have patient limit fluid intake 2 hours before bedtime.
  3. Elevate head of bed and assume a side or prone position.
  4. Encourage patient to take an over-the-counter sleep aid.
10. Which statement made by the parent of a school-age child requires follow-up by the nurse?
  1. "I encourage evening exercise about an hour before bedtime."
  2. "I offer my daughter a glass warm milk before bedtime."
  3. "I make sure that the room is dark and quiet at bedtime."
  4. "We use quiet activities such as reading a book before bedtime."
11. Which sleep-hygiene actions at bedtime can the nurse delegate to the nursing assistant? (Select all that apply.)
  1. Giving the patient a backrub
  2. Turning on quiet music

  3. Dimming the lights in the patient's room
  4. Giving a patient a cup of coffee
  5. Monitoring for the effect of the sleeping medication that was given
12. Which statement made by the patient indicates a need for further teaching on sleep hygiene?
  1. "I'm going to do my exercises before I eat dinner."
  2. "I'm going to go to bed every night at about the same time."
  3. "I set my alarm to get up at the same time every morning."
  4. "I moved my computer to the bedroom so I could work before I go to sleep."
13. Which statement made by an older adult best demonstrates understanding of taking a sleep medication?
  1. "I'll take the sleep medicine for 4 or 5 weeks until my sleep problems disappear."
  2. "Sleep medicines won't cause any sleep problems once I stop taking them."
  3. "I'll talk to my health care provider before I use an over-the-counter sleep medication."
  4. "I'll contact my health care provider if I feel extremely sleepy in the mornings."
14. The school nurse is teaching health-promoting behaviors that improve sleep to a group of high-school students. Which points should be included in the education? (Select all that apply.)
  1. Go to bed at the same time each night.
  2. Study in your bedroom to have a quiet place.
  3. Turn on the television to help you fall asleep.
  4. Avoid drinking coffee or soda before bedtime.
  5. Turn off your cell phone at bedtime.
15. The nurse is taking a sleep history from a patient. Which statement made by the patient needs further follow-up?
  1. "I feel refreshed when I wake up in the morning."
  2. "I use soft music at night to help me relax."
  3. "It takes me about 45 to 60 minutes to fall asleep."
  4. "I take the pain medication for my leg pain about 30 minutes before I go to bed."

Answers: 1. 1, 4, 5; **2.** 2, 3; **3.** 2, 4; **4.** 2, 3, 5; **5.** 3; **6.** 4; **7.** 2, 1, 4, 3; **8.** 2; **9.** 3; **10.** 1; **11.** 1, 2, 3; **12.** 4; **13.** 3; **14.** 1, 4, 5; **15.** 3.

Pain Management

OBJECTIVES

- Discuss common misconceptions about pain.
- Describe the physiology of pain.
- Identify components of the pain experience. Explain how the physiology of pain relates to selecting interventions for pain relief.
- Assess a patient experiencing pain.
- Explain how cultural factors influence the pain experience.
- Describe guidelines for selecting and individualizing pain therapies.
- Explain various pharmacological approaches to treating pain.
- Describe applications for use of nonpharmacological pain interventions.
- Discuss nursing implications for administering analgesics.
- Identify barriers to effective pain management.
- Evaluate a patient's response to pain interventions.

Pain is a universal but individual experience and a condition that nurses encounter among patients in all settings. It is the most common reason that people seek health care; yet it is often underrecognized, misunderstood, and inadequately treated. A person in pain often feels distress or suffering and seeks relief. One of the major challenges of pain is that as a nurse you cannot see or feel a patient's pain. It is purely subjective. No two people experience pain in the same way, and no two painful events create identical responses or feelings in a person. The International Association for the Study of Pain (IASP) defines it as "an unpleasant, subjective sensory *and* emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (IASP, 2014b).

Recently there has been a call to increase research efforts related to pain. Congress declared 2000 to 2010 the Decade of Pain Control and Research; and, although the body of evidence has grown, pain continues to be a leading public health problem in the United States. The 2010 Patient Protection and Affordable Care Act required the Department of Health and Human Services to obtain the support of the Institute of Medicine (IOM) in conducting an extensive examination of pain as a public health problem. The results of the IOM study were released in the 2011 report, *Relieving Pain in America: a Blueprint for Transforming Prevention, Care, Education, and Research.* This report acknowledges the tragic epidemic of pain in the United States and calls for major coordinated efforts to develop safe, effective, preventive, and management strategies (IOM, 2011). The IASP, in the "Declaration of Montreal," declared that access to pain management is a fundamental human right (IASP, 2015). Nurses are legally and ethically responsible for managing pain and relieving suffering.

Pain management should be patient centered, with nurses practicing patient advocacy, empowerment, compassion, and respect. Caring for patients in pain requires recognition that pain can and should be relieved. Effective communication among the patient, family, and professional caregivers is essential to achieve adequate pain management. Recognition of the subjective nature of pain and respect for the patient

in pain is demonstrated when a nurse accepts McCaffery's classic definition: "Pain is whatever the experiencing person says it is, existing whenever he says it does" (Pasero and McCaffery, 2011). Effective pain management improves quality of life; reduces physical discomfort; promotes earlier mobilization and return to previous baseline functional activity levels; results in fewer hospital and clinic visits; and decreases hospital lengths of stay, resulting in lower health care costs.

SCIENTIFIC KNOWLEDGE BASE

Nature of Pain

The pain experience is complex, involving more than a single physiological sensation caused by a specific stimulus. It has physical, emotional, and cognitive components. It is subjective and highly individualized. It depletes a person's energy and may contribute to chronic fatigue. It interferes with interpersonal relationships and influences the meaning of life. Left untreated, it may lead to serious physical, psychological, social, and financial consequences. Pain itself cannot be measured objectively. Only the patient knows whether pain is present and how the experience feels. However, careful assessment is critical as you assess the effects (e.g., behaviors and physiological changes) associated with pain. It is not the responsibility of a patient to prove that he or she is in pain; it is a nurse's responsibility to assess a patient's condition and accept his or her subjective report (APS, 2009).

Physiology of Pain

There are four physiological processes of normal pain: transduction, transmission, perception, and modulation (Pasero and McCaffery, 2011). A patient in pain cannot discriminate among the processes. Understanding each process helps you recognize factors that cause pain, symptoms that accompany it, and the rationale for selected therapies.

Transduction. Thermal, chemical, or mechanical stimuli usually cause pain. **Transduction** converts energy produced by these stimuli into electrical energy. It begins in the periphery when a pain-producing stimulus (e.g., exposure to pressure or a hot surface) sends an impulse across a sensory peripheral pain nerve fiber (**nociceptor**), initiating an action potential. Once transduction is complete, **transmission** of the pain impulse begins.

Transmission. Cellular damage caused by thermal, mechanical, or chemical stimuli results in the release of excitatory **neurotransmitters** such as **prostaglandins**, bradykinin, substance P, and histamine (Box 44-1). The neurotransmitters affect the sending of nerve stimuli. They either excite during transmission or inhibit during modulation. Excitatory neurotransmitters send electrical impulses across the synaptic cleft between two nerve fibers, enhancing transmission of the pain impulse. These pain-sensitizing substances surround the pain fibers in the extracellular fluid, spreading the pain message and causing an inflammatory response (Pasero and McCaffery, 2011). The pain stimulus enters the spinal cord via the dorsal horn and travels one of several routes until ending within the gray matter of the spinal cord. At the dorsal horn substance P is released, causing a synaptic transmission from the afferent (sensory) peripheral nerve to spinothalamic tract nerves, which cross to the opposite side (Pasero and McCaffery, 2011) (Figure 44-1).

Nerve impulses resulting from the painful stimulus travel along afferent (sensory) peripheral nerve fibers. Two types of peripheral nerve fibers conduct painful stimuli: the fast, myelinated A–delta fibers and the very small, slow, unmyelinated C fibers. The A fibers send

---

BOX 44-1   Neurophysiology of Pain: Neuroregulators

Neurotransmitters (Excitatory)
Prostaglandins
- Generated from the breakdown of phospholipids in cell membranes
- Thought to increase sensitivity to pain

Bradykinin
- Released from plasma that leaks from surrounding blood vessels at the site of tissue injury
- Binds to receptors on peripheral nerves, increasing pain stimuli
- Binds to cells that cause the chain reaction producing prostaglandins

Substance P
- Found in pain neurons of dorsal horn (excitatory peptide)
- Needed to transmit pain impulses from periphery to higher brain centers
- Causes vasodilation and edema

Histamine
- Produced by mast cells causing capillary dilation and increased capillary permeability

Serotonin
- Released from the brainstem and dorsal horn to inhibit pain transmission

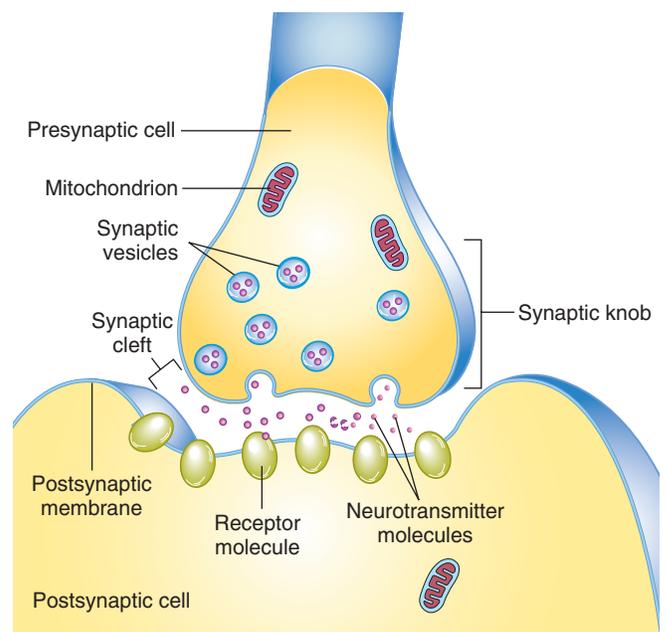
Neuromodulators (Inhibitory)
- Are the natural supply of morphinelike substances in the body
- Activated by stress and pain
- Located within the brain, spinal cord, and gastrointestinal tract
- Cause analgesia when they attach to opiate receptors in the brain
- Present in higher levels in people who have less pain than others with a similar injury


FIGURE 44-1 Chemical synapses involve transmitter chemicals (neurotransmitters) that signal postsynaptic cells. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)
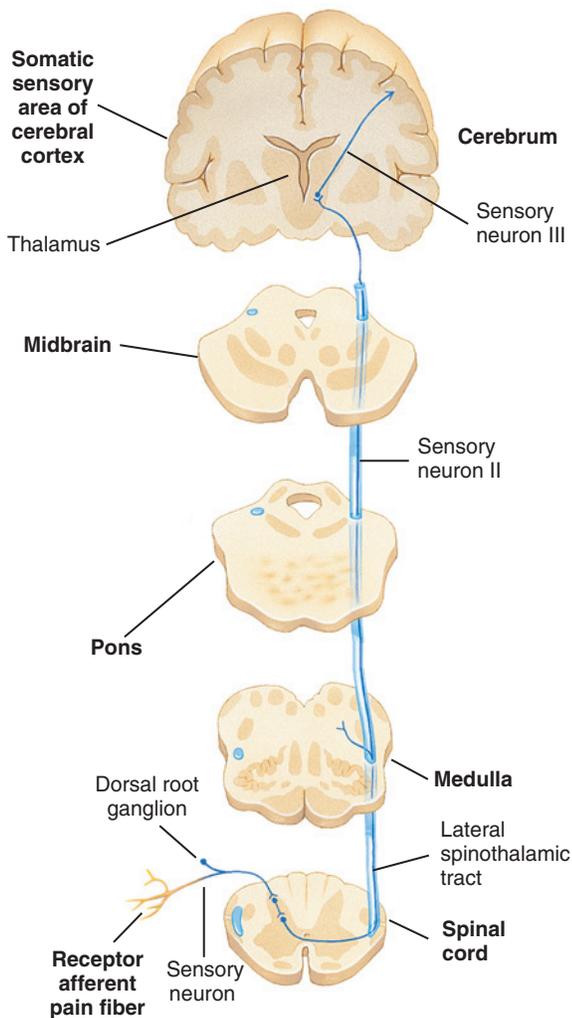

FIGURE 44-2 Spinothalamic pathway that conducts pain stimuli to the brain.

FIGURE 44-3 Protective reflex to pain stimulus.

sharp, localized, and distinct sensations that specify the source of the pain and detect its intensity. The C fibers relay impulses that are poorly localized, visceral, and persistent. For example, after stepping on a nail, a person initially feels a sharp, localized pain, which is a result of A-fiber transmission, or first pain. Within a few seconds the whole foot aches from C-fiber transmission, or second pain (Pasero and McCaffery, 2011).

Pain impulses travel up the spinal cord by way of the spinothalamic tract (Figure 44-2). After the pain impulse ascends the spinal cord, the thalamus transmits information to higher centers in the brain, including the reticular formation, limbic system, somatosensory cortex, and association cortex.

Perception.   Once a pain stimulus reaches the cerebral cortex, the brain interprets the quality of the pain and processes information from past experience, knowledge, and cultural associations in the perception of the pain (Pasero and McCaffery, 2011). **Perception** is the point at which a person is aware of pain. The somatosensory cortex identifies the location and intensity of pain, whereas the association cortex, primarily the limbic system, determines how a person feels about it. There is no single pain center.

As a person becomes aware of pain, a complex reaction occurs. Psychological and cognitive factors interact with neurophysiological ones. Perception gives awareness and meaning to pain, resulting in a

reaction. The reaction to pain includes the physiological and behavioral responses that occur after an individual perceives pain (Pasero and McCaffery, 2011).

Modulation. Once the brain perceives pain, there is a release of inhibitory neurotransmitters (see Box 44-1) such as endorphins (endogenous opioids), serotonin, norepinephrine, and gamma-aminobutyric acid (GABA), which hinder the transmission of pain and help produce an analgesic effect (Pasero and McCaffery, 2011). The neurotransmitters decrease neuron activity without directly transferring a nerve signal through a synapse. This inhibition of the pain impulse is the fourth and last phase of the normal pain process known as **modulation** (Pasero and McCaffery, 2011).

A protective reflex response also occurs with pain reception (Figure 44-3). A–delta fibers send sensory impulses to the spinal cord, where they synapse with spinal motor neurons. The motor impulses travel via a reflex arc along efferent (motor) nerve fibers back to a peripheral muscle near the site of stimulation, thus bypassing the brain. Contraction of the muscle leads to a protective withdrawal from the source of pain. For example, when you accidentally touch a hot iron, you feel a burning sensation, but your hand also reflexively withdraws from the surface of the iron. Pain processes require an intact nervous system and spinal cord. Common factors that disrupt the pain process include trauma, drugs, tumor growth, and metabolic disorders.

Gate-Control Theory of Pain

Melzack and Wall's gate-control theory (1965) was the first to suggest that pain has emotional and cognitive components in addition to physical sensations. According to this theory, gating mechanisms located along the central nervous system regulate or block pain impulses. Pain impulses pass through when a gate is open and are blocked when a gate is closed. Closing the gate is the basis for nonpharmacological pain-relief interventions. You gain a useful conceptual framework for pain management by understanding the physiological, emotional, and cognitive influences on the gates. For example, factors such as stress and exercise increase the release of endorphins, often raising an individual's **pain threshold** (the point at which a person feels pain). Because the amount of circulating substances varies with every individual, the response to pain varies.

Physiological Responses. As pain impulses ascend the spinal cord toward the brainstem and thalamus, the stress response stimulates the autonomic nervous system (ANS). Pain of low-to-moderate intensity and superficial pain elicit the fight-or-flight reaction of the general adaptation syndrome (see Chapter 38). Stimulation of the sympathetic

TABLE 44-1 Physiological Reactions to Pain

Response	Cause or Effect
Sympathetic Stimulation*	
Dilation of bronchial tubes and increased respiratory rate	Provides increased oxygen intake
Increased heart rate	Provides increased oxygen transport
Peripheral vasoconstriction (pallor, elevation in blood pressure)	Elevates blood pressure with shift of blood supply from periphery and viscera to skeletal muscles and brain
Increased blood glucose level	Provides additional energy
Increased cortisol level (short term)	Heightened memory functions, a burst of increased immunity, and lower sensitivity to pain
Diaphoresis	Controls body temperature during stress
Increased muscle tension	Prepares muscles for action
Dilation of pupils	Affords better vision
Decreased gastrointestinal motility	Frees energy for more immediate activity
Parasympathetic Stimulation†	
Pallor	Causes blood supply to shift away from periphery
Nausea and vomiting	Vagus nerve sends impulses to chemoreceptor trigger zone in the brain
Decreased heart rate and blood pressure	Results from vagal stimulation
Rapid, irregular breathing	Causes body defenses to fail under prolonged stress of pain

*Pain of low-to-moderate intensity and superficial pain.
†Severe or deep pain.

branch of the ANS results in physiological responses (Table 44-1). Continuous, severe, or deep pain typically involving the visceral organs (e.g., with a myocardial infarction or colic from gallbladder or renal stones) activates the parasympathetic nervous system. Sustained physiological responses to pain sometimes seriously harm individuals. Except in cases of severe traumatic pain, which cause a person to go into shock, most people adapt to their pain reflexively, and their physical signs return to normal baseline. Note that normal is not the same for each individual. Thus patients in pain do *not* always have changes in their vital signs. Changes in vital signs more often indicate problems other than pain.

Behavioral Responses. The pain response is complex, influenced by a person's culture, pain experiences, perception of pain, and ability to manage stress. If left untreated or unrelieved, pain significantly alters quality of life with physical and psychological consequences. The widespread effects of pain support why effective pain management is essential. Some patients choose not to report pain if they believe that it inconveniences others or if it signals loss of self-control. Others endure severe pain without asking for assistance. Be familiar with behavioral responses to pain. Clenching the teeth, facial grimacing, holding or guarding the painful part, and bent posture are common indications of acute pain. Chronic pain affects a patient's activity (eating, sleeping, socialization), thinking (confusion,

forgetfulness), or emotions (anger, depression, irritability) and quality of life and productivity (IOM, 2011). You soon learn to recognize patterns of behavior that reflect pain even when there is no verbal report. This ability becomes especially important in patients who are unable to report their pain such as individuals who are cognitively impaired or unable to communicate (e.g., intubated with artificial airway). However, lack of pain expression does not indicate that a patient is not experiencing it (Pasero and McCaffery, 2011). Critically analyze the conditions that cause pain and advocate for appropriate management even if a patient cannot.

Recognizing a patient's unique response to pain is important in assessing success of pain-management therapies. Encourage your patients to accept pain-relieving measures so they remain active and continue to maintain daily activities. A patient's ability to tolerate pain significantly influences your perceptions of the degree of his or her discomfort. Patients who have a low **pain tolerance** (level of pain a person is willing to accept) are sometimes inaccurately perceived as complainers. Teach patients the importance of reporting their pain sooner rather than later to facilitate better control and optimal functional status.

Acute and Chronic Pain

Pain is categorized by duration (acute or chronic) or pathological condition (e.g., cancer or neuropathic). The two types of pain that you observe in patients are acute (transient) and chronic (persistent), which includes cancer and noncancer pain.

Acute/Transient Pain. **Acute pain** is protective, usually has an identifiable cause, is of short duration, and has limited tissue damage and emotional response. It is common after acute injury, disease, or surgery. Acute pain warns people of injury or disease; thus it is protective. It eventually resolves, with or without treatment, after an injured area heals. Patients in acute pain are frightened and anxious and expect relief quickly. It is self-limiting; therefore a patient knows than an end is in sight. Because acute pain has a predictable ending (healing) and an identifiable cause, health team members are usually willing to treat it aggressively.

Acute pain seriously threatens a patient's recovery by hampering his or her ability to become active and involved in self-care. This results in prolonged hospitalization from complications such as physical and emotional exhaustion, immobility, sleep deprivation, and pulmonary complications. Physical and psychological progress is delayed as long as acute pain persists because a patient focuses all energy on pain relief. Efforts aimed at teaching and motivating a patient toward self-care can be hindered until the pain is managed successfully. Complete pain relief is not always achievable, but reducing pain to a tolerable level is a realistic goal. A primary nursing goal is to provide pain relief that allows patients to participate in their recovery, prevent complications, and improve functional status. Unrelieved acute pain can progress to chronic pain (Althaus et al., 2014).

Chronic/Persistent Noncancer Pain. The IOM (2011) estimates that chronic pain affects approximately 100 million American adults, more than the total affected by heart disease, cancer, and diabetes combined. Unlike acute pain, **chronic pain** is not protective and thus serves no purpose, but it has a dramatic effect on a person's quality of life. Chronic noncancer pain is prolonged, varies in intensity, and usually lasts longer (typically at least 6 months) than is expected or predicted (IOM, 2011). It does not always have an identifiable cause and leads to great personal suffering. Examples of chronic noncancer pain include arthritis, low back pain, headache, fibromyalgia, and peripheral neuropathy. It may result from an initial injury such as a

---

TABLE 44-2 Classification of Pain by Inferred Pathology

Nociceptive Pain	Neuropathic Pain

I. *Nociceptive pain:* Normal stimulation of special peripheral nerve endings—called *nociceptors;* usually responsive to nonopioids and/or opioids
 	
A. *Somatic pain:* Comes from bone, joint, muscle, skin, or connective tissue; is usually aching or throbbing in quality and well localized
B. *Visceral pain:* Arises from visceral organs such as the gastrointestinal tract and pancreas; is sometimes subdivided:
  1. Tumor involvement of organ capsule that causes aching and fairly well-localized pain
  2. Obstruction of hollow viscus, which causes intermittent cramping and poorly localized pain
	II. *Neuropathic pain:* Abnormal processing of sensory input by the peripheral or central nervous system; treatment usually includes adjuvant analgesics.
	A. Centrally generated pain
	  1. *Deafferentation pain:* Injury to either the peripheral or central nervous system. *Examples:* Phantom pain indicates injury to the peripheral nervous system; burning pain below the level of a spinal cord lesion reflects injury to the central nervous system.
	  2. *Sympathetically maintained pain:* Associated with impaired regulation of the autonomic nervous system.
	  Examples: Pain is associated with complex regional pain syndrome, type I, type II.
	B. Peripherally generated pain
	  1. *Painful polyneuropathies:* Pain felt along the distribution of many peripheral nerves.
	  Examples: Diabetic neuropathy, alcohol-nutritional neuropathy, and Guillain-Barré syndrome.
	  2. *Painful mononeuropathies:* Usually associated with a known peripheral nerve injury; pain is felt at least partly along the distribution of the damaged nerve.
	  Examples: Nerve root compression, nerve entrapment, trigeminal neuralgia.

From Pasero C, McCaffery M: *Pain assessment and pharmacologic management,* St Louis, 2011, Mosby.

back sprain, or there may be an ongoing cause such as illness. Chronic noncancer pain may be viewed as a disease since it has a distinct pathology that causes changes throughout the nervous system that may worsen over time (IOM, 2011). It has significant psychological and cognitive effects and can constitute a serious, separate disease entity itself. Chronic noncancer pain is usually non–life threatening. In some cases an injured area healed long ago, yet the pain is ongoing and does not respond to treatment.

The possible unknown cause of chronic pain, combined with ineffective treatments and the unrelenting nature and uncertainty of its duration, frustrates a patient, frequently leading to psychological depression and even suicide. Chronic pain is a major cause of psychological and physical disability, leading to problems such as job loss, inability to perform simple daily activities, sexual dysfunction, and social isolation. The goal of treating chronic noncancer pain is to improve functional status with a multimodality plan.

The person with chronic noncancer pain often experiences pain that may not have the same physiological response as acute pain; however, the subjective reports and interference with activities of daily living (ADLs), socialization, and ability to perform work duties is very real. Patients often suffer more with time because of physical and mental exhaustion. Associated symptoms of chronic pain include fatigue, insomnia, anorexia, weight loss, apathy, hopelessness, depression, and anger. Chronic pain creates the uncertainty of how one will feel from day to day. A person with chronic noncancer pain often does not show obvious symptoms and does not adapt to the pain. Health care providers are usually less willing to treat chronic pain with opioids, although there are guidelines that support their use (Chou et al., 2009). In addition, the American Society of Anesthesiologists (2010) released *Practice Guidelines for Chronic Pain Management*, which includes opioid use. Often a person with chronic pain who consults with numerous health care providers is labeled a drug seeker, when he or she is actually seeking adequate pain relief. Nurses need to discourage patients from having multiple health care providers for treating pain and refer them to specialists. Pain centers offer nonpharmacological and pharmacological strategies for a holistic approach to pain management.

Chronic Episodic Pain. Pain that occurs sporadically over an extended period of time is episodic pain. Pain episodes last for hours, days, or weeks. An example of chronic episodic pain is the migraine headache that occurs up to 14 days per month compared to chronic migraine that occurs more than 15 days per month (Katsarava et al., 2012).

Cancer Pain. Not all patients with cancer experience pain. For those who do, many are able to have their pain managed with relatively simple means (Burchum and Rosenthal, 2016). Some patients with cancer experience acute and/or chronic pain. The pain is normal (nociceptive), resulting from stimulus of an undamaged nerve and/or neuropathic, arising from abnormal or damaged pain nerves (Table 44-2). Cancer pain is usually caused by tumor progression and related pathological processes, invasive procedures, toxicities of chemotherapy, infection, and physical limitations. A patient senses pain at the actual site of the tumor or distant to the site, called *referred pain*. Always completely assess reports of new pain by a patient with existing pain. Despite the availability and wide use of opioids and updated guidelines from reliable leading professional societies, undertreatment of cancer pain is still frequent. More than 75% of patients with advanced cancer experience pain, yet research shows that approximately one third of patients still do not receive pain medication proportional to their pain intensity (Greco et al., 2014; Paice and Ferrell, 2011).

Idiopathic Pain. **Idiopathic pain** is chronic pain in the absence of an identifiable physical or psychological cause or pain perceived as excessive for the extent of an organic pathological condition. An example of idiopathic pain is complex regional pain syndrome (CRPS). Research is needed to better identify the causes of idiopathic pain to identify more effective treatment (Pasero and McCaffery, 2011).

NURSING KNOWLEDGE BASE

Nursing knowledge of pain mechanisms and interventions continues to grow through nursing research. This section explores factors that influence the pain experience.

Knowledge, Attitudes, and Beliefs

Attitudes of nurses and other health care providers affect pain management. The traditional medical model of illness generates attitudes about pain. This model suggests that physical problems result from

BOX 44-2 Common Biases and Misconceptions About Pain

The following statements are *false:*
- Patients who abuse substances (e.g., use drugs or alcohol) overreact to discomforts.
- Patients with minor illnesses have less pain than those with severe physical alteration.
- Administering analgesics regularly leads to drug addiction.
- The amount of tissue damage in an injury accurately indicates pain intensity.
- Health care personnel are the best authorities on the nature of a patient's pain.
- Psychogenic pain is not real.
- Chronic pain is psychological.
- Patients who are hospitalized experience pain.
- Patients who cannot speak do not feel pain.

BOX 44-3 FOCUS ON OLDER ADULTS

Factors Influencing Pain in Older Adults

- With aging, muscle mass decreases, body fat increases, and percentage of body water decreases. This increases the concentration of water-soluble drugs such as morphine given in normal doses. The volume of distribution for fat-soluble drugs such as fentanyl increases (Burchum and Rosenthal, 2016; Tracy and Morrison, 2013).
- Older adults frequently eat poorly, resulting in low serum albumin levels. Many drugs are highly protein bound. In the presence of low serum albumin, more free drug (active form) is available, thus increasing the risk for side and/or toxic effects (Burchum and Rosenthal, 2016; Tracy and Morrison, 2013.
- A decline of liver and renal function naturally occurs with aging. This results in reduced metabolism and excretion of drugs. Thus older adults often experience a greater peak effect and longer duration of analgesics (Arnstein, 2010).
- Age-related changes in the skin such as thinning and loss of elasticity affect the absorption rate of topical analgesics.

physical causes. Thus pain is a physical response to organic dysfunction. When there is no obvious source of pain (e.g., the patient with chronic low back pain or neuropathies), health care providers sometimes stereotype pain sufferers as malingerers, complainers, or difficult patients.

Studies of nurses' attitudes regarding pain management show that a nurse's personal opinion about a patient's report of pain affects pain assessment and titration of opioid doses. It has been shown that nurses' assessment of pain intensity underestimates patients' pain reports (Goulet et al., 2013). A number of nurse and patient variables, including cultural (e.g., gender, age, education), knowledge, and patient diagnosis, may contribute to the differences in pain ratings. The amount of analgesia administered may vary on the basis of whether a patient is grimacing or smiling during the nurse's assessment (Pasero and McCaffery, 2011). Nurses with more than 6 years of work experience, higher job motivation, and perceived higher levels of pain-care skills in themselves often use more patient advocacy skills in providing pain management for patients (Vaartio et al., 2009).

Nurses' assumptions about patients in pain seriously limit their ability to offer pain relief. Biases based on culture, education, and experience influence everyone. Too often nurses allow misconceptions about pain (Box 44-2) to affect their willingness to intervene. Some nurses avoid acknowledging a patient's pain because of their own fear and denial. They do not believe a patient's report of pain if he or she does not look in pain. A nurse is entitled to personal beliefs; however, he or she must *accept* a patient's report of pain and act according to professional guidelines, standards, position statements, policies and procedures, and evidence-based research findings (Pasero and McCaffery, 2011).

To help a patient gain pain relief, it is important to view the experience through the patient's eyes. Acknowledging a personal prejudice or misconception helps to address patient problems more professionally. When one becomes an active, knowledgeable observer of a patient in pain, it is possible to more objectively analyze the pain experience. The patient makes the diagnosis that pain is present, and the nurse provides interventions that ultimately offer relief.

Factors Influencing Pain

Pain is a complex process, involving physiological, social, spiritual, psychological, and cultural influences. Thus each individual's pain experience is different. Consider all factors that affect a patient in pain to ensure a holistic approach to the assessment and care of the patient.

Physiological Factors

Age. Age influences the pain experience. It is important to consider how a painful event affects a patient developmentally. For example pain may prevent an adolescent from engaging socially with friends. A middle-age adult may be unable to continue work in cases when it is severe. It is particularly important to recognize how developmental differences affect how infants and older adults react to pain. Young children have trouble understanding pain, its meaning, and the procedures that cause it. If they have not developed full vocabularies, they have difficulty verbally describing and expressing pain to parents or caregivers. Toddlers and preschoolers are unable to recall explanations about pain or associate it with experiences that may not be related to the painful condition. With these developmental considerations in mind, it is necessary to adapt approaches for assessing a child's pain (e.g., what to ask, including parents), the behaviors to observe, and how to prepare a child for a painful medical procedure.

Pain is not an inevitable part of aging. Likewise pain perception does not decrease with age. However, older adults have a greater likelihood of developing pathological conditions, which are accompanied by pain. In addition, age-related changes and increased frailty may lead to a less predictable response to analgesics, increased sensitivity to medications, and potential harmful drug effects (van Ojik et al., 2012). The person in pain, his or her family, and health care providers frequently take their chronic medical conditions for granted and underestimate the pain. Serious impairment of functional status often accompanies pain in older patients. It potentially reduces mobility, ADLs, social activities, and activity tolerance. The presence of pain in an older adult requires aggressive assessment, diagnosis, and management (Box 44-3).

The ability of older patients to interpret pain is sometimes complicated. They often suffer from multiple diseases with symptoms that affect similar parts of the body. The nurse must make detailed assessments when the source of pain is not clear. Different diseases sometimes cause similar symptoms. For example, chest pain does not always indicate a heart attack; it also is a symptom of arthritis of the spine or an abdominal disorder. When older adults experience cognitive impairment and confusion, they have difficulty recalling pain experiences and providing detailed explanations of their pain (Pasero and McCaffery, 2011). It is necessary to address misconceptions about pain

TABLE 44-3   Pain in Infants

Misconception	Correction
Infants cannot feel pain.	Infants have the anatomical and functional requirements for pain processing by mid-to-late gestation.
Infants are less sensitive to pain than older children and adults.	Term neonates have the same sensitivity to pain as older infants and children. Preterm neonates have a greater sensitivity to pain than term neonates or older children.
Infants cannot express pain.	Although infants cannot verbalize pain, they respond with behavioral cues and physiological indicators that are observable.
Infants must learn about pain from previous painful experiences.	Pain requires no prior experience; infants do not need to learn it from earlier painful experience. It occurs with the first insult.
You cannot accurately assess pain in infants.	You use behavioral cues (e.g., facial expressions, cry, body movements) and physiological indicators of pain (e.g., changes in vital signs) to reliably and validly assess pain in infants.
You cannot safely give analgesics and anesthetics to infants and neonates because of their immature capacity to metabolize and eliminate drugs and their sensitivity to opioid-induced respiratory depression.	Infants are very sensitive to drugs. Response to drugs is often intense and prolonged. Absorption is faster than expected. Dosages of drugs excreted by the kidneys need to be reduced (Burchum and Rosenthal, 2016). Prescribers carefully select the medication, dosage, administration route, and time. Nurses monitor frequently for desired and undesired effects. They also follow medication orders to titrate and wean medications to minimize adverse effects.

TABLE 44-4   Misconceptions About Pain in Older Adults

Misconception	Correction
Pain is a natural outcome of growing old.	Older adults are at greater risk (as much as twofold) than younger adults for many painful conditions; however, pain is not an inevitable result of aging.
Pain perception, or sensitivity, decreases with age.	This assumption is unsafe. Although there is evidence that emotional suffering specifically related to pain may be less in older than in younger patients, no scientific basis exists for the claim that a decrease in perception of pain occurs with age or that age dulls sensitivity to pain.
If the older patient does not report pain, he or she does not have pain.	Older patients commonly underreport pain. Reasons include expecting to have pain with increasing age; not wanting to alarm loved ones; being fearful of losing their independence; not wanting to distract, anger, or bother caregivers; and believing that caregivers know they have pain and are doing all they can to relieve it. The absence of a report of pain does not mean the absence of pain.
If an older patient appears to be occupied, asleep, or otherwise distracted from pain, he or she does not have pain.	Older patients often believe that it is unacceptable to show pain and have learned to use a variety of ways to cope with it (e.g., many patients use distraction successfully for short periods of time). Sleeping is sometimes a coping strategy; alternately, it indicates exhaustion, not pain relief. Do not make assumptions about the presence or absence of pain solely on the basis of a patient's behavior.
The potential side effects of opioids make them too dangerous to use to relieve pain in older adults.	Opioids are safe to use in older adults with moderate-to-severe pain (Arnstein, 2010). Although the opioid-naive older adult is usually more sensitive to opioids, this does not justify withholding their use in pain management. Slow titration prevents potentially dangerous opioid-induced side effects. Regular, frequent monitoring and assessment of a patient's response are necessary. Adjust dose and the interval between doses when you detect side effects. If necessary, administer an opioid antagonist drug to reverse clinically significant respiratory depression.
Patients with Alzheimer's disease and other cognitive impairments do not feel pain, and their reports of pain are most likely invalid.	No evidence exists that cognitively impaired older adults experience less pain or that their reports of pain are less valid than those of individuals with intact cognitive function (Herr, 2010). Patients with dementia or other deficits of cognition most likely suffer significant unrelieved pain and discomfort. Assessment of pain in these patients is challenging but possible. The best approach is to accept a patient's report of pain and treat it as you would treat it in an individual with intact cognitive function.
Older patients report more pain as they age.	Even though older patients experience a higher incidence of painful conditions such as arthritis, osteoporosis, peripheral vascular disease, and cancer than younger patients, studies show that they underreport pain. Many older adults grew up valuing the ability to "grin and bear it" (Pasero and McCaffery, 2011).

management in the very young and in older adults before intervening for a patient (Tables 44-3 and 44-4).

Fatigue. Fatigue heightens the perception of pain and decreases coping abilities. If it occurs along with sleeplessness, the perception of pain is even greater. Pain is often experienced less after a restful sleep than at the end of a long day.

Genes. Research on healthy human subjects suggests that genetic information passed on by parents possibly increases or decreases a person's sensitivity to pain and determines pain threshold or tolerance. Recent advances in the study of genetics and pain have shown that even slight changes in deoxyribonucleic acid (DNA) could partially explain individual differences in pain. Genetic influences have been

shown to play a role in sensitivity, perception, and expression of pain (James, 2013).

Neurological Function. A patient's neurological function influences the pain experience. Any factor that interrupts or influences normal pain reception or perception (e.g., spinal cord injury, peripheral neuropathy, or neurological disease) affects a patient's awareness of and response to pain. Some pharmacological agents (analgesics, sedatives, and anesthetics) influence pain perception and response because of the manner in which they affect the nervous system.

Social Factors

Attention. The degree to which a patient focuses attention on pain influences its perception. Increased attention is associated with increased pain, whereas distraction is associated with a diminished pain response. This concept is one that nurses apply in various pain-relief interventions such as relaxation, guided imagery, and massage. By focusing patients' attention and concentration on other stimuli, their perception of pain declines (see Chapter 33).

Previous Experience. Each person learns from painful experiences. Prior experience does not mean that a person accepts pain more easily in the future. Previous frequent episodes of pain without relief or bouts of severe pain cause anxiety or fear. In contrast, if a person repeatedly experiences the same type of pain that was relieved successfully in the past, he or she finds it easier to interpret the pain sensation. As a result, the patient is better prepared to take necessary actions to relieve the pain.

When a patient has no experience with a painful condition, the first perception of pain often impairs the ability to cope. For example, after abdominal surgery patients often experience severe incisional pain for several days. Unless a patient knows that this is a common occurrence following surgery, the onset of pain seems like a serious complication. Rather than participate actively in postoperative breathing exercises (see Chapter 50), the patient lies immobile in bed and breathes shallowly because of fear that something is not right. In the anticipatory phase of the pain experience, you need to prepare a patient with a clear explanation of the type of pain to expect and methods to reduce it. This usually results in a reduced perception of pain.

Family and Social Support. People in pain often depend on family members or close friends for support, assistance, or protection. Although pain still exists, the presence of family or friends can often make the experience less stressful. Conversation with family is a useful distraction. The presence of parents is especially important for children experiencing pain.

Spiritual Factors. Spirituality is an active searching for meaning in situations in which one finds oneself (Chapter 36). Spiritual beliefs affect the way patients view or cope with pain. Research studies have demonstrated that spiritual beliefs and preferences for spiritual interventions have been useful in pain management (Dezutter et al., 2011; Weinstein et al., 2014). Patients often ask spiritually based questions such as, "Why has this happened to me?" "Why am I suffering?" Spiritual pain goes beyond what we can see. "Why has God done this to me?" "Is this suffering teaching me something?" Other spiritual concerns include loss of independence and becoming a burden to family. Consider making a referral to pastoral care for patients in pain. Recall that pain is an experience that has physical *and* emotional components. Thus providing interventions designed to treat both aspects is essential for the best possible pain management.

Psychological Factors

Anxiety. A person perceives pain differently if it suggests a threat, loss, punishment, or challenge. For example, a woman in labor perceives pain differently than a woman with a history of cancer who is

experiencing a new pain and fearing recurrence. In addition, the degree and quality of pain perceived by a patient influences its meaning. The relationship between pain and anxiety is complex. Anxiety often increases the perception of pain, and pain causes feelings of anxiety. It is difficult to separate the two sensations.

Critically ill or injured patients who perceive a lack of control over their environment and care have high anxiety levels. This anxiety leads to serious pain-management problems. Pharmacological and non-pharmacological approaches to the management of anxiety are appropriate; however, anxiolytic medications are not a substitute for analgesia (Pasero and McCaffery, 2011).

Coping Style. Pain is a lonely experience that often causes patients to feel a loss of control. Coping style influences the ability to deal with it. People with internal loci of control perceive themselves as having control over events in their life and the outcomes such as pain. They ask questions, desire information, and make choices about treatment. In contrast, people with external loci of control perceive that other factors in their life such as nurses are responsible for the outcome of events. These patients follow directions and are more passive in managing their pain. Learn to understand patients' coping resources during painful experiences so you can incorporate these into your plan of care. For example, a patient who does not ask for pain medication but shows behavioral signs of discomfort might require you to be more responsive in offering prn medications on time (see Chapter 38).

Cultural Factors. The meaning that a person associates with pain affects the experience of pain and how one adapts to it. This is often closely associated with a person's cultural background, including age, education, race, and familial factors. Cultural beliefs and values affect how individuals cope with pain. They learn what is expected and accepted by their culture, including how to react to pain. Health care providers often mistakenly assume that everyone responds to pain in the same way. Different meanings and attitudes are associated with pain across various cultural groups. An understanding of the cultural meaning of pain helps you design culturally sensitive care for people with pain (Pasero and McCaffery, 2011).

Culture affects pain expression. Some people believe that it is natural to be demonstrative about pain. Others tend to be more introverted. When a person moves to another country, it is important to know to what extent the individual has assimilated into his or her new home. For example, if several generations of a Hispanic patient's family have lived in the United States, the influence of the Spanish culture may be limited, whereas newly immigrated patients still often embrace their cultural norms.

As a nurse explore the impact of cultural differences on a patient's pain experience and make adjustments to the plan of care (Box 44-4). Ask if the patient has had any previous bad experiences with pain management. Work with a patient and family to learn their cultural beliefs, values, and preferences to adequately assess and manage pain (Chapter 9). Find a culturally appropriate assessment tool and communicate use of that tool to other health care providers.

CRITICAL THINKING

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. To make clinical judgments, you anticipate the information you need, analyze the data, and make decisions regarding patient care. A patient's condition or situation is always changing. During assessment consider all critical thinking elements that lead to appropriate nursing diagnoses.

⊕ BOX 44-4   CULTURAL ASPECTS OF CARE

Assessing Pain in Culturally Diverse Patients

Pain is a biopsychosocial phenomenon. Culture shapes the experience of pain, including its expression and a patient's behaviors, or coping responses. For example, an individual from a higher socioeconomic group has more resources for managing pain and is more likely to adapt behaviors that will lessen pain. One research study showed that people in the lowest as compared to the highest socioeconomic class were 2 to 3 times more likely to feel disabled through pain (Dorner et al., 2011). Culture also affects a person's choice of lay remedies, help-seeking activities, and receptivity to medical treatment. Some health care providers undertreat pain because they do not understand the cultural effects on the perception of pain intensity. Nurses care for patients with pain from a variety of cultural backgrounds; thus you need to develop strategies to assess and manage pain in culturally diverse patients.

Implications for Patient-Centered Care

- Use culturally appropriate assessment tools such as tools written in the patient's native language to assess pain (Pasero and McCaffery, 2011).
- Assess the patient's health literacy level because this affects your ability to provide appropriate education about pain management and therapies.
- Recognize variations in subjective responses to pain. Some patients are stoic and less expressive, whereas others are emotive and more likely to verbalize pain.
- Be sensitive to variations in communication styles. Some cultures believe that nonverbal expression of pain is sufficient to describe the pain experience, whereas others assume that, if pain medication is appropriate, the nurse will bring it; thus asking is inappropriate.
- Understand that expression of pain is unacceptable within certain cultures. Some patients believe that asking for help indicates a lack of respect, whereas others believe acknowledging pain is a sign of weakness.
- The meaning of pain varies among cultures. Pain is personal and related to religious beliefs. Some cultures consider suffering a part of life to be endured to enter heaven.
- Use knowledge of biological variations of pain. Significant differences in drug metabolism, dosing requirements, therapeutic response, and adverse effects occur in cultural groups. A wide range of responses is also possible within this group. Therefore assess each patient's response to pain medication carefully.
- Develop a personal awareness of your own values and beliefs that affect your responses to patients' reports of pain.

Knowledge of pain physiology and the many factors that influence pain help you manage a patient's pain. Previous experience in caring for patients with pain sharpens your assessment skills and ability to choose effective therapies. Critical thinking attitudes and intellectual standards ensure the aggressive assessment, creative planning, and thorough evaluation needed to obtain an acceptable level of patient pain relief while balancing treatment benefits with treatment-associated risks. Successful pain management does not necessarily mean pain elimination but rather attainment of a mutually agreed-on pain-relief goal that allows patients to control their pain instead of the pain controlling them.

❖ NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care.

Nurses approach pain management systematically to understand and treat a patient's pain. Successful management of pain depends on establishing a relationship of trust among health care providers, patient, and family. Pain management extends beyond relief, encompassing the patient's quality of life and ability to work productively, enjoy recreation, and function normally in the family and society.

The American Nurses Association (ANA, 2005) upholds that pain assessment and management is within the scope of every nurse's practice. Thus the ANA offers a certification examination in pain management to staff nurses (http://www.aspmn.org/certification). Several clinical guidelines are available for managing pain in specific disorders. Guidelines are available through the American Pain Society (APS) on the management of pain in the primary care setting; sickle cell pain; cancer pain in adults and children; and pain in osteoarthritis, rheumatoid arthritis, and juvenile chronic arthritis. Sigma Theta Tau International offers guidelines for the older adult on its website (www.geriatricpain.org). In addition, the National Guidelines Clearinghouse (www.guideline.gov) posts a variety of pain-management guidelines.

◆ Assessment

During the assessment process thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care. A comprehensive assessment of pain aims to gather information about the cause of a person's pain and determine its effect on his or her ability to function.

Through the Patient's Eyes.   Many people view pain as a part of life. Some patients experience it for hours or days before seeking health care assistance. They often expect and even accept a certain amount of pain while being hospitalized. It is important to learn a patient's own values and beliefs about the management of pain and recognize that patient expectations will influence your ability to achieve outcomes in its management (QSEN, 2014). Asking a patient about his or her tolerable pain level is a first step in helping a patient regain control. Assessing previous pain experiences and effective home interventions provides a foundation on which you can build. Patients expect nurses to accept their reports of pain and be prompt in meeting their pain needs.

When assessing pain, be sensitive to the level of discomfort and determine which level will allow your patient to function. For example, when caring for a patient with pain, ask, "Which level of pain will allow you to walk down the hall?" The patient answers that walking is possible when pain is at a level of 2 on a scale of 0 to 10, with 0 being no pain and 10 being worst pain imaginable. You then plan therapies to decrease the patient's pain to that level. Be sure that he or she is a partner in making decisions about the best approaches for managing pain.

Another aspect of assessing pain through the patient's eyes is determining his or her health literacy. People who struggle to find a range of words to talk about their pain lack the ability to use language for symptom relief. Psychologists suggest that having a wide vocabulary with which to describe pain symptoms helps equip a person to better manage pain and reduce distress. Many agencies have assessment tools that allow you to get a more accurate measure of a patient's literacy skills.

If pain is acute or severe, it is unlikely that a patient is able to provide a detailed description of the entire experience. During an episode of acute pain, streamline your assessment and assess its location, severity, and quality. Collect a more detailed acute pain assessment when the patient is more comfortable (Box 44-5). For patients with chronic pain, a thorough pain assessment includes affective,

BOX 44-5 Nursing Assessment Questions

Current Pain: (Modify Assessment for Patient's Age, Cognitive Ability, Culture, Language, and Other Factors)

Palliative or Provocative factors: What makes your pain worse? What makes it better?

Quality: How do you describe your pain?

Relief measures: What do you take at home to gain pain relief?

Region (location): Show me where you hurt.

Severity: On a scale of 0 to 10, how bad is your pain now?
  • What is the worst pain you have had in the past 24 hours?
  • What is the average pain you have had in the past 24 hours?

Timing: Is your pain constant, intermittent, or both?

U: Effect of pain: What are you not able to do because of your pain?
  • With whom do you live, and how do they help you when you have pain?

Current Medications
• Which medications/herbs are you taking now?
• Are these medications and herbs effective in relieving the pain?
• Which nonpharmacological treatments have you tried to relieve the pain?
• Which medications have you tried in the past that worked to stop your pain?
• Have you ever used recreational drugs or alcohol to alleviate pain?

Activity
• What level of daily exercise can you maintain with your pain?
• Which type of movement increases or relieves your pain?
• Which type of activities do you now avoid because of your pain?

BOX 44-6 Routine Clinical Approach to Pain Assessment and Management: ABCDE

A: ***Ask*** about pain regularly. Assess pain systematically.
B: ***Believe*** patient and family in their report of pain and what relieves it.
C: ***Choose*** pain control options appropriate for the patient, family, and setting.
D: ***Deliver*** interventions in a timely, logical, and coordinated fashion.
E: ***Empower*** patients and their families. Enable them to control their course to the greatest extent possible.

From Jacox A et al: *Management of cancer pain,* Clinical Practice Guideline No. 9, AHCPR Publication No. 94-0592, Rockville, MD, 1994, Agency for Health Care Policy and Research, Public Health Service, US Department of Health and Human Services.

cognitive, behavioral, spiritual, and social dimensions. In the home care setting family members assess pain. Using the ABCs of pain management is an effective way to manage pain (Box 44-6).

Because pain is dynamic, accurate assessment requires you to monitor it on a regular basis along with other vital signs. Some institutions treat it as the fifth vital sign. Pain assessment is *not* simply a number. Relying solely on a number fails to capture the multidimensionality of pain and may be unsafe, particularly when the number fails to reflect the entire pain experience or when the patient does not understand the use of the selected pain-rating scale. Pain assessment is a nursing function. However, nursing assistive personnel (NAP), physical therapists, social workers, and others also screen for pain by asking patients if they are having pain. When pain is noted by any care provider, it is essential that a nurse be informed immediately so he or she can make a thorough assessment to confirm the patient's discomfort and provide appropriate treatment.

Knowledge
• Physiology of pain
• Factors that potentially increase or decrease responses to pain
• Pathophysiology of conditions causing pain
• Awareness of biases affecting pain assessment and treatment
• Cultural variations in how pain is interpreted and expressed
• Knowledge of nonverbal communication

Experience
• Caring for patients with acute, chronic, and cancer pain
• Caring for patients who experienced pain as a result of a health care therapy
• Personal experience with pain

ASSESSMENT
• Determine the patient's perspective of pain, including history of pain, its meaning, and its physical, emotional, and social effects
• Obtain the patient's description of the characteristics of the pain
• Use pain scales that are valid and reliable for the specific patient population
• Review potential factors affecting the patient's pain (e.g., time since surgery or injury, patient's position in bed)
• Identify medical comorbidities (e.g., diabetes, cancer)

Standards
• Refer to AHRQ guidelines for acute pain management
• Refer to clinical guidelines of APS and ASPMN
• Apply intellectual standards (e.g., clarity, specificity, accuracy, and completeness) when gathering assessment
• Apply relevance when letting the patient explore the pain experience

Attitudes
• Persevere in exploring causes and possible solutions for chronic pain
• Display confidence when assessing pain to relieve the patient's anxiety
• Display integrity and fairness to prevent prejudice from affecting assessment

FIGURE 44-4 Critical thinking model for pain assessment. *AHRQ,* Agency for Healthcare Research and Quality; *APS,* American Pain Society; *ASPMN,* American Society for Pain Management Nursing.

The ability to establish a nursing diagnosis, decide on appropriate interventions, and evaluate a patient's response (outcomes) to interventions depends on the fundamental activity of a factual, timely, accurate pain assessment (Figure 44-4). The core of this complex activity is the exploration of the pain experience through the eyes of the patient. Nurses use a variety of tools to assess nociceptive and neuropathic pain. In selecting a tool to be used with a patient, be aware of the clinical usefulness, reliability, and validity of the tool in that specific patient population. For example, a tool that has been validated for use with preverbal children may not have validity or reliability for use with adults. Assessment tools (or scales) are available for use with a number of different patient populations, including critically ill adults, young

children, or adults with advanced dementia. The goal in using these tools is to identify how much pain exists, not to identify how much pain the patient tolerates.

It is necessary to be aware of possible errors in pain assessment (Box 44-7). Using the right tools and methods helps to avoid errors and ensures the selection of the right pain interventions. Failure of clinicians to accurately assess a patient's pain, accept the findings, and treat the report is a common cause of unrelieved pain and suffering.

BOX 44-7   Possible Sources for Error in Pain Assessment

- Bias, which causes nurses to consistently overestimate or underestimate the pain that patients experience
- Vague or unclear assessment questions, which lead to unreliable assessment data
- Use of pain assessment tools that are not evidence based or validated in a particular patient population
- Use of medical terms that patients with low health literacy cannot understand
- Patients who do not always provide complete, relevant, and accurate pain information
- Patients who are cognitively impaired and unable to use pain scales

---

Patient's Expression of Pain. A patient's self-report of pain is the single most reliable indicator of its existence and intensity (APS, 2009; Pasero and McCaffery, 2011). Pain is individualistic. Many patients fail to report or discuss discomfort. At the same time many nurses believe that patients report pain if they have it. If patients sense that you doubt that pain exists, they share little information about their pain experience or minimize their report. A caring therapeutic relationship must be established with the patient that allows for open communication. Simple measures such as sitting when talking to patients about pain lets them know that you are sincerely concerned about their pain.

Patients unable to communicate effectively often require special attention during assessment. Infants and children, people who are developmentally delayed, patients who are psychotic, the patient who is critically ill or at end of life, patients with dementia, and patients who are aphasic or do not speak English all require different approaches. Herr et al. (2011) examined various pain behavior-assessment tools used with patients who were cognitively impaired. Although no one tool had sufficient reliability and validity, there are clinical practice recommendations (Box 44-8). However, you need to understand that "the number obtained when using a pain-behavior scale is a pain-behavior score, not a pain-intensity rating" (Pasero and McCaffery, 2011). These tools identify the presence of pain but do not determine its intensity.

BOX 44-8   EVIDENCE-BASED PRACTICE

Pain Assessment in the Nonverbal Patient

PICO Question: In elderly nonverbal patients, which pain-assessment tool is most effective in determining presence of pain?

Evidence Summary

A common misconception is that individuals who are nonverbal as a result of dementia or cognitive impairments do not experience pain (Herr et al., 2011). Patients who are nonverbal often present with atypical manifestations of pain caused by pathophysiological changes in the brain. Manifestations often include hitting, fearful expressions, combativeness, and resistance to care (Herr et al., 2011). An appointed task force of the American Society for Pain Management Nursing developed an evidence-based position statement and clinical practice recommendations for pain assessment in nonverbal patients (Herr et al., 2011). No single assessment strategy such as interpretation of behaviors, pathology, or estimates of pain by others is sufficient by itself in determining the presence of pain in a nonverbal patient.

A number of tools have been developed to assess for the presence of pain in cognitively impaired adults. Although research studies have demonstrated that these tools can be used to determine the presence of pain, there has been little evidence to determine whether they can be used to identify pain intensity. In a study by Lukas et al (2013), the Abbey Pain Scale, Pain Assessment in Advanced Dementia Scale (PAINAD), and Noncommunicative Patient's Pain Assessment Instrument (NOPPAIN) were shown to enable observers to recognize the presence or absence of pain and provide a rating of pain severity in older people with impaired cognition.

Application to Nursing Practice
- Recommended assessment considerations:
  - Attempt a self-report of pain using simple yes/no responses or vocalizations or a numerical rating scale (Herr et al., 2011).
  - Search for potential causes of pain (Herr et al., 2011). Examples include pain associated with intravenous insertion site infiltrations, abdominal cramping and fullness, urinary retention, muscle spasm, and prolonged pressure on body parts associated with immobility.
  - Assume that pain is present (APP) after ruling out other problems (infection, constipation) that cause pain.
  - Identify pathological conditions or procedures that cause pain.
  - Observe patient behaviors and list behaviors (e.g., facial expressions, vocalizations, body movements, changes in interactions or mental status) that indicate pain. These vary, depending on patient's developmental level (Herr et al., 2011).
  - Ask family members, parents, or caregivers for a surrogate report.
- Use behavioral pain assessment tools.
  - Use evidence-based tools to ensure appropriate pain assessment (Herr et al., 2011).
  - Evidence supports use of the PAINAD for assessment of pain in patients with advanced dementia (Mosele et al., 2012).
  - Determine the appropriate scale on the basis of individual patient needs; no one scale measures pain accurately for all groups of patients.
- Vital signs are not sensitive indicators for the presence of pain.
- Choose analgesic, dose, and titration on the basis of estimated intensity of pain.
- For mild-to-moderate pain, confer with health care provider to give nonopioid analgesics around the clock.
- After 24 hours reassess. If behaviors improve, assume that pain was the cause.
- If behaviors persist, consult with physician about giving a single, low-dose short-acting opioid (e.g., morphine). Observe effect.
- If behaviors continue, obtain order to titrate dose upward by 25% to 50% and observe effect.
- Continue to titrate up until a therapeutic effect or bothersome adverse effects occur or if there is no benefit.
- If behaviors continue after a reasonable analgesic trial, explore other potential causes.

TABLE 44-5 Classification of Pain by Location

Location	Characteristics	Examples of Causes
Superficial or Cutaneous Pain resulting from stimulation of skin	Pain is of short duration and localized. It usually is a sharp sensation.	Needlestick; small cut or laceration
Deep or Visceral Pain resulting from stimulation of internal organs	Pain is diffuse and radiates in several directions. Duration varies, but it usually lasts longer than superficial pain. Pain is sharp, dull, or unique to organ involved.	Crushing sensation (e.g., angina pectoris); burning sensation (e.g., gastric ulcer)
Referred Common in visceral pain because many organs themselves have no pain receptors (The entrance of sensory neurons from affected organ into same spinal cord segment as neurons from areas where individual feels pain causes perception of pain in unaffected areas.)	Pain is in part of body separate from source of pain and assumes any characteristic.	Myocardial infarction, which causes referred pain to the jaw, left arm, and left shoulder; kidney stones, which refer pain to groin
Radiating Sensation of pain extending from initial site of injury to another body part	Pain feels as though it travels down or along body part. It is intermittent or constant.	Low back pain from ruptured intravertebral disk accompanied by pain radiating down leg from sciatic nerve irritation

Patients with cognitive impairments often require insightful assessment approaches involving close observation of vocal response, facial movements (e.g., grimacing, clenched teeth), and body movements (e.g., restlessness, pacing). Also assess social interaction (e.g., does the patient avoid conversation?). Patients who are critically ill and have a clouded sensorium or the presence of nasogastric tubes or artificial airways require specific questions that they can answer with a nod of the head or by writing out a response. If the patient speaks a different language, pain assessment is difficult. A professional interpreter is often necessary (Pasero and McCaffery, 2011).

When a patient is in pain, conduct a focused physical and neurological examination and observe for nonverbal responses to pain (e.g., grimacing, rigid body posture, limping, frowning, or crying) (Pasero and McCaffery, 2011). Examine the painful area to see if palpation or manipulation of the site increases pain.

Characteristics of Pain. Assessment of the characteristics of pain allows you to understand the type of pain, its pattern, and the types of interventions that bring relief. Use of instruments to quantify the extent and degree of pain depends on a patient being cognitively alert enough to be able to understand and follow instructions.

Timing (Onset, Duration, and Pattern). Ask questions to determine the onset, duration, and time sequence of pain. When did it begin? How long has it lasted? Does it occur at the same time each day? Is it intermittent, constant, or a combination? How often does it recur? It is sometimes easier to diagnose the nature of pain by identifying time factors. Knowing the time cycle or pattern of pain helps you intervene before the pain occurs or worsens.

Location. Ask a patient to describe or point to all areas of discomfort to assess pain location. To localize the pain specifically, have him or her trace the area from the most severe point outward. This is difficult to do if pain is diffuse or involves several sites or parts of the body. Do not assume that your patient's pain always occurs in the same location. When describing pain location to other health care providers, use anatomical landmarks and descriptive terminology. The statement

"Pain is localized in the upper right abdominal quadrant" is more specific than "The patient states the pain is in the abdomen." Pain classified by location is superficial or cutaneous, deep or visceral, referred, or radiating (Table 44-5).

Severity. One of the most subjective and therefore most useful characteristics for reporting pain is its severity. Nurses teach patients how to use pain scales to help them communicate pain severity or intensity. Many scales are available in several languages to aid nurses when a professional interpreter is not present (Pasero and McCaffery, 2011). The purpose of using a pain scale is to identify pain intensity over time so the effectiveness of interventions can be evaluated (Pasero and McCaffery, 2011). It is important to select the scale that is appropriate for a patient's age, language, and ability and to ensure that the patient understands how to use it. Examples of pain-intensity scales include numerical rating scales (NRSs), verbal descriptor scales (VDSs), and visual analog scales (VASs) (Figure 44-5).

An NRS requires patients to rate pain on a line scale of 0 to 10, with 0 representing no pain and 10 representing the worst pain the patient can imagine. These scales work best when assessing pain intensity before and after therapeutic interventions. A VDS consists of a line with three to six word descriptors equally spaced along the line. Show a patient the scale and ask him or her to choose the descriptor that best represents the severity of pain. A VAS consists of a straight line without labeled subdivisions. The straight line shows a continuum of intensity and has labeled end points. A patient indicates pain by marking the appropriate point on the line. Use a scale to measure the current severity of a patient's pain. Also ask patients to rate their average pain and the worst pain they have had in the past 24 hours. This information allows you to see trends in pain severity.

A good pain scale is easy to use, understandable, and not time consuming. If a patient is able to read and understand a scale easily, the pain description is more accurate. If patients use a hearing aid or glasses, be sure that they are using them when answering pain-assessment questions or marking a pain scale. Once you select a scale

that works for a patient, be sure to use it consistently. Do not use a pain scale to compare the pain of one patient to that of another.

Assessing pain intensity in children requires special techniques. Children's verbal statements are most important (Hockenberry and Wilson, 2015). Young children do not always know what the word *pain* means; therefore assessment requires you to use words such as *owie, boo-boo,* or *hurt.* Some unique tools are available to measure pain intensity in children. Faces Pain Scales are commonly used, with four having undergone extensive psychometric testing for reliability and validity: Faces Pain Scale (FPS) (scored 0-6); Faces Pain Scale—revised (FPS-R) (0-10); Oucher pain scale (0-10); and Wong-Baker Faces Pain-Rating Scale (WBFPRS) (0-10) (Tomlinson et al., 2010). The "Oucher" (Beyer et al., 1992) uses photographs of the face of a child (in increasing levels of discomfort) to cue children into understanding pain and its severity. A child points to a face on the tool, thus simplifying the task of describing the pain. There are cultural versions of the tool (Figure 44-6). The WBFPRS (Wong and Baker, 1988) assesses pain in verbal children (Figure 44-7). The scale consists of six cartoon faces ranging from a smiling face ("no hurt") to increasingly less happy faces; to a final sad, tearful face ("hurts worst"). Children as young as 3 years of age use the scale. The FPS was adapted by the IASP in 2001 to facilitate a rating score from 0-10. This version, known as the FPS-R (Figure 44-8) has the advantage of not displaying emotion such as

smiles or tears and may be used with children ages 4 to 16 years (IASP, 2014a). Nurses use a variety of other tools to assess pain in neonates, infants, nonverbal toddlers, and children with cognitive impairments.

Quality. There is no common or specific pain vocabulary in general use. Patients describe pain in their own way. A study conducted in 1990 showed that Hispanics, American Indians, blacks, and whites all rated pain as the most intense term, followed by hurt; ache was the least intense (Gaston-Johansson et al., 1990). The research is dated, but it

Oucher®

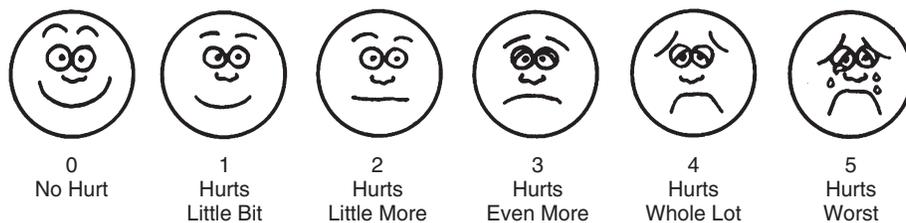
FIGURE 44-5 Sample pain scales. **A,** Numerical. **B,** Verbal descriptive. **C,** Visual analog.


Brief word instructions: Point to each face using the words to describe the pain intensity. Ask the child to choose face that best describes own pain and record the appropriate number.

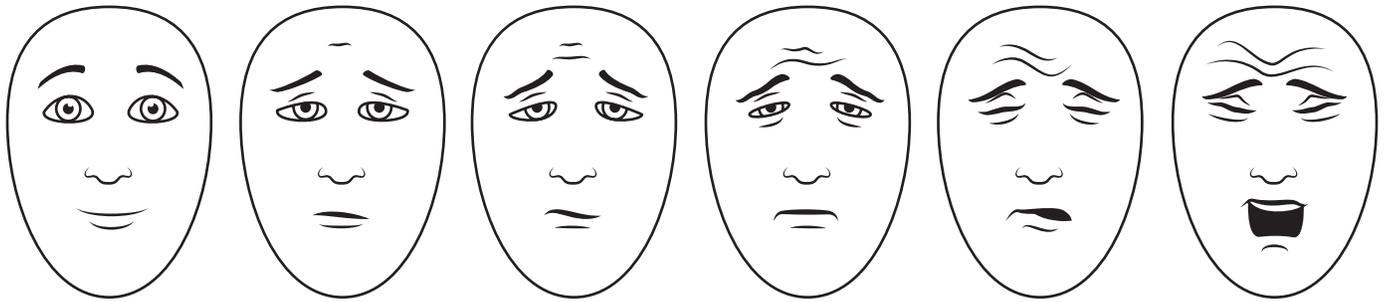
FIGURE 44-7 Wong-Baker Faces Pain Scale. (From Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children,* ed 10, St Louis, 2015, Mosby.)


FIGURE 44-8 Faces Pain Scale-revised (FPS-R). (From the International Association for the Study of Pain.)

shows the importance of not assuming that one patient perceives pain differently than another only on the basis of cultural background. Assess the terms that patients use to describe their discomfort and then always use these words consistently to obtain an accurate report. For example, say, "Tell me what your discomfort feels like." The patient may describe the pain as crushing, throbbing, sharp, or dull. For example, if it is dull, when you return to the patient, ask if it is still "dull." It is always more accurate to have patients describe the pain in their own words whenever possible.

There is some consistency in the way people describe certain types of pain. The pain associated with a myocardial infarction is often described as crushing or viselike; whereas the pain of a surgical incision is often described as dull, aching, and throbbing, indicating nociceptive pain. Neuropathic pain is usually burning, shooting, or electric-like (Sadler, 2013). When a patient's descriptions fit the pattern forming in the assessment, you then make a clearer analysis of the nature and type of pain. This leads to more appropriate pain management because you treat nociceptive and neuropathic pain differently.

Aggravating and Precipitating Factors. Various factors or conditions precipitate or aggravate pain. Ask a patient to describe activities that cause or aggravate pain such as physical movement, positions, drinking coffee or alcohol, urination, swallowing, eating food, or psychological stress. Also ask them to demonstrate actions that cause a painful response such as coughing or turning a certain way. Some symptoms (depression, anxiety, fatigue, sedation, anorexia, sleep disruption, spiritual distress, and guilt) cause worsening of pain or may be aggravated by it. Assess for these associated symptoms and evaluate their effects on the patient's pain perception. After identifying specific aggravating or precipitating factors, it is easier to plan interventions to avoid worsening the pain.

Relief Measures. It is useful to know whether a patient has an effective way of relieving pain such as changing position, using ritualistic behavior (pacing, rocking, or rubbing), eating, meditating, praying, or applying heat or cold to the painful site. The patient's methods are ones that can often be used for treatment if appropriate to the cause of pain. Patients gain trust when they know that nurses are willing to try their relief measures. This is particularly the case in home settings. Patients gain a sense of control over the pain instead of the pain controlling them. Assessment of relieving factors also includes identification of all the patient's health care providers (e.g., internist, orthopedist, acupuncturist, chiropractor, or dentist).

Effects of Pain on the Patient.   Pain alters a person's lifestyle and psychological well-being. For example, chronic/persistent pain causes suffering, loss of control, loneliness, exhaustion, and an impaired quality of life. To understand a pain experience, ask the patient what the pain prevents him or her from doing.

BOX 44-9   Behavioral Indicators of Effects of Pain

Vocalizations
- Moaning
- Crying
- Gasping
- Grunting

Facial Expressions
- Grimace
- Clenched teeth
- Wrinkled forehead
- Tightly closed or widely opened eyes or mouth
- Lip biting

Body Movement
- Restlessness
- Immobilization

- Muscle tension
- Increased hand and finger movements
- Pacing activities
- Rhythmic or rubbing motions
- Protective movement of body parts
- Grabbing or holding a body part

Social Interaction
- Avoidance of conversation
- Focus only on activities for pain relief
- Avoidance of social contacts
- Reduced attention span
- Reduced interaction with environment

Behavioral Effects. When a patient has pain, assess verbalization, vocal response, facial and body movements, and social interaction. A verbal report of pain is a vital part of assessment. You need to be willing to listen and understand. When a patient is unable to communicate pain, it is especially important for you to be alert for behaviors that indicate it (Box 44-9).

The nonverbal expression of pain either supports or contradicts other information about it. If a woman in labor reports that her labor pains are occurring more frequently and if she begins to massage her abdomen more often, this confirms her report. If a patient reports severe abdominal pain but continues to grasp the chest, a more detailed assessment is likely needed.

Influence on Activities of Daily Living. Patients who live with daily pain or have prolonged pain during a hospitalization are less able to participate in routine activities, which results in physical deconditioning. This deconditioning can slow recovery of hospitalized patients. Assessment of these changes reveals the extent of the patients' disabilities and adjustments necessary to help them participate in self-care. The primary goal of the nurse is to improve patient function.

Ask a patient whether pain interferes with sleep. Some patients experience difficulty in falling asleep and/or staying asleep. The pain may awaken the patient during the night and make it hard to fall back

to sleep. Consider giving medications or trying nonpharmacological interventions to promote sleep (see Chapter 43). Patients should be instructed not to use pain medications for the purpose of sleep promotion, and they should not use medications that promote sleep as a substitute for pain relief.

Depending on the location of the pain, some patients have difficulty independently performing ADLs. For example, some pain restricts mobility to the point at which a patient is no longer able to bathe in a bathtub or dress himself or herself. Patients with severe arthritis find it painful to grasp eating utensils or lower themselves to a toilet seat. Assess the patient's need for help with self-care activities, determine if a family caregiver provides assistance at home, and collaborate with members of the health care team (e.g., physical and occupational therapy).

Pain sometimes impairs the ability to maintain normal sexual relations. Physical conditions such as arthritis or back pain may prevent patients from assuming usual positions during intercourse. Pain or fatigue may reduce a patient's desire for sex. An assessment should include the extent to which pain affects the patient's usual sexual activity (i.e., physically unable or reduced desire). Pain threatens a person's ability to work. The more physical activity required in a job, the greater the risk of discomfort when the pain is associated with movement. Pain related to emotional stress increases in individuals whose jobs involve stressful decision making. Assess the work that patients do and their abilities to function in their jobs. Assess the daily chores of homemakers in the same manner as the duties involved in jobs outside the home. Also assess whether it is necessary for patients to stop activity occasionally because of pain and help them select ways to minimize or control it so they are able to remain productive.

Include an assessment of the effect of pain on social activities. Some pain is so debilitating that the patient becomes too exhausted to socialize. Identify a patient's normal social activities, the extent to which activities have been disrupted, and the desire to participate in these activities.

Concomitant Symptoms. Concomitant symptoms, including nausea, headache, dizziness, urge to urinate, constipation, depression and restlessness, occur with pain and usually increase a patient's pain severity. Certain types of pain have predictable concomitant symptoms. For example, severe rectal pain often leads to constipation. These symptoms are as much a problem to a patient as the pain itself.

◆ Nursing Diagnosis

An accurate nursing diagnosis may be made only after you perform a complete assessment. The development of accurate nursing diagnoses for a patient in pain results from thorough data collection and analysis (Box 44-10). Careful assessment reveals the presence or potential for pain. Be sure that your assessment includes the patient's history of recent procedures or preexisting painful conditions.

The nursing diagnosis focuses on the specific nature of a patient's pain to identify the most useful types of interventions for alleviating it and improving the patient's function. *Acute Pain related to physical trauma* and *Acute Pain related to natural childbirth processes* require very different nursing interventions. Accurate identification of related factors is necessary in choosing appropriate nursing interventions. For example, interventions for *Acute Pain related to physical trauma* usually require pharmacological intervention, whereas *Acute Pain related to natural childbirth processes* is sometimes managed more appropriately with nonpharmacological interventions such as controlled breathing techniques.

A pain assessment often directs you to identify additional diagnoses other than that of *Acute* or *Chronic Pain.* The extent to which pain

---

BOX 44-10 Nursing Diagnostic Process

Chronic Pain

Assessment Activities	Defining Characteristics
Have patient describe pain intensity.	Pain constant; patient verbally reports 5 on a scale of 0 to 10
Assess onset and location of pain.	Present for 7 months in lower lumbar area
Observe patient behaviors.	Grimaces and grunts with movement, rubs flanks frequently; reduced movement
Assess effect of pain on activities of daily living (ADLs).	Appetite poor; gets little sleep; difficulty dressing
Review medical history.	Previous trauma; effectiveness of past pain control measures

---

affects a patient's function and general state of health determines whether other nursing diagnoses are relevant. For example, your assessment reveals that a patient reports having pain of the hands and shoulders and has difficulty removing or fastening necessary items of clothing. The patient has had osteoarthritis for over 3 years with persistent discomfort and weakness of the upper extremities. The nursing diagnoses for this patient are *Dressing Self-Care Deficit* and *Chronic Pain.* The diagnosis of *Dressing Self-Care Deficit* requires involvement by members of the interdisciplinary health care team to provide the patient with assistive devices for performing self-care. Examples of other diagnoses that may be related to pain follow:

• *Activity Intolerance*
• *Anxiety*
• *Bathing Self-Care Deficit*
• *Ineffective Coping*
• *Fatigue*
• *Impaired Physical Mobility*
• *Insomnia*
• *Impaired Social Interaction*

◆ Planning

During the planning step of the nursing process, analyze information from multiple sources. Critical thinking ensures that a patient's plan of care (see the Nursing Care Plan) integrates all that is known about the individual and key critical thinking elements (Figure 44-9). Professional standards are especially important to consider when developing a plan of care. These standards establish evidence-based guidelines for selecting effective nursing interventions. Professional standards of care regarding pain management are available as agency policies or through professional organizations such as the American Society for Pain Management Nursing (ASPMN).

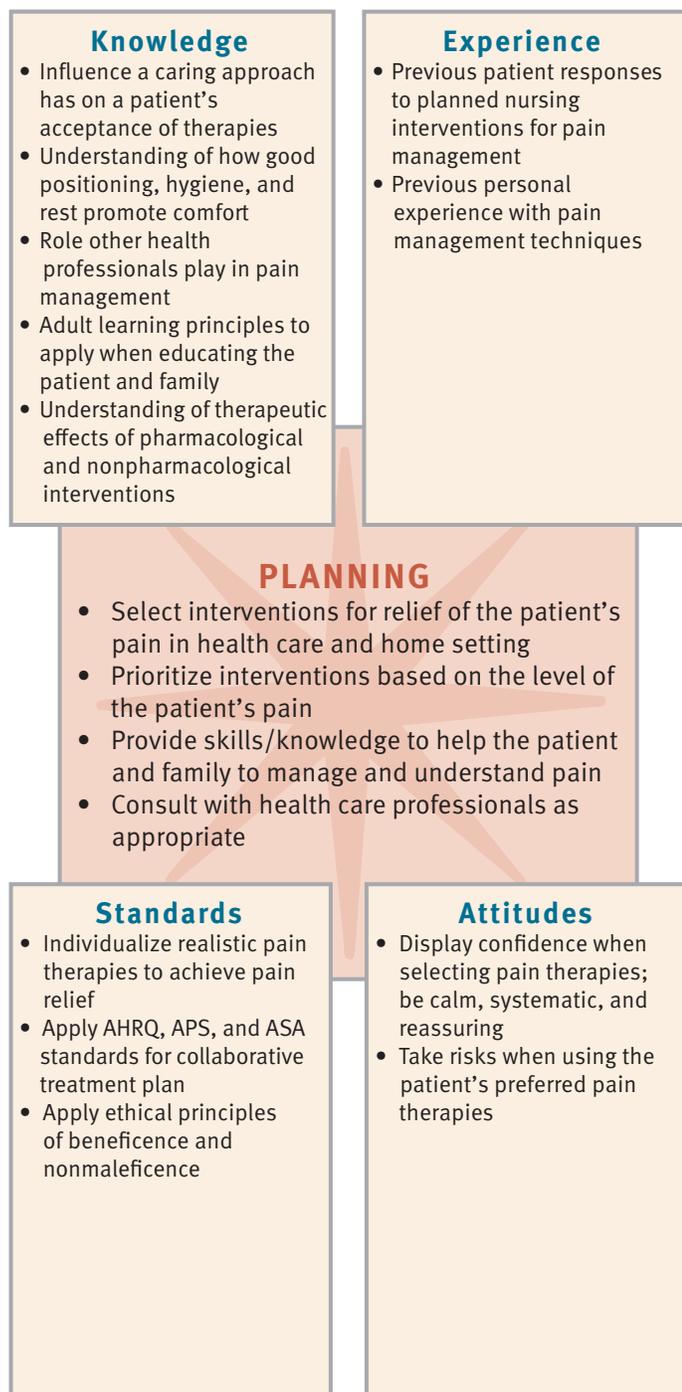
Another strategy for planning care is using a concept map. Patients who are in pain frequently have interrelated problems. As one problem gets worse, other aspects of a patient's level of health also change. A concept map helps you determine how the nursing diagnoses are interrelated with one another and linked to the patient's medical diagnosis. This eventually allows you to also see how interventions are related for different diagnoses. Using the example for Mrs. Mays, the patient with osteoarthritis, note the relationships among *Acute Pain, Impaired Physical Mobility, Dressing and Feeding Self-Care Deficit,* and *Fatigue* (Figure 44-10). Identifying these relationships helps you develop a holistic and patient-centered plan of care.


FIGURE 44-9 Critical thinking model for pain management planning. *AHRQ,* Agency for Healthcare Research and Quality; *APS,* American Pain Society; *ASA,* American Society of Anesthesiologists.

Knowledge
- Influence a caring approach has on a patient's acceptance of therapies
- Understanding of how good positioning, hygiene, and rest promote comfort
- Role other health professionals play in pain management
- Adult learning principles to apply when educating the patient and family
- Understanding of therapeutic effects of pharmacological and nonpharmacological interventions

Experience
- Previous patient responses to planned nursing interventions for pain management
- Previous personal experience with pain management techniques

PLANNING
- Select interventions for relief of the patient's pain in health care and home setting
- Prioritize interventions based on the level of the patient's pain
- Provide skills/knowledge to help the patient and family to manage and understand pain
- Consult with health care professionals as appropriate

Standards
- Individualize realistic pain therapies to achieve pain relief
- Apply AHRQ, APS, and ASA standards for collaborative treatment plan
- Apply ethical principles of beneficence and nonmaleficence

Attitudes
- Display confidence when selecting pain therapies; be calm, systematic, and reassuring
- Take risks when using the patient's preferred pain therapies

Goals and Outcomes. When managing pain, goals of care promote a patient's optimal function. Along with the patient, determine the realistic expectations for pain relief. Decide on a mutually acceptable level of pain that allows return of function. Make sure that the patient understands that complete pain relief is probably not possible but that every effort will be made to allow him or her to safely reach a pain level that allows for maximum function.

It is important to remember that a successful plan of care requires a therapeutic relationship with a patient and family to focus on a

relevant education plan. Helping patients learn how to manage their pain is always a goal of care. You help best by listening to the patient's concerns, needs, and understanding of available pain relief measures. A patient knows the most about his or her pain and is an important partner in selecting successful pain therapies.

An indication of the success of a plan of care is determined through attainment of goals and outcomes. For example, for the goal "the patient will achieve a satisfactory level of pain relief within 24 hours," the following are possible outcomes:
- Reports that pain is a 3 or less on a scale of 0 to 10
- Avoids factors that intensify pain
- Uses pain-relief measures safely
- Level of discomfort does not interfere with dressing self

Setting Priorities. When setting priorities in pain management, consider the type of pain the patient is experiencing and the effect that it has on various body functions. Work with the patient to select interventions that are appropriate. For example, if an analgesic is relieving acute pain, turn your attention to how the pain is affecting the patient's activity, appetite, and sleep. In contrast, when a patient's pain continues to be severe, preventing implementation of other interventions, immediate pain relief is the obvious priority. Priorities change as a patient's pain experience changes.

Teamwork and Collaboration. A comprehensive plan includes a variety of resources from the health care team such as advanced practice nurses, doctors of pharmacology (PharmDs), physical therapists, occupational therapists, physicians, social workers, psychologists, and clergy. An oncology or pain clinical nurse specialist is very familiar with pharmacological and nonpharmacological interventions that are most effective for chronic/persistent pain. PharmDs are knowledgeable about pharmacological treatments of pain. Physical therapists plan exercises that strengthen muscle groups and lessen pain in affected areas. Occupational therapists devise splints to support painful body parts. Physicians are familiar with pharmacological interventions, and some are skilled in interventional pain procedures such as nerve blocks and spinal cord stimulator implantations. Social workers and psychologists may offer nonpharmacological approaches to pain management such as cognitive behavioral therapy or mindfulness training. Clergy members help patients focus on spiritual health. It is important to also involve family caregivers in the plan of care. They will often administer care in the home after discharge. If the pain-management plan is not successful in achieving the identified pain-relief goal, talk with the patient's health care provider about revising it. Consultation with a pain expert is sometimes necessary.

◆ Implementation

Pain therapy requires an individualized approach, perhaps more so than any other patient problem. The nurse, patient, and frequently the family are partners in pain management. You are responsible for administering and monitoring therapies ordered by health care providers for pain relief and independently providing measures that complement those prescribed. Generally try the least invasive or safest therapy first along with previously used successful patient remedies. If you question a medical therapy, consult with the health care provider.

Regardless of the therapies chosen, your ability to show compassionate care toward patients has the potential for maximizing their pain control. You can help the patient minimize pain through caring behaviors such as listening, offering a gentle touch, and responding promptly to a pain request.

◎ NURSING CARE PLAN

Acute Pain

ASSESSMENT

Mrs. Mays, 72 years old, was diagnosed with a cancerous tumor in her left lung 2 months ago. She also has a history of osteoarthritis, which was diagnosed 8 years ago. The arthritis causes chronic inflammation with mild-to-moderate pain in the joints of her hands and wrists that affects her daily. After chemotherapy and radiation therapy, she took ibuprofen (Advil) 200 mg on an as-needed (prn) basis to manage her osteoarthritis pain and other physical discomforts. Until today she was able to clean her home and climb the stairs to her bedroom without difficulty. She also maintained her body weight and slept well through the night. However, she is now admitted to the hospital with uncontrollable chest pain, shortness of breath, and possible pneumonia. Her husband is with her. The nurse practitioner orders a patient-controlled analgesia (PCA) of morphine 0.5 mg demand dose with a 10-minute lockout.

Assessment Activities	*Findings/Defining Characteristics**
Ask Mrs. Mays what she did at home to control her acute onset of chest pain.	Her chest **pain rapidly escalated** over several hours from a 3 to a 10 on a scale of 0 to 10, so she doubled her ibuprofen and went to bed; but this did not help.
Ask Mrs. Mays to describe the pain she is having now.	She responds that she is having sharp and stabbing, constant pain on the lower left side of her chest.
Ask Mrs. Mays what her chest pain intensity is now.	On a scale of 0 to 10, **she reports a 7.**
Ask Mrs. Mays what has helped and worsened her chest pain.	She responds that her pain is lessened by being very still and taking shallow breaths. It is worsened by deeper breaths and coughing. Walking causes her to breathe more deeply, which worsens the pain.
Ask Mrs. Mays what her pain has prevented her from doing.	She responds that she is **unable to concentrate, sleep, complete her own hygiene activities, or eat.**
Ask Mrs. Mays what her joint pain intensity is now.	She responds that on a day-to-day basis she doesn't even notice it anymore, unless she has periods of increased activity. On a scale of 0 to 10, she reports a 1.
Observe Mrs. Mays's nonverbal behavior.	She is **restless,** is **unable to stay focused,** her **muscles tense, and** she is **frowning** during the history taking.
Ask Mrs. Mays what her pain-intensity goal (on a scale of 0 to 10) is?	She says that a pain intensity of 5 on a scale of 0 to 10 would help her function better right now. A goal of 3 is preferable.

****Defining characteristics** are shown in bold type.

NURSING DIAGNOSIS: Acute pain related to abrupt onset of inflammation

PLANNING

Goals	*Expected Outcomes (NOC)*[†]
	Pain Control
Mrs. Mays will reach a tolerable level of pain before discharge.	Mrs. Mays reports pain at target goal of 3 or below.
	Mrs. Mays demonstrates correct use of PCA device.
	Pain: Disruptive Effects
Mrs. Mays will actively participate in activities of daily living (ADLs).	Mrs. Mays reports sleeping for 5 to 6 hours without interruption from pain.
	Mrs. Mays completes her own hygiene with minimal assistance.
	Mrs. Mays is able to take deep breaths, cough, and use the incentive spirometer every hour.
	Mrs. Mays walks the hallway with her husband every 4 hours for 15 minutes.
	Medication Response
Mrs. Mays will be free of opioid side effects.	Mrs. Mays reports having a normal bowel movement every other day.

[†]Outcome classification labels from Moorhead S et al: *Nursing outcomes classification (NOC),* ed 5, St Louis, 2013, Mosby.

INTERVENTIONS (NIC)[‡]	**RATIONALE**
Pain Management	
Begin PCA at ordered dose. Explain to patient how to use the PCA. Explain to patient and spouse the purpose of the pump and emphasize the importance of only the patient pushing the button, not the husband.	Severe acute pain requires immediate-release opioid. Discouraging the husband from pushing the button prevents unnecessary doses and reduces potential dangerous effects of the opioid. Patient needs to be awake to perceive the pain and push the button (Pasero and McCaffery, 2011).
Monitor intravenous (IV) PCA morphine use. Explain to patient and spouse the action of the medication, potential side effects, and the importance of reporting unrelieved pain.	Pain is easier to prevent than to treat. Side effects are usually transient, except for constipation. Calculating 24-hour dosage of opioid helps determine appropriate oral dose (Pasero and McCaffery, 2011).
Have patient select nonpharmacological interventions that have relieved her pain in the past (e.g., distraction, music, simple relaxation therapy) or that are acceptable to her.	Nonpharmacological approaches augment pharmacological therapy and help patients improve quality of life and decrease anxiety and depression (Kolanowski, 2013).
Teach spouse how to perform slow-stroke back massage.	Slow-stroke back massage is easy to do, takes a short time, and induces relaxation (Buyukyilmaz and Asti, 2013).

[‡]Intervention classification labels from Bulechek GM et al: *Nursing interventions classification (NIC),* ed 6, St Louis, 2013, Mosby.

◎ **NURSING CARE PLAN**

Acute Pain—cont'd

EVALUATION

Nursing Actions	Patient Response/Finding	Achievement of Outcome
Ask Mrs. Mays if she has attained her pain-relief goal most of the time.	She responds, "My pain usually runs around a 3, except when I start coughing or walking."	Mrs. Mays reports an acceptable level of pain. Instruct her to push her button before ambulating or when she feels the pain intensity rising above 3 out of 10.
Observe Mrs. Mays while using the incentive spirometer.	Mrs. Mays is using the incentive spirometer and is able to cough and take deep breaths without splinting every hour.	Ability to cough, breathe deeply, and use the incentive spirometer has improved. Encourage her to continue pulmonary exercises hourly.
Observe Mrs. Mays performing ADLs, walking, and during sleep.	Mrs. Mays is dressed for breakfast, walking the hallway every 4 hours with her husband. The night nurse's notes indicate that she slept through the night.	Ability to perform ADLs and sleep has improved. Continue to monitor.
Observe Mrs. Mays as she ambulates in the hallway.	Mrs. Mays successfully ambulated in the hallway with her husband twice during the shift with minimal increase in pain intensity.	Improved pain control has increased her activity, a nonverbal indicator of pain. Continue to monitor.
Ask Mr. Mays if he was able to give his wife a backrub.	Mr. Mays reported that she did not want a backrub but preferred to have her feet rubbed, which he was happy to do. "She said it made her feel more relaxed."	Nonpharmacological intervention was successful but needs to be changed from backrub to footrub in the nursing care plan.
Ask Mrs. Mays when she last had a bowel movement and its consistency.	She has not had a bowel movement in 3 days (since starting the morphine PCA).	Assess her abdomen for bowel sounds and distention and return of flatus. Consult with health care provider about starting a stimulant laxative once intestinal obstruction is ruled out (Pasero and McCaffery, 2011).
Observe Mrs. Mays for excessive drowsiness.	Mrs. Mays is awake and alert during conversations and interacts frequently with her husband.	Sedation, an indicator of too much opioid, is not identified. Continue to monitor.

Health Promotion. When providing pain-relief measures, choose therapies suited to a patient's unique pain experience. Apply guidelines for individualizing pain therapy, including the following:

- Use different types of pain-relief measures.
- Use measures that patient believes are effective.
- Keep an open mind about ways to relieve pain.
- Keep trying. When efforts at pain relief fail, do not abandon the patient but reassess the situation.

Maintaining Wellness. Patients are better prepared to handle almost any situation when they understand it. The experience of pain and related therapies are no exception. However, patients with moderate-to-severe pain are not always able to participate in decision making until the pain is controlled at an acceptable level. Once you accomplish this, you can begin teaching.

Health literacy significantly affects a patient's pain experience and understanding of pain-management strategies. Low health literacy poses significant barriers to optimal pain management. In a study of patients with chronic pain, patients with low health literacy were found to have low overall pain medication knowledge and did not know where to find health care professionals to help them with their pain (Devraj et al., 2013). The patients in the study also lacked knowledge about nonpharmacological approaches to pain management and did not know which nonprescription pain medications could provide pain relief. Research conducted with patients with chronic back pain and other patient groups provides evidence for why educational materials and approaches must be adapted so they are suited for low–health literacy patients. In addition, combat any cultural norms that may stop patients from talking about pain at all. Stoicism not only potentially obscures dangerous signs about which you should know, but it also denies people the opportunity to use labels as a tool to cope with pain. Help patients who don't have the words to describe their pain find them (Bucher, 2014). Because pain affects physical and mental functioning, holistic health approaches are important interventions for maintaining wellness. Holistic health is an ongoing state of wellness that involves taking care of the whole person: body, mind, spirit, and emotions. To achieve optimal health and well-being, it is necessary to have balance of all of the interdependent elements of the whole person (Matthews-Kozanecka, 2014).

Patients actively participate in their own well-being whenever possible. Common holistic health approaches include wellness education, regular exercise, rest, attention to good hygiene practices and nutrition, and management of interpersonal relationships. When a person develops pain, you can offer nonpharmacological and pharmacological strategies. Several nonpharmacological interventions are nurse initiated.

Nonpharmacological Pain-Relief Interventions. A number of nonpharmacological interventions are available for lessening pain. However, more research is needed to truly know the best approach, intensity, duration, and content of these interventions, especially for the treatment of chronic pain (Park and Hughes, 2012). The researchers suggest that nonpharmacological interventions may be useful for patients who cannot tolerate pain medications, those who wish to reduce multiple medications, and those who are seeking alternative methods of relieving chronic pain.

Nonpharmacological interventions can be used alone or in combination with pharmacological measures. However, in the case of acute pain, they should never be used in place of pharmacological therapies. Nonpharmacological interventions include cognitive-behavioral and physical approaches. Cognitive-behavioral interventions change patients' perceptions of pain, alter pain behavior, and provide patients with a greater sense of control. Distraction, prayer, relaxation, guided imagery, music, and **biofeedback** are examples.

Physical approaches aim to provide pain relief, correct physical dysfunction, alter physiological responses, and reduce fears associated with pain-related immobility. Complementary and alternative medicine (CAM) therapies such as therapeutic touch and mindfulness meditation help to alleviate pain in some patients (see Chapter 33). An evidence-based practice protocol for pain management in older

CONCEPT MAP

Nursing diagnosis: Acute pain
- Patient reports tenderness in joints of fingers in right hand, aching in joints of fingers in left hand
- Tenderness in right wrist when assessing ROM
- Patient rates pain a 6 on a scale of 0 to 10
- Patient grimaces when using hands to pick up 5-lb objects

▼

Interventions
- Administer ordered analgesic ATC for 24 to 48 hours
- Apply cool compresses to hands with prescriber's approval
- Encourage distraction through music or watching television

Nursing diagnosis: Impaired physical mobility
- Unable to grasp knife and fork without discomfort
- Reduced ROM: moves 15 degrees right wrist, 10 degrees left wrist
- Reports stiffness in wrists and fingers bilaterally, worse in morning

▼

Interventions
- Premedicate patient before physical therapy
- Elevate extremity to reduce swelling
- Apply warm or cool compresses to wrists, with prescriber's approval
- Plan for active and passive ROM after applying compresses

Primary health problem: Rheumatoid arthritis of both hands and wrists
Priority assessments: Joint ROM, comfort, activity tolerance, general mobility

Nursing diagnosis: Dressing and feeding self-care deficit
- Unable to fasten buttons on clothes
- Reports difficulty removing socks and underwear
- Appearance is disheveled, hair is uncombed
- Has difficulty opening food containers
- Reports unable to cut many foods with knife

▼

Interventions
- Collaborate with OT to provide assist devices for grooming
- Schedule analgesic dose 30 minutes before meals

Nursing diagnosis: Fatigue
- Reports being tired, especially after joint flare-ups
- Requires more frequent rest periods during day
- Reports participating in fewer social activities because of feeling tired

▼

Interventions
- Plan rest periods before major activities (e.g., morning hygiene, meals, social events)
- Plan sleep therapies for uninterrupted sleep

——— Link between medical diagnosis and nursing diagnosis   - - - - - Link between nursing diagnoses

FIGURE 44-10 Concept map for Mrs. Mays. *ATC,* Around the clock; *OT,* occupational therapist; *ROM,* range of motion.

adults recommends these guidelines for nonpharmacological therapies (Horgas et al., 2012):
- Tailor nonpharmacological techniques to the individual.
- Cognitive behavioral strategies may not be appropriate for the cognitively impaired.
- Physical pain-relief strategies focus on promoting comfort and altering physiological responses to pain and are generally safe and effective.

Relaxation and Guided Imagery. Relaxation and **guided imagery** allow patients to alter affective-motivational and cognitive pain per-

ception. **Relaxation** is mental and physical freedom from tension or stress that provides individuals a sense of self-control. You use relaxation techniques at any phase of health or illness. Physiological and behavioral changes associated with relaxation include the following: decreased pulse, blood pressure, and respirations; heightened awareness; decreased oxygen consumption; a sense of peace; and decreased muscle tension and metabolic rate (Topcu and Findik, 2012). Relaxation techniques include meditation, yoga, Zen, guided imagery, and progressive relaxation exercises (see Chapter 33). For effective relaxation, teach techniques only when a patient is not distracted by

acute discomfort. Sometimes a combination of these techniques is needed to achieve optimal pain relief. With practice the patient performs relaxation exercises independently.

Distraction. The reticular activating system inhibits painful stimuli if a person receives sufficient or excessive sensory input. With sufficient sensory stimuli, a person ignores or becomes unaware of pain. People who are bored or in isolation have only their pain to think about and thus perceive it more acutely. Distraction directs a patient's attention to something other than pain and thus reduces awareness of it. A disadvantage of distraction is that, if it works, health care providers or family members may question the existence or severity of the pain. Distraction works best for short, intense pain lasting a few minutes such as during an invasive procedure or while waiting for an analgesic to work. Use activities enjoyed by the patient as distractions (e.g., singing, praying, listening to music, or playing games).

Music. Music therapy may be useful in treating acute or chronic pain, stress, anxiety, and depression (Allred et al., 2010; Korhan et al., 2014). It diverts a person's attention away from the pain and creates a relaxation response. Music creates positive changes in mood and emotional states and allows patients to actively participate in treatment. Music therapy uses all kinds of music. It is important to let patients select the type of music they prefer. Music produces an altered state of consciousness through sound, silence, space, and time. Therapeutic sessions usually last 20 to 30 minutes (Hughes, 2008). Patients may use earphones to enhance their concentration on the music. This allows them to adjust the volume without interrupting other patients or staff. Evidence shows that music contributes to the pain relief of hospitalized patients and may decrease the use of analgesics in some postoperative patients (Cole and LoBiondo-Wood, 2014).

Cutaneous Stimulation. Stimulation of the skin through a massage, warm bath, cold application, and **transcutaneous electrical nerve stimulation (TENS)** may be helpful in reducing pain perception. How **cutaneous stimulation** works is unclear. One suggestion is that it causes release of endorphins, thus blocking the transmission of painful stimuli. The gate-control theory suggests that cutaneous stimulation activates larger, faster-transmitting A-beta sensory nerve fibers. This closes the gate, thus decreasing pain transmission through small-diameter C fibers (Melzack and Wall, 1965).

Cutaneous stimulation gives patients and families some control over pain symptoms and treatment in the home. Using it properly helps to reduce muscle tension, resulting in less pain. When using cutaneous stimulation, eliminate sources of environmental noise, help the patient to assume a comfortable position, and explain the purpose of the therapy. Do not use it directly on sensitive skin areas (e.g., burns, bruises, skin rashes, inflammation, and underlying bone fractures).

Massage is effective for producing physical and mental relaxation, reducing pain, and enhancing the effectiveness of pain medication. Massaging the back, shoulders, hands, and/or feet for 3 to 5 minutes relaxes muscles and promotes sleep and comfort. Cutshall et al. (2010) reported a significant decrease in pain, anxiety, and tension in patients with cardiac problems who received a 20-minute massage. In older adults slow back massage and a 20-minute hand massage improved pain, anxiety, tension, and insomnia (Harris and Richards, 2010). Massages communicate caring and are easy for family members or other health care personnel to learn (Box 44-11).

Cold and heat applications (see Chapter 48) relieve pain and promote healing. The selection of heat-versus-cold interventions varies with patients' conditions (Guild, 2012). For example, moist heat helps to relieve the pain from a tension headache, and cold applications reduce the acute pain from inflamed joints. When using any form of heat or cold application, instruct the patient to avoid injury to the skin

by checking the temperature and not applying cold or heat directly to the skin. Especially at risk for injury are patients with diabetic neuropathies, spinal cord or other neurological disorders, older adults, and patients who are confused.

Cold therapies are particularly effective for acute pain relief. Ice massage involves the use of a large ice cube or a small paper cup filled with water and frozen (water rises out of the cup as it freezes to create a smooth surface of ice for massage). A nurse or the patient applies the ice with firm pressure to the skin, which is covered with a lightweight cloth. Then use a slow, steady, circular massage over the area. Apply cold within a 6-inch circular area near the pain site or on the opposite side of the body corresponding to the pain site. Limit application to 5 minutes or when the patient feels numbness (Spine Health, 2006). Each patient responds differently to the site of application. Application near the actual site of pain tends to work best. A patient feels cold, burning, and aching sensations and numbness. You can apply ice 2 to 5 times a day (Spine Health, 2006). Cold is effective for tooth or mouth pain when you place the ice on the web of the hand between the thumb and index finger. This point on the hand is an **acupressure** point that influences nerve pathways to the face and head. Cold applications are also effective before invasive needle punctures.

Heat application is more effective for some patients, especially those with chronic pain. Chapter 48 discusses in detail the type of heat devices (e.g., warm compresses and commercial heat packs) that are safe to use. Never place a heat application in a microwave unless it is directed by the manufacturer. Then follow directions carefully. Teach patients to check the temperature of the compress carefully and not to lie on the heating element because burning can occur.

Another form of cutaneous stimulation is TENS, involving stimulation of the skin with a mild electrical current passed through external electrodes. A TENS unit consists of a battery-powered transmitter, lead wires, and electrodes. TENS works both peripherally and centrally: centrally it acts by activating sites in the spinal cord and brainstem that use opioid and serotonin receptors; peripherally neuroreceptors at the site of the TENs application produce analgesia (DeSantana et al., 2008). It can be applied at various frequencies (<10 Hz to >50 Hz) and intensity (sensory versus motor) (DeSantana et al., 2008). Stimulation intensity has been shown to be the critical factor in TENS efficacy. A TENS unit requires a health care provider's order that identifies the site for the TENS electrode placement. Remove any hair or skin preparations before attaching the electrodes. Then place the electrodes directly over or near the pain site. Turn the transmitter on to the ordered level when the patient feels pain. The TENS creates a buzzing or tingling sensation. After assessing the patient's tolerance, he or she can then turn on the transmitter and adjust the intensity and quality of skin stimulation until pain relief occurs. TENS is effective for acute, emergent, and postsurgical and procedural pain control (DeSantana et al., 2008).

Herbals. Many patients use herbals and dietary supplements such as echinacea, ginseng, ginkgo biloba, and garlic despite conflicting research evidence supporting their use in pain relief. Significant attention has been paid to the potential benefits of glucosamine and chondroitin in the treatment of osteoarthritis, but the evidence is inconclusive (Fouladbakhsh, 2012). Herbal supplements may interact with prescribed analgesics; thus it is important to ask patients to report to their health care provider all of the substances they take to relieve pain (see Chapter 33).

Reducing Pain Perception and Reception. One simple way to promote comfort is to remove or prevent painful stimuli (Box 44-12). This is especially important for patients who are immobilized or have difficulty expressing themselves. For example, your patient becomes constipated and has abdominal distention and cramping. You should

BOX 44-11   PROCEDURAL GUIDELINES

Massage

Delegation Considerations

The skill of administering a massage may be delegated to nursing assistive personnel (NAP). However, the nurse must first assess for any possible contra-indication and evaluate the patient's response to massage. Direct the NAP to:

- Use massage techniques that are effective for patient.
- Massage specific body parts.
- Avoid massaging reddened skin areas.
- Notify the nurse of early signs of impaired skin integrity or changes in skin appearance.
- Report worsening in patient's pain.

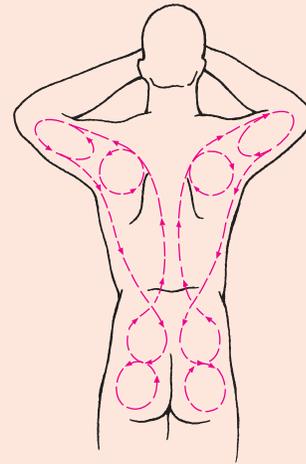
Equipment

Bath towel, lotion, blanket

Steps

1. On the basis of patient assessment, decide on performing massage on one or more body parts.
2. Assess skin areas for reddened areas or impaired skin integrity.
3. Collect appropriate equipment.
4. Explain procedure to the patient.
5. Identify patient using two identifiers (e.g., name and birthday or name and medical record) according to agency policy.
6. Perform hand hygiene.
7. Help patient assume a comfortable lying or sitting position.
8. Dim room lights and/or turn on soft music according to patient preference.
9. Use warm body lotion as lubricant.

   CLINICAL DECISION: Do not give back or neck massages to patients who have had neck or spinal trauma and/or surgery without an order from their health care provider.

10. Massage each body part at least 10 minutes.
    a. *Back:* Begin at the sacral area and massage in a circular motion (see illustration) while moving upward from buttocks to shoulders. Use a firm, smooth stroke over scapula. Continue in one smooth stroke to upper arms and laterally along sides of back down to iliac crests. Use long, gliding strokes along muscles of spine. Knead any muscles that feel tense or tight. Knead skin by gently grasping tissue between thumb and fingers. Knead upward along one side of spine from buttocks to shoulders around nape of neck. Knead or stroke downward toward sacrum. Repeat along other side of back.


STEP 10a Back massage pattern.

b. *Neck:* Support neck at hairline with one hand and massage up with a gliding stroke. Knead muscles on one side. Switch hands to support neck and knead other side. Stretch neck slightly, with one hand at top and the other at bottom.
c. *Arms:* Use gliding stroke to massage from patient's wrist or forearm. With thumb and forefinger of both hands, knead muscles from forearm to shoulder. Continue kneading biceps, deltoid, and triceps muscles. Finish with gliding strokes from wrists to shoulder.
d. *Hands:* Using both hands, slowly open patient's palm; glide fingers over palmar surface. While supporting patient's hand, use both thumbs to apply friction to palm and move them in a circular motion to stretch palm outward. Massage each finger with a corkscrew-like motion from base of finger to tip. With thumb and forefinger gently knead each muscle in patient's fingers. Glide hands smoothly from fingertips to wrists. Repeat for other hand.
e. *Feet:* Gently massage top and bottom of each foot. Using gliding motion, massage from heel to toe. Gently massage dorsal surface of foot and each toe. Repeat for other foot.

CLINICAL DECISION: Do not massage patient's legs or calf muscles because of the risk of dislodging a vascular clot.

11. At end of massage have patient relax, taking slow, deep breaths.
12. Ask patient to rate level of pain.
13. Note any areas of muscle pain or tension.
14. Note any areas of redness or impairment.
15. Report any areas of skin breakdown to the health care team.

BOX 44-12   Controlling Painful Stimuli in Patient's Environment

- Tighten and smooth wrinkled bed linen.
- Reposition patient anatomically to relieve any pressure points.
- Reposition patient to avoid lying on tubing (e.g., intravenous tubing, chest tubes).
- Loosen constricting bandages (unless specifically applied as a pressure dressing).
- Change wet dressings and linens.
- Position patient in anatomical alignment according to individual preference or requirements.
- Check temperature of hot or cold applications, including bath water.
- Lift patient in bed—do not pull. Use safe patient–handling lift devices.
- Position patient correctly on a bedpan.
- Avoid exposing skin or mucous membranes to irritants (e.g., urine, stool, wound drainage).
- Keep patients clean, dry, and turned if needed. Use urinary incontinence pads if indicated.
- Prevent urinary retention by keeping Foley catheters patent and free flowing if in use, while also monitoring urinary output.
- Prevent constipation with fluids, diet, exercise, and stimulant laxatives if needed.

intervene to ensure that the normal elimination process continues: increasing fluids, ambulating the patient, and/or requesting stool softeners or laxatives. Another example involves reducing pain perception during procedures using techniques such as proper patient positioning and coaching to perform progressive muscle relaxation. Always consider the patient's condition, aspects of the procedure that are uncomfortable, and techniques to avoid causing pain. In a patient with severe arthritic knee pain who has severe discomfort during any extreme flexion of the knee, take precautions before walking the patient to the bathroom. Use an elevated toilet seat to allow him or her to sit and rise with minimal discomfort.

Acute Care. Nurses often care for patients who have acute pain resulting from invasive procedures (e.g., surgery) or trauma. Many professional organizations such as the APS, American Society of Anesthesiologists (ASA), ASPMN, and the American Society of PeriAnesthesia Nurses (ASPAN), have published guidelines and position papers related to acute pain management. The key to success is ongoing pain assessment and evaluation of the efficacy of interventions. Does the patient feel relief? Are there any unacceptable side effects from the medications? It is the responsibility of the health care team to collaborate to find the combination of therapy that works best for a patient.

Pharmacological Pain Therapies. Many pharmacological agents are available to provide pain relief. Your judgment in the use and management of analgesics with or without other pain therapies ensures the best pain relief possible. Unfortunately the ideal analgesic (i.e., one that provides highly effective pain relief without significant risks or side effects) has yet to be developed.

Analgesics. **Analgesics** are the most common and effective method of pain relief. However, health care providers and nurses still tend to undertreat patients because of insufficient knowledge about pain management, incorrect drug information, concerns about addiction, exaggerated concerns about opioid analgesic safety, and administration of less medication than was ordered (D'Arcy, 2008; Gordon et al., 2008). You need to understand the medications available for pain relief, their indications for use, and their pharmacological effects. Reassure patients that treatment of pain is necessary to aid recovery and that addiction is highly unlikely when analgesics are taken correctly.

There are three types of analgesics: (1) nonopioids, including acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs); (2) **opioids** (traditionally called *narcotics*); and (3) **adjuvants** or co-analgesics, a variety of medications that enhance analgesics or have analgesic properties that were originally unknown (Pasero and McCaffery, 2011).

Acetaminophen (Tylenol), considered one of the most tolerated and safest analgesics available, is available in a variety of over-the-counter (OTC) oral medications (e.g., cold and flu remedies) or rectal forms and in an intravenous (IV) preparation (Ofirmev). The analgesic effect of acetaminophen is not entirely clear, but it is believed to have a direct effect on the central nervous system. It has no antiinflammatory effects. IV acetaminophen (Ofirmev) is an effective analgesic agent because it crosses the blood-brain barrier rapidly, thus providing nonopioid analgesia for postoperative patients, especially those who cannot take oral medications. The maximum 24-hour dose is 4 g (the same limitation as aspirin). Acetaminophen is often combined with opioids (e.g., oxycodone [Percocet], hydrocodone [Lortab], tramadol [Ultracet]) because it reduces the dose of opioid needed to achieve successful pain control. When acetaminophen is combined with an opioid in these products, it is important to recognize the abbreviations that describe the contents of the product. The order and package label often state "name of opioid/acetaminophen (abbreviated as APAP)

5/325" which means that the opioid is 5 mg and the acetaminophen (APAP) is 325 mg per tablet. For example, oxycodone/APAP 5/325 indicates that each tablet contains 5 mg of oxycodone and 325 mg of acetaminophen. Similar abbreviations are used for combination products of hydrocodone and tramadol.

The major adverse effect of acetaminophen is hepatotoxicity; and, because the drug is so widely used, the Food and Drug Administration (USFDA, 2014) issued an order to limit the amount of acetaminophen in prescription combination products to 325 mg per tablet, capsule, or other dosage unit. Instructions for acetaminophen-containing products such as 1 to 2 tablets every 4 to 6 hours, were not required to change in the order. Higher dosing units continue to be available in OTC products, but the products are required to include dosage labeling information about safety risks, including liver injury and the risks of serious skin rashes. Although some manufacturers have voluntarily reduced the maximum daily acetaminophen dose labeling on their OTC products, the FDA has not reduced the maximum daily dose limit of 4 g for adults. Reduced doses are necessary for inadequate liver function and are recommended to prevent accidental overdose in the outpatient setting. It is important to read and understand these warning labels. Dangerous hepatotoxic overdoses of acetaminophen are treated with acetylcysteine (Mucomyst) (Pasero and McCaffery, 2011).

Nonselective NSAIDs such as aspirin, ibuprofen, and naproxen relieve mild-to-moderate acute intermittent pain such as that from headache or muscle strain. Treatment of mild-to-moderate postoperative pain begins with an NSAID unless contraindicated (Pasero and McCaffery, 2011). NSAIDs likely act by inhibiting the synthesis of prostaglandins (Day and Graham, 2013) and thus inhibit cellular responses to inflammation. Most NSAIDs act on peripheral nerve receptors to reduce transmission of pain stimuli and inflammation. Unlike opioids, NSAIDs do not depress the central nervous system, nor do they interfere with bowel or bladder function (Pasero and McCaffery, 2011). However, NSAID use in the older patient is not recommended because it is associated with more frequent adverse effects (gastrointestinal bleeding and renal insufficiency) (AGS, 2009). Mild-to-moderate musculoskeletal pain in older adults is managed effectively with acetaminophen (AGS, 2009; Pasero and McCaffery, 2011). Some patients with asthma or an allergy to aspirin are also allergic to other NSAIDs (Morales et al., 2015). As with all OTC medications, patients should be advised to discuss their use of NSAIDs and their pain with their health care provider.

Opioid or opioid-like analgesics are prescribed for moderate-to-severe pain. These analgesics act on higher centers of the brain and spinal cord by binding with opiate receptors to modify perceptions of pain. Examples of opioids include morphine, codeine, hydromorphone (Dilaudid), fentanyl, oxycodone, and hydrocodone (Vicodin, Lortab). Some are available in IV and oral preparations (morphine and hydromorphone), whereas others are only available in oral formulations (oxycodone and hydrocodone). Most are available in a short-acting form, which provides relief for about 4 hours; some are also available in longer-acting preparations (oral morphine, oxycodone, hydromorphone, and a transdermal fentanyl patch).

Opioids can cause numerous common side effects (Box 44-13). Except for constipation and central nervous system changes, patients usually become tolerant to many of them. Other side effects associated with long-term use include depression, impaired sleep patterns, endocrine effects (decreased testosterone levels, decreased libido), and immune system suppression. To reduce side effects, patients should take the lowest dose of an opioid needed to manage pain. For example, if the prescriber initially ordered oxycodone 10 mg PO every 4 hours and the patient has nausea and is very drowsy, the nurse might suggest

BOX 44-13 Common Opioid Side Effects

Central Nervous System (CNS) Toxicity
- Drowsiness
- Cognitive impairment
- Confusion
- Hallucinations
- Myoclonic jerks
- Euphoria
- Sedation
- Sleep disturbances
- Dizziness

Ocular
- Pupil constriction

Respiratory
- Bradypnea
- Hypoventilation

Cardiac
- Hypotension
- Bradycardia
- Peripheral edema

Gastrointestinal
- Constipation
- Nausea
- Vomiting
- Delayed gastric emptying

Genitourinary
- Urinary retention

Endocrine
- Hormonal and sexual dysfunction

Skin
- Pruritus

Immunological
- Immune system impairment possible with chronic use

Tolerance
- Over time, increased doses needed to obtain analgesic effect

Withdrawal Syndrome
- Rapid or sudden cessation or marked dose reduction may cause rhinitis, chills, pupil dilatation, diarrhea, "gooseflesh"

that the prescriber reduce the dose to 5 mg. After administration, reassess a patient for the effect of the lowered dose on pain level and side effects. If reducing a dose does not relieve a side effect, confer with the prescriber about a change in the type of opioid. If side effects persist, it may be necessary to prevent or treat them by administering other medications (antihistamines, antiemetics, stimulants). Constipation should always be anticipated and prevented through diet, hydration, and the use of stool softeners and stimulants as needed.

A rare adverse effect of opioids in opioid-naïve patients (patients who have used opioid around the clock (ATC) *less* than approximately 1 week) is respiratory depression. Respiratory depression is only clinically significant if there is a decrease in the rate and depth of respirations from a patient's baseline assessment (Pasero and McCaffery, 2011). All patients who receive opioids are at risk, but patients who are opioid naïve (new or restarting opioids) are at greater risk than those who have been taking them daily on a regular basis (TJC, 2012). It is important for nurses to obtain a complete opioid medication history, including dose, frequency, and duration of use to determine whether patients are opioid naïve or tolerant. Patients who breathe deeply rarely have clinical respiratory depression. Sedation always occurs before respiratory depression. Closely monitor for sedation in opioid-naïve patients (Pasero and McCaffery, 2011). If an adult patient experiences respiratory depression, administer naloxone (Narcan) (0.4 mg diluted with 9 mL saline) IV push (IVP) at a rate of 0.5 mL every 2 minutes until the respiratory rate is greater than 8 breaths/min with good depth (Pasero and McCaffery, 2011). Administering naloxone faster than recommended may cause severe pain and serious complications such as

hypotension and hypertension, cardiac arrhythmias, dyspnea, and pulmonary edema (Pasero and McCaffery, 2011). Evaluate patients who receive naloxone every 15 minutes for 2 hours following drug administration because its duration may be less than that of the opioid and respiratory depression sometimes returns.

One way to maximize pain relief while potentially decreasing opioid use is to administer analgesics ATC rather than a prn basis. This approach ensures a more constant therapeutic blood level of an analgesic. The APS (2009) supports ATC administration if pain is anticipated for the majority of the day. There are also a variety of extended- or controlled-release oral opioid formulations (dosing intervals of 8, 10, 12 or 24 hours) and transdermal patches (72 hours). These formulations maintain constant serum opioid concentration, minimizing toxic and subtherapeutic concentrations (Burchum and Rosenthal, 2016). An ATC medication lessens the severity of end-of-dose pain, allowing a patient to sleep through the night and reduce "clock watching" for the next dose.

Careful assessment and critical thinking are required to safely administer analgesics (Box 44-14). The current pharmacological approach to acute and chronic pain management is to provide **multimodal analgesia**. Multimodal analgesia combines drugs with at least two different mechanisms of action so pain control can be optimized. Medications are combined to target different sites in the peripheral or central pain pathways (Figure 44-11). A main benefit of multimodal analgesia is that the use of different agents allows for lower-than-usual

BOX 44-14 Nursing Principles for Administering Analgesics

Know Patient's Previous Response to Analgesics
- Determine whether patient has allergies.
- Know whether patient is at risk for using NSAIDs (e.g., history of GI bleeding or renal insufficiency) or opioids (e.g., history of obstructive or central sleep apnea).
- Identify previous doses and routes of analgesic administration to avoid undertreatment.
- Determine whether patient obtained relief.
- Ask whether a nonopioid was as effective as an opioid.

Select Proper Medications When More Than One Is Ordered
- Use nonopioid analgesics or opioid combination drugs for mild-to-moderate pain.
- Give opioids with nonopioids to provide a multimodal analgesia approach.
- Avoid using multiple opioids with the same duration and mechanism of action.
- Intravenous medications act more quickly and usually relieve severe, acute pain within 1 hour; whereas oral medications take as long as 2 hours to relieve pain.
- Avoid intramuscular analgesics, especially in older adults.
- Use an opioid with a nonopioid analgesic for severe pain because such combinations treat pain peripherally and centrally.
- For chronic pain give sustained-release oral formulations ATC.

Know Accurate Dosage
- Recall that 4 g is considered the maximum 24-hour dosage for acetaminophen and acetylsalicylic acid (ASA); 3200 mg for ibuprofen.
- Adjust doses as appropriate for children and older patients.
- Large doses of opioids are acceptable in opioid-tolerant patients but not in opioid-naive patients.
- When titrating opioid, it is important to titrate to effect or to uncontrollable side effects.

Assess Right Time and Interval for Administration
- Administer analgesics as soon as pain occurs and before it increases in severity.
- An ATC administration schedule is usually best.
- Give analgesics before pain-producing procedures or activities.
- Know the average duration of action for a drug and the time of administration so the peak effect occurs when the pain is most intense.
- Use extended-release opioid formulations to treat chronic pain.
- Avoid stopping opioids abruptly in patients who are opioid tolerant.

ATC, Around the clock; *GI,* gastrointestinal; *NSAIDs,* nonsteroidal antiinflammatory drugs.

BOX 44-15 Patient Characteristics Associated with Higher Risk for Opioid-Related Adverse Drug Events

- Sleep apnea or sleep disordered breathing
- Morbid obesity with high risk of sleep apnea
- Snoring
- Older age
- Significant co-morbidities (cardiac, pulmonary, or major organ failure)
- No recent opioid use
- Increased opioid dose requirement
- Receiving other sedating medications (e.g., antihistamines, antipsychotics)
- Recent surgery, especially thoracic or upper abdominal
- Prolonged general anesthesia
- Smoker

Modified from The Joint Commission: 2013, *Sentinel Event Alert: safe use of opioids in hospitals,* Issue 49; August 8, 2012. http://www.jointcommission.org/assets/1/18/SEA_49_opioids_8_2_12_final.pdf. Accessed August 12, 2014.

When you convert a patient from an IV to an oral form of the same opioid, understand that the dose of the oral opioid is usually much higher than the IV dose because of the first-pass effect (Pasero and McCaffery, 2011). When a patient takes oral opioids, the opioid first goes to the liver, where most (but not all) of the medication is inactivated. Thus the body needs larger doses of oral opioids to achieve the same level of pain relief as with IV opioids. Know the comparative potencies of analgesics in oral and injectable form. In addition, know the route of administration most effective for a patient so controlled, sustained pain relief is achieved. The intramuscular (IM) route for analgesic administration should not be used because the IM injection is painful and drug absorption is inconsistent and erratic (Pasero and McCaffery, 2011). When comparing opioids, equianalgesic charts (i.e., charts converting one opioid to another or parenteral forms of opioids [e.g., morphine to hydromorphone] to oral forms [or vice versa]) should be available on nursing units or by contacting pharmacy staff. There are "smartphone apps" for opioid dosing conversions, but check with the pharmacy staff to ensure accuracy before using these electronic conversion tools.

Opioids are usually necessary and effective for acute pain and cancer pain of moderate or severe intensity. The goal of opioid therapy is a reduction in pain intensity to a level of acceptable comfort. In both types of pain, progress toward pain relief is measured by changes in pain-intensity scores. Opioid doses often need to be adjusted up or down according to individual patient circumstances and conditions. A prescriber must carefully individualize drug selection, dosing, and schedule. Many patients are at higher risk for opioid-related adverse drug events (Box 44-15).

According to the American Geriatrics Society (AGS, 2009), opioids are probably not used enough with older people. The AGS suggests a "start-low" (dose) and "go-slow" (upward dose titration) philosophy. Careful use of multiple drugs together can be seen as potentially helpful. Combining smaller doses of more than one medication may minimize the dose-limiting adverse effects of using a particular single drug (ACPA, 2014). The elderly require special consideration because age-related changes and increased frailty lead to less predictable drug responses, including increased drug sensitivity and severity of side effects (van Ojik et al., 2012). Opioids may place the elderly at increased risk for falls and other injuries. Many elderly patients have multiple co-morbidities and require various medications, placing them at risk for polypharmacy and drug-drug interactions. Dizziness, confusion, and changes in vision are opioid-related side effects that pose

doses of each medication, therefore lowering the risk of side effects while providing pain relief that is as good as or even better than could be obtained from each of the medications alone.

A person's response to an analgesic is highly individualized. If the pain is caused by inflammation, an NSAID is sometimes as effective as, or more effective than, an opioid. An orally administered analgesic usually has a longer onset and duration of action than an injectable form. In addition, for pain that persists for most of the day, controlled- or extended-release opioid formulations (morphine [MS Contin, Kadian, Avinza], oxycodone [OxyContin], and methadone) are available for administration every 8 to 12 hours ATC; they are not ordered prn.

increased safety risks for the elderly; special care must be taken to ensure that the environment is safe and patients are educated about the need for caution. Despite these concerns, elderly patients should not be deprived of opioid therapy when needed to treat pain. Carefully selected opioids and doses, along with patient education and monitoring, are important in providing safe and effective pain management. Most opioids present similar risks and benefits; but methadone, because of its long half-life, drug-drug interactions, and risk for cardiac abnormalities, is generally avoided in the elderly (van Ojik et al., 2012).

TJC requires health care agencies, where permissible, to have range-order policies in place to guide nurses in selecting the most appropriate dose of a medication. "Range orders are medication orders in which the dose varies over a prescribed range depending on the situation or a patient's status" (Drew et al., 2013). Range orders enable needed and safe adjustments in doses on the basis of individual patient responses to treatment (Drew et al., 2013). However, improperly written orders can lead to problems in pain management and patient safety. Review the following order, "Administer 5 to 10 mg morphine sulfate IVP q3h prn for acute pain." Such an order is dangerous when there are no clinical guidelines to use for selecting the exact dose. Follow these guidelines from the ASPMN (Drew et al., 2013):

- Avoid administration of partial doses at more frequent intervals so as to not underdose a patient with small, frequent, ineffective doses from within a range (e.g., giving oxycodone 10 mg q2h when the order reads oxycodone 10 to 20 mg q3h prn).
- Avoid making a patient wait a full time interval after giving a partial dose within the allowed range.
- Wait until peak effect of the first dose has been reached before giving a subsequent dose.

A proper range order offers specifics for when a range of doses can be given and gives nurses the flexibility needed to treat patients' pain in a timely way while allowing for differences in patient response to pain and analgesia. Safe and effective range orders consider the patient's age, pain intensity, and co-morbidities and prescribe a maximum dose that is at least 2 times but not more than 4 times the minimum dose in the range (Drew et al., 2013; Pasero and McCaffery, 2011).

Co-analgesics or adjuvants are drugs originally developed to treat conditions other than pain but also have analgesic properties. For example, tricyclic antidepressants (e.g., nortriptyline [Pamelor]), anticonvulsants (e.g., gabapentin [Neurontin]), and infusional lidocaine successfully treat chronic pain, especially neuropathic pain. Corticosteroids relieve the pain from inflammation and bone metastasis. Other examples of co-analgesics are bisphosphonates and calcitonin for bone pain (Pasero and McCaffery, 2011). Adjuvants have analgesic properties, enhance pain control, or relieve other symptoms associated with neuropathic pain. You give adjuvants alone or with analgesics. Sedatives, antianxiety agents, and muscle relaxants have *no* analgesic effect, although they may be effective for their specific indications.

Patient-Controlled Analgesia. When patients depend on nurses for prn analgesia, an erratic cycle of alternating pain and analgesia often occurs. A patient feels pain and asks for medication; but the patient first must be assessed, and then the medication must be obtained and prepared. Under this circumstance analgesia finally occurs in about an hour, but pain relief may last only 30 minutes. Gradually the patient again feels discomfort, and the cycle begins again. The patient is constantly going in and out of analgesic therapeutic range.

A drug delivery system called **patient-controlled analgesia (PCA)** is a method for pain management that many patients prefer (see Skill 44-1 on pp. 1046-1049). It is a drug delivery system that allows patients

FIGURE 44-12 Patient-controlled analgesia pump with cassette. (Courtesy Smiths Medical ASD, Inc., St Paul, MN.)

to self-administer opioids (usually morphine, hydromorphone, or fentanyl) with minimal risk of overdose. The goal is to maintain a constant plasma level of analgesic to avoid the problems of prn dosing. Systemic PCA traditionally involves IV or subcutaneous drug administration; however, a controlled analgesia device for oral medications is available. This device allows patients access to their own oral prn mediations, including opioids and other analgesics, antiemetics, and anxiolytics, at the bedside.

PCA infusion pumps are portable and computerized and contain a chamber for a syringe or bag that delivers a small, preset dose of opioid (Figure 44-12). To receive a demand dose, a patient pushes a button attached to the PCA device. The PCA infusion pumps are designed to deliver a specific dose, which is programmed to be available at specific time intervals (usually in the range of 8 to 15 minutes) when the patient activates the delivery button. A limit on the number of doses per hour or a 4-hour interval may also be set. Most pumps have locked safety systems that prevent tampering by patients or family members and are generally safe to be managed in the home. For opioid-tolerant patients such as those with cancer pain, a low-dose continuous infusion (basal rate) is sometimes programmed to deliver a steady dose of continuous medication (Pasero and McCaffery, 2011).

There are many benefits to PCA use. The patient gains control over pain, and pain relief does not depend on nurse availability. Patients also have access to medication when they need it. This decreases anxiety and leads to decreased medication use. Small doses of medications are delivered at short intervals, stabilizing serum drug concentrations for sustained pain relief.

Patient preparation and teaching are critical to the safe and effective use of PCA devices (Box 44-16). A patient needs to understand PCA and be physically able to locate and press the button to deliver a dose. Family members and visitors must be instructed not to "push the button" for the patient (a dangerous action known as "PCA by Proxy"),

BOX 44-16 PATIENT TEACHING

Patient-Controlled Analgesia

Objective
- Patient will achieve pain control with proper use of the patient-controlled analgesia (PCA) device.

Teaching Strategies
- Teach how to use the PCA before procedures so patient understands how to use it after awakening from anesthesia or sedation. Reinforce as needed with Teach Back.
- Instruct patient in the purpose of PCA, emphasizing that patient controls medication delivery.
- Explain that the pump reduces risk of overdose.
- Tell family members or friends *not* to operate the PCA device for patient.

Evaluation
- Ask patient to tell you the purpose of the PCA device and when the button should be activated.
- Observe patient administering a dose.
- Evaluate the severity of patient's pain while using the PCA device.

as this bypasses the safety feature of PCA, which requires an awake patient to activate the device. In particular situations, when patients are unable to activate the PCA device, a carefully selected family member or nurse may be authorized to activate the device based on specific criteria. The authorized agent–controlled analgesia (AACA) guidelines should be used to guide this practice when appropriate (Cooney et al., 2013).

An established and properly functioning IV catheter is needed for IV PCA. Check the IV line and PCA device per institutional policy to ensure proper functioning (see Chapter 42). Programming of settings usually requires independent verification by two nurses to ensure accuracy. Even though patients control administration of analgesics, a nurse's diligence is needed to prevent errors related to programmable PCA devices. In opioid-naive patients, do not increase demand or basal dose *and* shorten the interval time simultaneously because this increases the risk for oversedation and respiratory depression. Document drug dosages and track medication wastes according to agency policy (Pasero and McCaffery, 2011). PCA basal doses are *not* recommended for opioid-naive patients following surgery because of the possibility for respiratory depression.

Topical Analgesics. Topical analgesics include prescription and OTC creams, ointments, and patches that are applied to a painful area. Commonly used topical agents include NSAID products (ketoprofen patch) and capsaicin (Pasero and McCaffery, 2011). Other topical analgesics contain local anesthetics. Products such as ELA-Max/LMX and eutectic mixture of local anesthetics (EMLA) are available for children. Apply EMLA via a disk or thick cream to the skin 30 to 60 minutes before minor procedures (e.g., IV start, intramuscular injection) or anesthetic infiltration of soft tissue. Do not place EMLA around the eyes, the tympanic membrane, or over large skin surfaces. The Lidoderm patch is a topical analgesic effective for cutaneous neuropathic pain such as postherpetic neuralgia in adults. Place three patches, cut to size, on and around the pain site using a 12-hour on, 12-hour off schedule (Pasero and McCaffery, 2011).

Local Anesthesia. Local anesthesia is the local infiltration of an anesthetic medication to induce loss of sensation to a body part. Health care providers often use local anesthesia during brief surgical procedures such as removing a skin lesion or suturing a wound by

applying local anesthetics topically on skin and mucous membranes or injecting them subcutaneously or intradermally to anesthetize a body part. **Regional anesthesia** is the injection or infusion of local anesthetics to block a group of sensory nerve fibers. The anesthetics produce temporary loss of sensation by inhibiting nerve conduction. Local anesthetics also block motor and autonomic functions, depending on the amount used and the location and depth of administration. Smaller sensory nerve fibers are more sensitive to local anesthetics than are large motor fibers. As a result, the patient loses sensation before losing motor function, and conversely motor activity returns before sensation.

Perineural Local Anesthetic Infusion. A type of regional anesthesia is the use of perineural injections and infusions of local anesthetic agents to relieve pain. This technique is used for a variety of inpatient and outpatient adult and pediatric surgical procedures. A surgeon places the tip of an unsutured catheter near a nerve or groups of nerves, and the catheter exits from the surgical wound. Infusions of local anesthetics (bupivacaine or ropivacaine) may be run on a pump similar to those used for IV infusions, on ambulatory pumps, or on disposable systems (e.g., On-Q). The pump may be set on demand or continuous mode, and the catheter is usually left in place for 48 hours. Some patients have pump systems that are left in place even after discharge. Patients learn how to discontinue the pump at home and bring the catheter to the next health care provider visit. Some patients still need oral analgesics, but **perineural infusions** often reduce the total dosage (Pasero and McCaffery, 2011).

Local anesthetics cause side effects, depending on their absorption into the circulation. Pruritus or burning of the skin or a localized rash is common after topical applications. Application to vascular mucous membranes increases the chance of systemic effects such as a change in heart rate. The use of local anesthetics in peripheral nerve and epidural infusions (see following paragraph) may block both motor nerves and sensory nerves. This effect resolves within hours of the reduction or discontinuation of an infusion.

Epidural Analgesia. Another pain therapy that often involves the administration of anesthetic agents is **epidural analgesia**, a form of regional anesthesia. Preservative-free opioids are often administered as single agents or in combination with local anesthetics into a patient's epidural space. Epidural analgesia effectively treats acute postoperative pain, rib fracture pain, labor and delivery pain, and chronic cancer pain. Research has shown that adults having surgery under general anesthesia experience fewer postoperative cardiovascular, respiratory, and gastrointestinal complications when receiving epidural analgesia compared with patients receiving systemic analgesia (IV analgesics) (Pöpping et al., 2014). Epidural analgesia controls or reduces severe pain and reduces a patient's overall opioid requirement, thus minimizing adverse effects. It is short or long term, depending on a patient's condition and life expectancy.

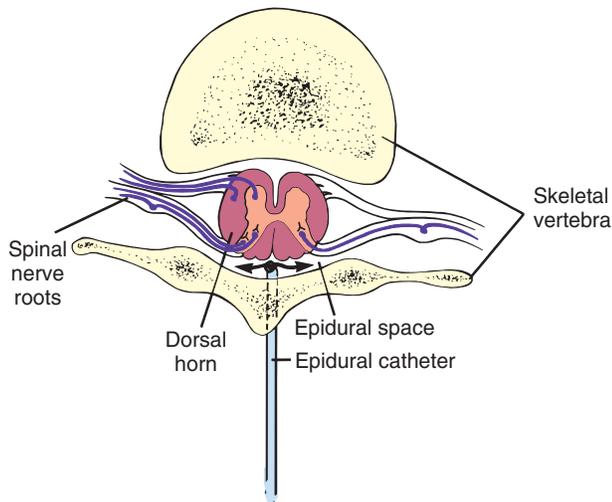
The health care provider administers epidural analgesia into the spinal epidural space (Figure 44-13) by inserting a blunt-tip needle into the level of the vertebral interspace nearest to the area requiring analgesia. He or she advances the catheter into the epidural space, removes the needle, and secures the remainder of the catheter with a dressing while ensuring that the catheter is taped securely. The end of the catheter is capped or, if a continuous infusion is prescribed, it is connected to special tubing and an infusion pump that is designated for epidural infusion. Nurse anesthetists, anesthesiologists, and certified nurses control epidural analgesia, depending on agency policy. Some patients are able to use a technique known as *patient-controlled epidural analgesia (PCEA),* which allows them to self-administer demand doses of epidural solution when connected to a special administration pump (Pasero and McCaffery, 2011).


FIGURE 44-13 Anatomical drawing of epidural space.

One of the concerns related to the use of peripheral and epidural anesthetic techniques is the risk of bleeding and subsequent hematoma formation near the injection/insertion site. Although relatively uncommon, the risk is increased when patients receive anticoagulant or antiplatelet medications. Safe placement or removal of these injections and catheters is made on the basis of knowledge of the patients' coagulation status and the timing of administration of anticoagulant or antiplatelet medications. Guidelines for the use of anticoagulation in patients with regional anesthesia are available (Narouze et al., 2015) Because the epidural space is a highly vascular area, patients with epidural catheters are at risk for the development of epidural hematomas, which may lead to ischemia of the spinal cord, and if unaddressed, serious neurological complications.

Nursing Implications for Local and Regional Anesthesia. Provide emotional support to patients receiving local or regional anesthesia by explaining the insertion technique and warning patients that they will temporarily lose sensory function within minutes of injection. Motor and autonomic (bowel and bladder control) function may also be lost quickly, depending on the area anesthetized. It is common for patients to fear paralysis because epidural and spinal injections come close to the spinal cord. To reassure the patient, explain that numbness, tingling, and coldness are common. Catheter insertion should be comfortable because the health care provider should first numb the injection site. Prepare patients for possible discomfort. Before a patient receives an analgesic, check for allergies. Also check to be sure that the drugs (e.g., morphine [Duramorph] and fentanyl [Sublimaze]) administered via the epidural catheter are free of potentially neurotoxic substances such as preservatives and additives. Assess vital signs to monitor systemic effects.

After administration of a local or regional anesthetic, protect the patient from injury until full sensory and motor function return. Patients are at risk for injuring an anesthetized body part without knowing it. For patients with topical anesthesia, avoid applying heat or cold to numb areas. After an injection into the knee joint, warn the patient to avoid standing without assistance because there is a high risk of falling. With peripheral nerve or epidural local anesthetics, patients may experience sensory loss along with significant motor weakness. Assess patients for sensory and motor nerve blockade and notify the prescriber when motor blockade is unintended. Protect patients from injury and educate about necessary precautions until full sensory and motor function return. During and

TABLE 44-6	**Nursing Care for Patients with Epidural Infusions**
Goal	**Actions**
Prevent catheter displacement.	Secure catheter (if not connected to implanted reservoir) carefully to outside skin.
Maintain catheter function.	Check external dressing around catheter site for dampness or discharge. (Leakage of epidural solution may occur if catheter is dislodged.) Use transparent dressing to secure catheter and aid inspection. Inspect catheter for breaks.
Prevent infection.	Use strict aseptic technique when caring for catheter (see Chapter 29). Do not change dressing routinely over site. Inspect insertions site for signs of infection. Follow institutional policies for tubing change.
Monitor for respiratory depression.	Monitor vital signs, especially respirations, per policy. Use pulse oximetry, end-tidal carbon dioxide, and apnea monitoring.
Prevent undesirable complications.	Assess for hemodynamic changes associated with use of local anesthetics that may cause vasodilation and subsequent hypotension: • Ensure adequate hydration and administer prescribed intravenous fluids. • Notify prescriber if significant change in vital signs occurs and reduce or stop epidural infusion. • Anticipate need for change in epidural solution. Assess for pruritus (itching) and nausea and vomiting associated with use of epidural opioids: • Notify prescriber for dose reduction or epidural solution change. • Administer antihistamines and antiemetics as ordered. Assess sensation and motor strength; notify health provider if deviation from baseline.
Maintain urinary and bowel function.	Monitor intake and output. Assess for bladder and bowel distention. Assess for discomfort, frequency, and urgency.

after epidural anesthesia a patient stays in bed until motor function returns. Help the patient the first time he or she tries to get out of bed.

When managing epidural infusions, if agency policy allows, connect the catheter to an infusion pump, a port, or a reservoir or cap it off for bolus injections. To reduce the risk of accidental epidural injection of drugs intended for IV use, clearly label the catheter *epidural catheter*. Always administer continuous infusions through appropriately labeled electronic infusion devices for proper control. Because of the catheter location, use surgical asepsis to prevent a serious and potentially fatal infection. Notify a patient's health care provider immediately of any signs or symptoms of infection or pain at the insertion site. Thorough hygiene is necessary during nursing procedures to keep the catheter system clean and dry. Maintain a closed system and prevent catheter disconnection by ensuring tight connections.

Nursing implications for managing epidural analgesia are numerous (Table 44-6). Do not administer supplemental doses of opioids or

sedative/hypnotics because of possible additive central nervous system adverse effects. Monitoring for effects of medications differs, depending on medication used and whether infusions are intermittent or continuous. Complications of epidural opioid use include nausea and vomiting, urinary retention, constipation, respiratory depression, and pruritus (Pasero and McCaffery, 2011). When patients receive epidural analgesia, initially monitor them as often as every 15 minutes, including assessment of vital signs, respiratory effort, and skin color. Once stabilized, monitoring occurs every hour in the first 12 to 24 hours and then with less frequency if the patient is stable (refer to agency policy).

To minimize bleeding risks and the potential for hematoma formation, anticoagulant and antiplatelet medications should not be administered until a pain specialist can verify safe use. To detect development of a possible epidural hematoma, notify the health care provider or pain specialist if the patient develops severe pain at the epidural insertion site or unexplained sensory or motor loss. The provider who performs the procedure should also be notified when patients with peripheral nerve injections/catheter have similar signs and symptoms.

The patient needs to receive thorough education about epidural analgesia in terms of the action of the medication and its advantages and disadvantages. Instruct patients about the potential for side effects and to notify their health care provider if side effects develop. If the patient requires long-term epidural use, the health care provider tunnels a permanent catheter through the skin. The catheter exits at the patient's side. Teach a patient on long-term therapy how to safely administer home infusions with minimal ongoing nursing intervention and coordinate with the case manager or social worker to ensure that appropriate home care services will be provided.

Invasive Interventions for Pain Relief. When severe pain persists despite medical treatment, available invasive interventions include intrathecal implantable pumps or injections, spinal cord and deep brain stimulation, neuroablative procedures (cordotomy, rhizotomy), trigger point injections, cryoablation, and intraspinal medications (e.g., opioids, steroids, local anesthetics). These techniques are useful for chronic pain. It is not acceptable to tell a patient with severe unrelieved pain that there is "nothing more we can do for you." Patients with severe chronic pain should be referred to comprehensive pain-management programs whenever possible. These programs offer many different interventional strategies, pharmacological options, physical medicine, and rehabilitation therapies to address the complex needs of patients with chronic pain. When comprehensive pain programs are not available, referral to a chronic pain-management program may be the best available option.

Procedure Pain Management. Diagnostic and treatment procedures potentially produce pain and anxiety, both of which should be assessed and treated before a procedure begins (Czarnecki et al., 2011). Barriers to successful pain control include numerous patient-specific factors, but perhaps more influential is the lack of acknowledgment by health care providers that pain may occur during or after a procedure. Without this acknowledgment, the necessary anticipation, prevention, and management of potential or actual procedural pain cannot occur (Czarnecki et al., 2011). The Thunder Project II (Puntillo et al., 2001) identified several procedures causing pain in critical care patients: turning, wound drain removal, tracheal suctioning, femoral catheter removal, placement of a central line, and changing of nonburn wound dressings. Common pharmacological agents for managing procedural comfort include local anesthetics, NSAIDs, acetaminophen, opioids, anxiolytics, and sedatives (Czarnecki et al., 2011). Premedicating patients before painful procedures allows them to cooperate more fully and reduces the experience of pain. Using nonpharmaco-

logical therapies such as relaxation techniques, meditation, imagery, and music, in addition to medications, has been effective in select situations (Czarnecki et al., 2011). When you premedicate a patient before a procedure, keep in mind the time to onset and time to peak effect of the analgesic to properly time the beginning of the painful procedure.

Cancer Pain and Chronic Noncancer Pain Management. Cancer pain is either chronic or acute. The prevalence of pain varies among cancer patients. A review of research spanning 40 years shows the prevalence ranging from 64% in patients with metastatic, advanced, or terminal phases of the disease, 59% in patients on anticancer treatment, and 33% in patients after curative treatment (van den Beuken-van Everdingen et al., 2007). Experts and consensus panels agree that cancer pain is still not adequately treated (Ripamonti et al., 2011). Organizations such as the APS and the National Comprehensive Cancer Network (NCCN) have published guidelines for assessing and treating cancer-related pain. The guidelines support comprehensive and aggressive treatment, including many options for pain relief. The best choice of pain treatment often changes as a patient's condition and the characteristics of pain change. You can use non-pharmacological interventions with pharmacological interventions to optimize care.

Similar recommendations are made for the treatment of pain in patients with chronic noncancer pain. In 2009 the APS and the American Academy of Pain Medicine jointly recommended that chronic opioid therapy can be an effective therapy for carefully selected and monitored patients with chronic noncancer pain (Chou et al., 2009). Analgesics for chronic pain should be prescribed on a regular basis and not on "as required" schedule (Ripamonti et al., 2011). However, chronic pain is complex and requires the careful selection of patients, identification of their risks, use of different treatments (often in combination), and ongoing monitoring to offer patients the best possible outcomes. Treatment options are continuously expanding and include a variety of pharmacological agents, physical therapies, behavioral medicine, surgical interventions, neuromodulation, complementary, and alternative approaches (Turk et al., 2011). No one approach has demonstrated superiority, and overall treatment effectiveness is poor and inconsistent (Turk et al., 2011). Patients are often desperate, frustrated, and anxious when presenting for treatment. It is important to provide emotional support and educate them about taking an active role in their pain management with realistic goals and expectations. Co-morbidities such as anxiety and depression can worsen pain and require separate assessment and treatment.

Many patients with cancer experience breakthrough cancer pain (BTCP), a transient worsening of pain that occurs either spontaneously or in relation to a specific predictable or unpredictable trigger, despite relatively stable and adequately controlled background pain (European Oncology Nursing Society, 2013). BTCP is a challenging aspect of cancer because, even though it is self-limiting in nature, its presence has a significant, negative impact on the quality of life of patients and family caregivers (European Oncology Nursing Society, 2013). Individualized assessment is critical for understanding how BTCP affects a patient's life. A holistic approach to care is often needed (Box 44-17) There is evidence for the proper treatment of **breakthrough pain** in cancer patients; however, there is little evidence for how to treat it in patients with chronic noncancer pain (Manchikanti et al., 2011). Multiple issues related to the concept of breakthrough pain in chronic noncancer pain evolve around extensive use, overuse, misuse, and abuse of opioids. In the era of eliminating opioids or significantly curtailing their use to only appropriate indications, the concept of breakthrough pain raises multiple questions without any scientific evidence.

BOX 44-17 Types of Breakthrough Pain and Treatment

Types of Breakthrough Pain

Incident pain: Pain that is predictable and elicited by specific behaviors or triggers such as a voluntary act (walking), involuntary act (coughing) or treatments (e.g., wound dressing changes)

End-of-dose failure pain: Pain that occurs toward the end of the usual dosing interval of a regularly scheduled analgesic

Spontaneous pain: Pain that is unpredictable and not associated with any activity or event

Treatment

- Lifestyle changes
- Management of reversible causes
- Modification of pathological processes
- Nonpharmacological management
- Pharmacological management—rescue dose of medication
- Interventional techniques

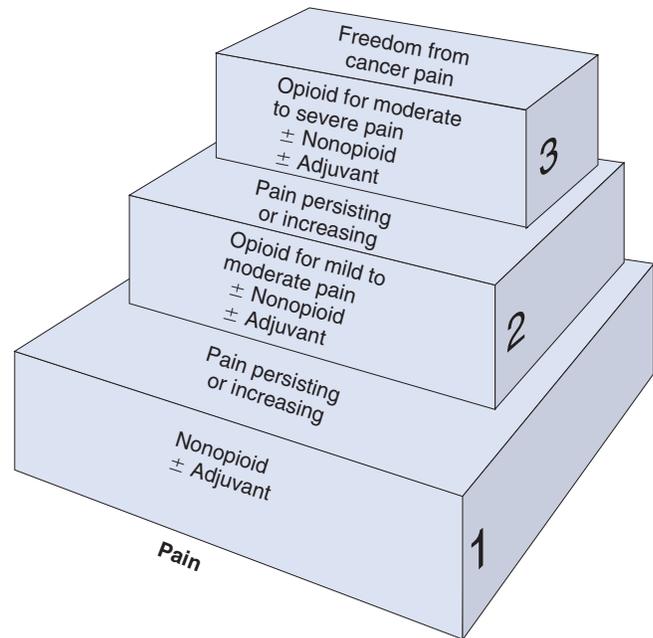
FIGURE 44-14 WHO analgesic ladder is a three-step approach in treating cancer pain. (Accessed September 27, 2010 from http://www.who .int/cancer/palliative/painladder/en/.)

The APS reports that the primary goal in treating chronic noncancer pain with opioids is to increase patients' level of function rather than just to provide pain relief (ACPA, 2014). The use of opioid therapy in patients with chronic pain requires careful patient selection and consideration of the risks and benefits of opioids. For example, to determine whether opioids are beneficial for a patient, it is necessary to assess his or her level of participation in ADLs, physical therapies, family activities, and work-related functions. Family members are often included in office visits to provide input about a patient's functional level. Research has not yet provided clear evidence to support or guide the use of chronic opioid therapy for patients with chronic noncancer pain (Chou et al., 2015). It is recommended that each person with chronic noncancer pain be medically managed individually; medication use should be determined by weighing benefit compared to other alternatives, cost, potential side effects, and the person's other medical problems (ACPA, 2014). Concerns about long-term opioid use are related to loss of beneficial effect over time, increasing tolerance, and escalating use with decreasing function (ACPA, 2014).

The World Health Organization (WHO) in 1986 introduced the WHO three-step analgesic ladder as a recommended approach for the management of cancer pain (Figure 44-14). This approach has been used worldwide and has been praised for its simplicity and ease of use. However, the ladder has been the object of criticism (Vargas-Schaffer, 2010). The three-step approach recommends that therapy begin at the first step with the use of nonopioid analgesics and/or adjuvants and progress to the next higher step as pain intensity increases. Weak opioids alone or in combination with the nonopioid analgesics and/or adjuvants are recommended at step two; and, if pain persists, strong opioids are recommended at step three. There have been efforts to modify the steps to facilitate use of the ladder for different pain presentations. A bidirectional approach has been suggested in which, in addition to the original step-up approach, a step-down approach would be used for patients with intense acute pain, uncontrolled cancer pain, and breakthrough pain (Thapa et al., 2011). With this


modification, therapy would begin at the third step with the strong opioids and descend down the ladder with improvement in pain. Another modification includes the addition of a fourth step, which recommends neurosurgical and other invasive procedures and also includes management of pediatric and acute pain in emergency departments and postoperative situations (Vargas-Schaffer, 2010) (Figure 44-15). The new fourth step is recommended for the treatment of crises of chronic pain. Many other modifications of the ladder have been proposed, including those that recommend the use of a multimodal approach at each level.

Long-acting or controlled-release medications may provide relief for all types of chronic pain, including cancer pain. These controlled-release medications (e.g., morphine [MS Contin, Roxanol SR], and oxycodone [OxyContin]) relieve pain for 8 to 12 hours. Long-acting or sustained-release opioids are dosed on a scheduled basis, not prn or "as needed." Transdermal fentanyl, which is 100 times more potent than morphine, is available for opioid-tolerant patients with cancer or chronic pain. It delivers predetermined doses that provide analgesia for up to 72 hours. The transdermal route is useful when patients are unable to take drugs orally. Patients find the transdermal patch easy to use because it allows for continuous opioid administration without needles or pumps. Self-adhesive patches release the medication slowly over time, achieving effective analgesia. Transdermal fentanyl is not for adult patients who weigh less than 100 lbs (too little subcutaneous tissue for absorption) or who are hyperthermic (increases drug absorption). *Do not place heating pads over a patch and never cut it.* To dispose of a patch, fold in half, adhesive side onto itself, and flush down the toilet (Pasero and McCaffery, 2011).

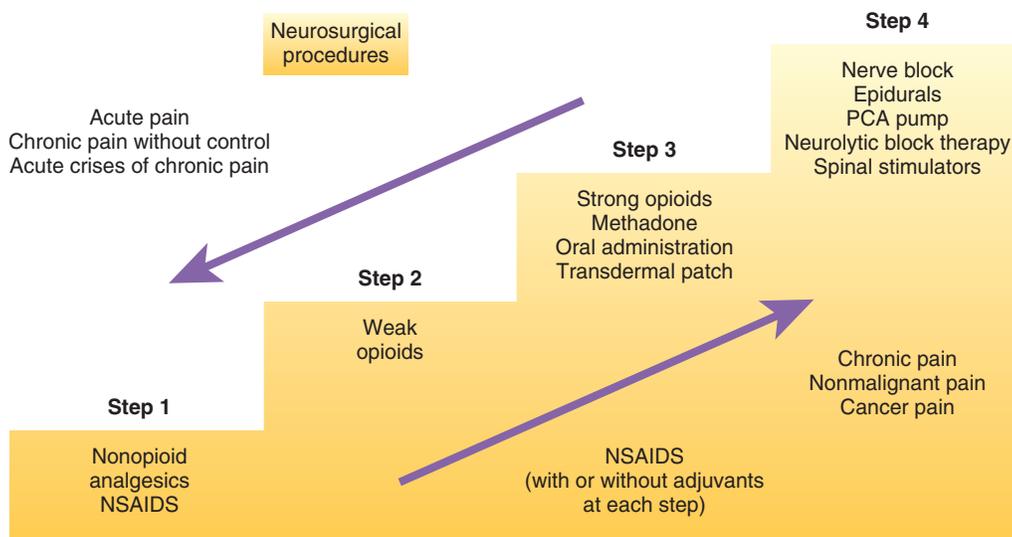
All patients on chronic opioid therapy require monitoring and follow-up. Side effects should be anticipated, prevented when possible, and treated when necessary. Over time, tolerance develops to the analgesic effect of opioids, necessitating dose escalation to achieve pain relief. The higher opioid dose is usually not lethal because patients also develop a tolerance to respiratory depression. Less commonly, chronic


FIGURE 44-15 Adaptation of the WHO analgesic ladder. *NSAID,* Nonsteroidal antiinflammatory drug; *PCA,* patient-controlled analgesia. (From Vargas-Schaffer G: Is the WHO analgesic ladder still valid?: Twenty-four years of experience, *Can Fam Physician* 56:514, 2010.)

opioid use may lead to hyperalgesia (increased pain sensitivity). Especially in the case of noncancer pain, patients should be closely monitored for signs of aberrant opioid-related behaviors such as misuse, abuse, and addiction. A transmucosal fentanyl "unit" now exists to treat breakthrough pain in opioid-tolerant patients. Swab the fentanyl unit in the mouth over the buccal mucosa and gums. The unit remains intact to dissolve in the mouth, not chewed. Allow to absorb over a 15-minute period, delaying swallowing as long as possible. Use no more than 2 units per breakthrough pain episode. If the patient's pain is not relieved after 2 units, notify the patient's health care provider (Pasero and McCaffery, 2011).

Many patients, family members, and health care providers have concerns about the risks of addiction associated with opioid use. Estimates of addiction in patients with chronic persistent pain range from 6% to 10% (Pasero and McCaffery, 2011). Often a person with chronic pain who consults with numerous health care providers is labeled a drug seeker, when he or she is actually seeking adequate pain relief. This situation may be associated with behaviors that are indicative of **pseudoaddiction**. Nurses need to discourage patients from "doctor shopping" and having multiple health care providers for treating pain and refer them to pain specialists. Pain centers offer a holistic approach to chronic pain, using both nonpharmacological and pharmacological strategies for chronic pain management (Pasero and McCaffery, 2011).

As with constant acute pain, it is necessary to give patients with chronic pain required analgesics on a regular basis. The oral route of administration of analgesic drugs should be advocated as the first choice (Ripamonti et al., 2011). Prescribing analgesics on a prn basis for chronic pain is ineffective and causes more suffering. The patient with chronic pain needs to take an analgesic ATC, even when the pain subsides. Regular administration maintains therapeutic drug blood levels for ongoing pain control.

Administer analgesics rectally when patients are unable to swallow, have nausea or vomiting, or are near death. This route is contraindicated for patients with diarrhea or cancerous lesions involving the anus or rectum. Morphine, hydromorphone, and oxymorphone are available in suppositories (Pasero and McCaffery, 2011).

Some patients use PCA devices to treat severe cancer pain in the home. PCA devices provide improved, uniform pain control with fewer peaks and valleys in plasma concentration, more effective drug action, and lower drug dosages overall. Patients who usually benefit from continuous infusions include those with severe pain for whom oral and injectable medications provide minimal relief, those with severe nausea and vomiting, and those unable to swallow oral medications.

When a patient first receives continuous-drip opioids, the IV access needs to be patent and without complications (see Chapter 42). A central venous catheter, an implanted venous access port, or a peripherally inserted central catheter is usually best for long-term IV infusion. When IV access is poor, the subcutaneous route with a concentrated dose is possible. When an infusion begins, monitor a patient's sedation level and respiratory status closely during the first 24 hours and with any increases in the infusion rate (follow agency policy). Patients who are placed on continuous analgesic infusions are opioid tolerant; thus respiratory depression is rare.

QSEN QSEN: BUILDING COMPETENCY IN PATIENT-CENTERED CARE Mrs. Mays in the care plan continues to have issues with uncontrollable pain. During your assessment you learn that she is reluctant to take medication to relieve the pain because it is a sign of weakness. Mrs. Mays usually takes as little medication as possible and prefers to shop in the organic market for her foods and dietary supplements, which do more for her health than any prescription medication. How would you initiate effective interventions to relieve her pain and suffering in light of her values, preferences, and expressed needs?

ⓔ *Answers to QSEN Activities can be found on the Evolve website.*

Barriers to Effective Pain Management. Barriers to effective pain management are complex, involving the patient, the patient's family caregivers, health care providers, and the health care system (Box 44-18). Lack of knowledge and misconceptions about pain and appropriate pain management present significant barriers. Various cultural

BOX 44-18   Barriers to Effective Pain Management

Patient Barriers
- Fear of addiction
- Worry about side effects
- Fear of tolerance (won't be there when I need it)
- Takes too many pills already
- Fear of injections
- Concern about not being a "good" patient
- Doesn't want to worry family and friends
- May need more tests
- Needs to suffer to be cured
- Inadequate education
- Reluctance to discuss pain
- Pain inevitable
- Pain part of aging
- Fear of disease progression
- Believes health care providers and nurses are doing all they can
- Just forgets to take analgesics
- Fear of distracting health care providers from treating illness
- Believes health care providers have more important or sicker patients to see
- Suffering in silence noble and expected

Health Care Provider Barriers
- Inadequate pain-assessment skills
- Concern with addiction or accidental overdose (could also use opioid-related adverse effect)
- Concern with co-morbid mental health conditions
- Opiophobia, fear of opioids
- Fear of legal repercussions
- No visible cause of pain
- Belief that patients need to learn to live with pain
- Reluctance to deal with side effects of analgesics
- Not believing patient's report of pain
- Fear that giving a dose will kill patient
- Time constraints
- Inadequate reimbursement
- Belief that opioids "mask" symptoms
- Belief that pain is part of aging
- Overestimation of rates of respiratory depression

Health Care System Barriers
- Concern with creating "addicts"
- Difficulty in filling prescriptions
- Absolute dollar restriction on amount reimbursed for prescriptions
- Mail-order pharmacy restrictions
- Advanced practice nurses not used efficiently
- Extensive documentation requirements
- Poor pain policies and procedures regarding pain management
- Lack of money
- Inadequate access to pain clinics
- Poor understanding of economic impact of unrelieved pain

BOX 44-19   Definitions Related to the Use of Opioids in Pain Treatment*

Physical Dependence
A state of adaptation that is manifested by a drug class–specific withdrawal syndrome produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist. Common symptoms of opioid withdrawal include shaking, chills, abdominal cramps, excessive yawning, and joint pain.

Addiction
A primary, chronic, neurobiological disease with genetic, psychosocial, and environmental factors influencing its development and manifestations. Addictive behaviors include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.

Drug Tolerance
A state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more effects of the drug over time.

*Approved by the Boards of Directors of the American Academy of Pain Medicine, the American Pain Society, and the American Society of Addiction Medicine, February 2001 (American Pain Society, 2011).

tolerance (Box 44-19). Experiencing a physical dependency does not imply addiction, and drug tolerance in and of itself is not the same as addiction. That is not to say that addiction does not occur or that patients who suffer from addiction should not be treated for pain. "Patients with addictive disease and pain have the right to be treated with dignity, respect, and the same quality of pain assessment and management as all other patients" (Oliver et al., 2012). An interdisciplinary team approach ensures a more effective pain-management plan for a patient with acute pain who also suffers from addiction. Nurses and health care providers need to avoid labeling patients as *drug seeking* because this term is poorly defined and can cause bias and prejudice. If there are concerns that a patient is abusing opioids, they should be voiced to the patient, and the patient's health care provider should be advised of the concerns. Many patients on long-term opioid medications have pain contracts with expected responsibilities of both the patient and health care provider. If the agreement is violated or other assessments dictate, additional resources may be identified to aid the patient in addressing the addictive illness.

Placebos. There are many different definitions and interpretations of the terms *placebo* and *placebo effect*. It is generally accepted that **placebos** are pharmacologically inactive preparations or procedures that produce no beneficial or therapeutic effect. Professional organizations discourage the use of placebos to treat pain. It is considered unethical and deceitful to administer them. Placebo use jeopardizes the trust between patients and their caregivers. If a placebo is ordered, question the order. Many health care agencies have policies that limit the use of placebos to research only (Pasero and McCaffery, 2011).

Restorative and Continuing Care
Pain Clinics, Palliative Care, and Hospices. Health professionals recognize pain as a significant health problem. Growth of pain centers, palliative care departments, and hospices designed to manage pain and suffering has increased. The Commission on Accreditation of Rehabilitation Facilities (CARF) accredits chronic pain treatment programs and sets standards for chronic pain management. A

beliefs about the meaning of pain and pain interventions also pose challenges to effective pain management. Controversy among health care providers exists related to the use of opioid therapy, particularly for treatment of patients with chronic noncancer pain.

Patients and health care providers often do not understand the differences among **physical dependence**, **addiction**, and **drug**

comprehensive pain center treats people on an inpatient or outpatient basis. Staff members representing all health care disciplines (e.g., nursing, medicine, physical therapy, psychology, pastoral care, and dietetics) work with patients to find the most effective pain-relief measures. A comprehensive clinic provides not only diverse therapy but also research into new treatments and training for professionals.

Many hospitals have palliative-care departments to help patients and their family members successfully manage their life-limiting conditions. The goal of palliative care is to help patients manage disease-related symptoms while living life fully with an incurable condition (see Chapter 37). Patients and their family members need ongoing assistance in managing pain at home. Teaching pain management during discharge and ensuring continuation of pain management after discharge is essential.

Hospices are programs that care for patients at the end of life (see Chapter 37). Hospice provides support and care for people in the last stages of incurable disease, with an emphasis on enhancing the quality of remaining life (National Hospice and Palliative Care Organization, 2010). It helps patients who are nearing the end of life to continue to live at home or in a health care setting in comfort and privacy. Pain control is a priority for hospices. Under the guidance of hospice nurses, families learn to monitor patients' symptoms and become the primary caregivers. Some hospice patients become hospitalized such as in the event of a brief acute care crisis or family problem.

Hospice programs help nurses overcome their fears of contributing to a patient's death when administering large doses of opioids. The ANA supports aggressive treatment of pain and suffering even if it hastens a patient's death (Fowler, 2015). The ANA position is supported by the ethical principle of double effect, which, when applied to pain at end of life, supports the use of opioids for the purpose of pain relief, despite the risk that a secondary effect may be the hastening of the patient's death from respiratory depression. Recent research suggests that moderate opioid dose increases in patients who are terminally ill do not hasten death (Bengoechea et al., 2010). The disease, not the opioid, is killing the patient.

◆ **Evaluation**

Through the Patient's Eyes. Evaluate patients' perceptions of the effectiveness of interventions used to relieve pain. Patients help decide the best times to attempt pain treatments. Essentially they are the best judge of whether a pain-relief intervention works. Often the family is another valuable resource, particularly in the case of a patient with pain who is not able to express discomfort. For patients with chronic pain, the effect of the pain intervention on the patient's function should be considered when evaluating the patient's perception of his or her response to treatment. If the intervention results in the patient feeling an improvement in the participation in self-care or activities such as physical therapy, the pain intervention should be viewed positively. Also ask patients about tolerance to therapy and the overall amount of relief obtained. If patients state that an intervention is not helpful or even aggravates the discomfort, stop it immediately and seek an alternative. Time and patience are necessary to maximize the effectiveness of pain management. Educate patients about what to expect. For a patient in acute pain, reassure him or her that you will check back frequently to assess for changes in pain level. Continually assess if the character of the patient's pain changes and whether individual interventions are effective.

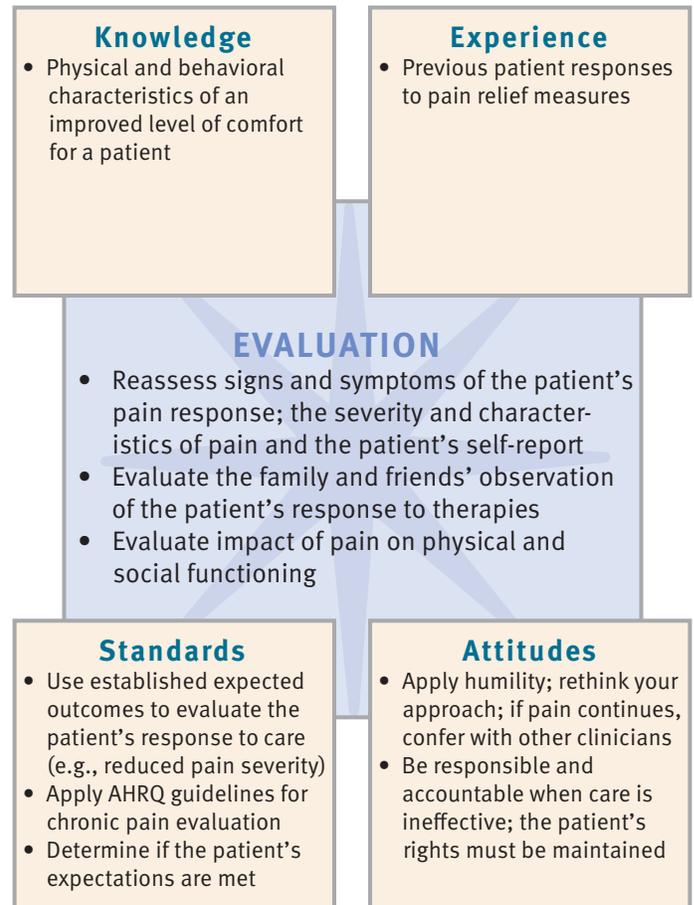
Patient Outcomes. Evaluation of pain is one of many nursing responsibilities that require effective critical thinking (Figure 44-16). Evaluate your success in achieving the outcomes of the plan of care. A patient's behavioral responses to pain-relief interventions are not


FIGURE 44-16 Critical thinking model for pain-management evaluation. *AHRQ,* Agency for Healthcare Research and Quality.

always obvious. Evaluating the effectiveness of a pain intervention requires you to evaluate for change in the severity and quality of the pain. Also be sure to evaluate after an appropriate period of time. For instance, oral medications usually peak in about 1 hour; whereas IVP medications peak in 15 to 30 minutes. Ask a patient if a medication alleviates the pain when it is peaking. Do not expect the patient to volunteer the information. Evaluate psychological and physiological responses to pain (e.g., vital sign changes and asking questions such as, "Do you feel more at ease or less anxious since we administered the medication?" It is also important to evaluate if the patient has any adverse effects from pain therapies.

If a patient continues to have discomfort after an intervention, try a different approach. For example, if an analgesic provides only partial relief, add relaxation exercises or guided-imagery exercises. Consult with the patient's health care provider about increasing the dose, decreasing the interval between doses, or trying different analgesics. If patient outcomes are not met, ask the patient:

- What is your current pain level?
- How far away is your pain level from your goal?
- Which side effects are you experiencing from your pain medication?
- What have you done to help manage your pain?
- Describe limitations in function that you are experiencing related to uncontrolled pain.
- How is your pain limiting or altering your rest and sleep?

Effective communication of the assessment of a patient's pain and the response to intervention is facilitated by accurate and thorough

documentation. This communication needs to happen from nurse to nurse, shift to shift, and nurse to other health care providers. The nurse caring for the patient has a professional responsibility to report the effectiveness of interventions for managing the patient's pain and evaluation of patient care goals and outcomes. A variety of tools such as a pain flow sheet or diary help centralize information about pain management. The patient expects you to be sensitive to his or her pain and to be attentive in attempts to manage that pain. Effectively communicating with colleagues (Box 44-20) helps you achieve optimal pain relief for patients.

BOX 44-20   Checklist for Communicating Patients' Unrelieved Pain to Colleagues

- What is the pain rating now? Over the past period of time?
- Which pain rating is acceptable to the patient?
- How do you recommend that the patient's treatment be changed to reduce the pain rating?
- Which professional reference can be used, if needed, to support this recommendation?

From Pasero C, McCaffery M: *Pain assessment and pharmacologic management,* St Louis, 2011, Mosby.

SAFETY GUIDELINES FOR NURSING SKILLS

Ensuring patient safety is an essential role of the professional nurse. To ensure patient safety, communicate clearly with members of the health care team, assess and incorporate the patient's priorities of care and preferences, and use the best evidence when making decisions about the patient's care. When performing the skills in this chapter, remember the following points to ensure safe, individualized patient care:

- The patient is the only person who should press the PCA button to administer the pain medication.
- Monitor the patient for signs and symptoms of oversedation and respiratory depression.
- Monitor for potential side effects of opioid analgesics.

SKILL 44-1   PATIENT-CONTROLLED ANALGESIA

DELEGATION CONSIDERATIONS

The skill of administration of patient-controlled analgesia (PCA) cannot be delegated to nursing assistive personnel (NAP). Instruct the NAP to:
- Notify the nurse if the patient complains of unrelieved pain or has signs of becoming oversedated.
- Notify the nurse if the patient has questions about the PCA process or equipment.
- Never administer a PCA dose for the patient and notify the nurse if anyone other than the patient is observed administering a dose for the patient.

EQUIPMENT
- PCA system
- Identification label and time tape (may already be attached and completed by pharmacy)
- Alcohol swab
- Adhesive tape
- Clean gloves, when applicable
- Equipment for vital signs and pulse oximeter

STEP	RATIONALE
ASSESSMENT	
1. Check accuracy and completeness of medical administration record (MAR) or computer printout with health care provider's order for patient's name, name of medication, dose, frequency of medication (continuous or demand or both), and lockout period.	Health care provider order required for administration of opioid medication. Ensures that patient receives right medications.
2. Review medication information in drug reference manual or consult with pharmacist if uncertain about any medications to be administered.	Understanding medications before administering them prevents medication errors (Adhikari et al., 2014).
3. Assess severity and character of patient's pain. Use standard pain scale. If patient is unable to provide a self-report, select an appropriate scale for assessing pain in patients who are nonverbal or not cognitively alert.	Reveals source and nature of pain and factors that may increase it.
4. Assess environment for factors that could contribute to pain (e.g., noise, room temperature).	Elimination of irritating stimuli may help to reduce pain perception.
5. Assess for conditions that predispose patients to unwanted effects from opioids. Known, untreated, or unknown obstructive sleep apnea (OSA) poses a significant risk for respiratory depression (Craft, 2010). Use the STOP-BANG questionnaire to assess for OSA (Chung et al., 2008) (see agency policy).	Assessment should be completed before surgery by anesthesia. Identification allows treatment teams (surgeon, respiratory therapy, anesthesia) to take appropriate precautions such as making continuous positive airway pressure or bilevel positive airway pressure ventilation devices available.
6. Perform hand hygiene. Assess patency of intravenous (IV) access and surrounding tissue for inflammation or swelling (see Chapter 42).	IV line needs to be patent for safe administration of pain medication. Confirmation of placement of IV catheter and integrity of surrounding tissues ensures that medication is administered safely.
7. If patient has had surgery, inspect incision while wearing clean gloves. Gently palpate around area for tenderness. Use sterile gloves if necessary to place hand directly on incision. Remove gloves and perform hand hygiene.	Reveals evidence of tissue trauma or damage, which stimulates peripheral pain receptors to transmit impulses to cortex to create conscious awareness of pain (Drew and St. Marie, 2011).
8. Check medical record for patient's history for drug allergies and typical reactions.	Avoids placing patient at risk for allergic reaction.

STEP	RATIONALE

CLINICAL DECISION POINT: *Be aware that nausea is not an allergic reaction and it can be treated; pruritus alone is not an allergic reaction and is common to opioid use. Pruritus is treatable and does not rule out the use of PCA.*

STEP	RATIONALE
9. Assess patient's knowledge and perceived effectiveness of previous pain-management strategies, especially previous PCA use.	Response to pain-control strategies helps identify learning needs and affects patient's willingness to try therapy.

PLANNING

1. Collect appropriate equipment.	Aids in organization.
2. Draw curtains around patient's bed or close door to room.	Maintains patient privacy.

IMPLEMENTATION

1. Perform hand hygiene.	Reduces transmission of infection.
2. Obtain PCA analgesic in module prepared by pharmacy. Check medication label 2 times: when removing from storage and when preparing for assembly.	Follows the six rights of medication administration to be sure of correct medication. *This is the first and second check for accuracy.*
3. At bedside, identify patient using two identifiers (e.g., name and birthday or name and medical record number) according to agency policy. Compare identifiers with information on patient's MAR or medical record.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2016).
4. At bedside compare the MAR or computer printout with name of medication on the drug cartridge. Have second registered nurse (RN) confirm health care provider's order and the correct setup of the PCA. Second RN should check order and device independently and not just look at existing setup.	Ensures that correct patient receives right medication. *This is the third check for accuracy*
5. Before initiating analgesia, explain purpose and demonstrate function of PCA to patient and family as follows:	Allows patient participation in care and independence in pain control. Preoperative education about PCA therapy improves postoperative pain relief (D'Arcy, 2011; Pasero and McCaffery, 2011).
a. Explain type of medication in device.	
b. Explain that device safely administers self-initiated small but frequent amounts of medication when needed to provide comfort and minimizes side effects from analgesia.	
c. Explain that self-dosing aids in repositioning, walking, or coughing and deep breathing.	
d. Explain that device is programmed to deliver ordered type and dose of pain medication, lockout interval, and 1- to 4-hour dosage limits. Explain how lockout time prevents overdose.	
e. Demonstrate to patient how to push medication demand button (see illustration).	
f. Instruct patient to notify nurse for possible side effects, problems in gaining pain relief, changes in severity or location of pain, alarm sounding, or questions.	
6. Apply clean gloves. Check infuser and patient-controlled module for accurate labeling or evidence of leaking.	Avoids medication error and injury to patient.
7. Position patient comfortably to be sure venipuncture or central line site is accessible.	Ensures unimpeded flow of infusion.

STEP 5e Explain purpose and demonstrate function of PCA.

SKILL 44-1	PATIENT-CONTROLLED ANALGESIA—cont'd

STEP	RATIONALE
8. Insert drug cartridge into infusion device (see illustration) and prime tubing.	Locks system and prevents air from infusing into IV tubing.
9. Attach needleless adapter to tubing adapter of patient-controlled module.	Needed to connect with IV line.
10. Wipe injection port of maintenance IV line vigorously with alcohol or antiseptic for 15 seconds and allow to dry.	Minimizes entry of surface microorganisms during needle insertion, reducing risk of catheter-related bloodstream infection.
11. Insert needleless adapter into injection port nearest patient (at Y-site of peripheral IV or central line, or connect to its own IV site). There should not be a chance to use PCA tubing for administering an IV push with another drug.	Establishes route for medication to enter main IV line. Needleless systems prevent needlestick injuries. Prevents medication interaction and incompatibility.
12. Secure connection and anchor PCA tubing with tape. Label PCA tubing.	Prevents dislodging of needleless adapter from port. Facilitates patient's ability to ambulate. Label prevents error from connecting tubing from different device to PCA.
13. Program computerized PCA pump as ordered to deliver prescribed medication dose and lockout interval. Have second RN check setting. (**NOTE:** Recheck with oncoming RN during shift hand-off to ensure line reconciliation.)	Ensures safe, therapeutic drug administration. With appropriate dose intervals (e.g., 10 minutes), usually an appreciable analgesic effect and/or mild sedation is achieved before the patient can access the next dose; thus there is a lower chance for oversedation and respiratory depression (Craft, 2010).
14. Administer loading dose of analgesia as prescribed. Manually give a 1-time dose or turn on pump and program dose into pump.	Establishes initial level of analgesia.
15. Discard gloves and supplies in appropriate containers. Dispose of empty cassette or syringe in compliance with institutional policy. Perform hand hygiene.	Reduces transmission of microorganisms. The Federal Controlled Substances Act regulates the control and dispensation of opioids for all institutions.
16. If experiencing pain, have patient demonstrate use of PCA system; if not, have patient repeat instructions given earlier.	Repeating instructions reinforces learning. Checking patient's understanding through return demonstration helps you determine patient's level of understanding and ability to manipulate device.
17. Be sure that venipuncture or central line site is protected and recheck before leaving patient.	Ensures patency of IV line.
18. To Discontinue PCA	
a. Check health care provider order for discontinuation. Obtain necessary PCA information from pump for documentation; note date, time, amount infused, amount of drug wasted, and reason for waste.	Ensures correct documentation of a schedule II drug.
b. Perform hand hygiene and apply clean gloves. Turn pump off. Disconnect PCA tubing from primary IV line but maintain IV access.	Reduces transmission of infection. Ensures continuation of IV line.
c. Dispose of empty cartridge according to agency policy.	Two RNs must witness wastage of opioids (narcotics) and sign record to meet requirements of Controlled Substances Act for scheduled drugs.

EVALUATION

1. Use pain-rating scale to evaluate patient's pain intensity following treatments and procedures according to agency policy.	Determines response to PCA dosing. Documenting "PCA in use" or "PCA effective" is not an adequate record of the patient's pain level.
2. Observe patient for nausea or pruritus.	Common side effects of opioid.
3. Monitor patient's level of sedation, vital signs, and pulse oximetry or capnography every 1 to 2 hours for the first 12 hours (APS and AAPM, 2009). Monitor more often at the start, during first 24 hours, and at night when hypoventilation and hypoxia tend to occur. Follow agency policy.	Patient is at highest risk the first 24 hours of use. Excess sedation (difficult to arouse) precedes respiratory depression.

STEP 8 Programming PCA pump.

STEP	RATIONALE
4. Have patient demonstrate dose delivery.	Evaluates skill in use of PCA.
5. According to agency policy, evaluate number of attempts (number of times patient pushed button), delivery of demand doses (number of times drug actually given and total amount of medication delivered in particular time frame), and basal dose if ordered.	Helps to evaluate effectiveness of PCA dose and frequency in relieving pain. Maintains compliance with Controlled Substances Act.
6. Observe patient initiate self-care.	Demonstrates pain relief.
7. Use **Teach Back** to determine patient's and family's understanding about PCA. For example, state, "I want to be sure I explained how PCA will help with your pain and how you should use the device. Can you explain to me how you should use the PCA?" Revise your instruction now or develop plan for revised patient teaching if patient is not able to teach back correctly.	Evaluates what patient and family are able to explain or demonstrate.

UNEXPECTED OUTCOMES AND RELATED INTERVENTIONS

1. Patient verbalizes continued or worsening discomfort or displays nonverbal behaviors indicative of pain, suggesting that underlying condition has changed or patient is undermedicated.
   - Perform complete pain assessment.
   - Check function of PCA device to ensure that the patient is receiving the medication.
   - Inspect IV site for possible catheter occlusion or infiltration.
   - Consult with health care provider.
2. Patient is not readily arousable.
   - Stop PCA; elevate head of bed unless contraindicated; and assess vital signs, including pulse oximetry (and end-tidal CO_2 if available). *Do not* leave patient's bedside and continue to try to arouse patient.
   - Notify health care provider and/or call for help.
   - Prepare to administer an opioid-reversing agent (naloxone [Narcan]).
3. Patient unable to manipulate PCA device to maintain pain control.
   - Consult with health care provider regarding alternative medication route or possible basal (continuous) dose if patient is opioid tolerant.
   - If agency allows, assess for feasibility of authorized agent–controlled analgesia if nurse (nurse-controlled analgesia) or patient's significant other (family-controlled analgesia) is available to responsibly manipulate analgesic pump (Cooney et al., 2013).

RECORDING AND REPORTING

- Record drug, dose, and time begun on MAR. Note lockout time, demand, and basal dose.
- Record regular assessments of patient's pain, vital signs, and oxygen saturation.
- Record amount of drug delivered and amount wasted.
- Document your evaluation of patient learning.

■ KEY POINTS

- Pain is a purely subjective physical and psychosocial experience.
- Misconceptions about pain often result in doubt about the degree of the patient's suffering and unwillingness to provide relief.
- Knowledge of the nociceptive pain processes of the pain experience (i.e., transmission, transduction, perception, and modulation) provides guidelines for selecting pain-relief measures.
- A person's cultural background influences the meaning of pain and how it is expressed.
- Older patients commonly underreport pain and believe that it is unacceptable to show or express pain.
- Cancer pain is still not adequately treated, despite clinical guidelines for the effective use of opioids and other pharmacological alternatives.
- The difference between acute and chronic pain involves the concept of harm. Acute pain is protective, thus preventing harm; chronic pain is no longer protective and does not provide any benefit.
- Do not collect an in-depth pain history when the patient is experiencing severe discomfort. Wait until the pain is better controlled.
- Pain often causes physical signs and symptoms similar to those of other diseases.
- Individualize pain interventions by collaborating closely with patient, using assessment findings and trying a variety of interventions.
- Eliminating sources of painful stimuli is a basic nursing measure for promoting comfort.
- Prescribing analgesics on a prn basis for chronic pain is ineffective and causes more suffering; thus patients with chronic pain need to take analgesics ATC, even when their pain subsides.
- Sedation is an adverse effect of opioids that always precedes respiratory depression.
- A PCA device (without a basal infusion) gives patients pain control with lower risk of overdose.
- While caring for a patient who receives local anesthesia, protect him or her from injury.

- Nursing implications for administering epidural analgesia include preventing infection, assessing sensation and motor function, and monitoring closely for respiratory depression.
- Addiction rarely occurs in patients who take opioids to relieve pain.
- Breakthrough pain is a challenging aspect of cancer because it can impact the quality of life of patients and family caregivers; thus it requires a holistic approach to treatment.
- Pain evaluation includes measuring the changing character of pain, the patient's response to interventions, and his or her perceptions of the effectiveness of a therapy.

■ CLINICAL APPLICATION QUESTIONS

Preparing for Clinical Practice

After three doses (0.5 mg each) of morphine from the patient-controlled analgesia (PCA) device, Mrs. Mays started vomiting and stated that she was feeling "out of her head." She rated her chest pain as 3 on a scale of 0 to 10. She is breathing comfortably on 2 L of nasal cannula oxygen, and her lung sounds are clear to auscultation. Her husband is very concerned and anxious about his wife and wants the morphine stopped so she will not become "addicted."

1. Do you think that Mrs. Mays is allergic to morphine? Support your answer.
2. What do you need to tell Mr. and Mrs. Mays about the adverse effects of morphine?
3. Which interventions do you need to complete before consulting the health care provider?

ⓔ *Answers to Clinical Application Questions can be found on the Evolve website.*

■ REVIEW QUESTIONS

Are You Ready to Test Your Nursing Knowledge?

1. Which of the following signs or symptoms in a patient who is opioid-naïve is of greatest concern to the nurse when assessing the patient 1 hour after administering an opioid?
   1. Oxygen saturation of 95%
   2. Difficulty arousing the patient
   3. Respiratory rate of 10 breaths/min
   4. Pain intensity rating of 5 on a scale of 0 to 10
2. A health care provider writes the following order for a patient who is opioid-naïve who returned from the operating room following a total hip replacement: "Fentanyl patch 100 mcg, change every 3 days." On the basis of this order, the nurse takes the following action:
   1. Calls the health care provider and questions the order
   2. Applies the patch the third postoperative day
   3. Applies the patch as soon as the patient reports pain
   4. Places the patch as close to the hip dressing as possible
3. A patient is being discharged home on an around-the-clock (ATC) opioid for chronic back pain. Because of this order, the nurse anticipates an order for which class of medication?
   1. Opioid antagonists
   2. Antiemetics
   3. Stool softeners
   4. Muscle relaxants
4. A new medical resident writes an order for oxycodone CR (Oxy Contin) 10 mg PO q2h prn. Which part of the order does the nurse question?
   1. The drug
   2. The time interval

3. The dose
4. The route

5. The nurse reviews a patient's medical administration record (MAR) and finds that the patient has received oxycodone/acetaminophen (Percocet) (5/325), two tablets PO every 3 hours for the past 3 days. What concerns the nurse the most?
   1. The patient's level of pain
   2. The potential for addiction
   3. The amount of daily acetaminophen
   4. The risk for gastrointestinal bleeding
6. A patient with chronic low back pain who took an opioid around-the-clock (ATC) for the past year decided to abruptly stop the medication for fear of addiction. He is now experiencing shaking chills, abdominal cramps, and joint pain. The nurse recognizes that this patient is experiencing symptoms of:
   1. Opioid toxicity.
   2. Opioid tolerance.
   3. Opioid addiction.
   4. Opioid withdrawal.
7. A patient has returned from the operating room, recovering from repair of a fractured elbow, and states that her pain level is 6 on a 0-to-10 pain scale. She received a dose of hydromorphone just 15 minutes ago. Which interventions may be beneficial for this patient at this time? (Select all that apply.)
   1. Transcutaneous electrical nerve stimulation (TENS)
   2. Administer naloxone (Narcan) 2 mg intravenously
   3. Provide back massage
   4. Reposition the patient
   5. Withhold any pain medication and tell the patient that she is at risk for addiction
8. Which of the following instructions is crucial for the nurse to give to both family members and the patient who is about to be started on a patient-controlled analgesia (PCA) of morphine? (Select all that apply.)
   1. Only the patient should push the button.
   2. Do not use the PCA until the pain is severe.
   3. The PCA system can set limits to prevent overdoses from occurring.
   4. Notify the nurse when the button is pushed.
   5. Do not push the button to go to sleep.
9. A patient with a 3-day history of a stroke that left her confused and unable to communicate returns from interventional radiology following placement of a gastrostomy tube. The patient has been taking hydrocodone/APAP 5/325 up to four tablets/day before her stroke for arthritic pain. The health care provider's order reads as follows: "Hydrocodone/APAP 5/325 1 tab, per gastrostomy tube, q4h, prn." Which action by the nurse is most appropriate?
   1. No action is required by the nurse because the order is appropriate.
   2. Request to have the order changed to around the clock (ATC) for the first 48 hours.
   3. Ask for a change of medication to meperidine (Demerol) 50 mg IVP, q3 hours, prn.
   4. Begin the hydrocodone/APAP when the patient shows nonverbal symptoms of pain.
10. A patient is prescribed morphine patient-controlled analgesia (PCA). Arrange the following steps for administering PCA in the correct order.
    1. Program computerized PCA pump to deliver prescribed medication dose and lockout interval.
    2. Check label of medication 3 times: when removed from storage, when brought to bedside, when preparing for assembly.

3. Administer loading dose of analgesia as prescribed.

4. Attach drug reservoir to infusion device, prime tubing, and attach needleless adapter to end of tubing.

5. Identify patient using two identifiers.

6. Insert and secure needleless adapter into injection port nearest patient.

11. A patient rates his pain as a 6 on a scale of 0 to 10, with 0 being no pain and 10 being the worst pain. The patient's wife says that he can't be in that much pain since he has been sleeping for 30 minutes. Which is the most accurate resource for assessing the pain?

1. Patient's self-report

2. Behaviors

3. Surrogate (wife) report

4. Vital sign changes

12. When using ice massage for pain relief, which of the following is correct? (Select all that apply.)

1. Apply ice using firm pressure over skin.

2. Apply ice for 5 minutes or until numbness occurs.

3. Apply ice no more than 3 times a day.

4. Limit application of ice to no longer than 10 minutes.

5. Use a slow, circular steady massage.

13. When teaching a patient about transcutaneous electrical nerve stimulation (TENS), which information do you include?

1. TENS works by causing distraction.

2. TENS therapy does not require a health care provider's order.

3. TENS requires an electrical source for use.

4. TENS electrodes are applied near or directly on the site of pain.

14. While caring for a patient with cancer pain, the nurse knows that a multimodal analgesia plan includes: (Select all that apply.)

1. Using analgesics such as nonsteroidal antiinflammatory drugs (NSAIDs) along with opioids.

2. Stopping acetaminophen when the pain becomes very severe.

3. Avoiding polypharmacy by limiting the use of medication to one agent at a time.

4. Avoiding total sedation, regardless of the severity of the pain.

5. The use of adjuvants (co-analgesics) such as gabapentin (Neurontin) to manage neuropathic type pain.

15. A postoperative patient currently is asleep. Therefore the nurse knows that:

1. The sedative administered may have helped him sleep, but it is still necessary to assess pain.

2. The intravenous (IV) pain medication given in recovery is relieving his pain effectively.

3. Pain assessment is not necessary.

4. The patient can be switched to the same amount of medication by the oral route.

Answers: 1. 2; **2.** 1; **3.** 4; **2.** 5; **3.** 6; **4.** 7; **1,** 3; **4,** 8; **1,** 3; **5,** 9; **2,** **10.** 2, 5; **1,** 4, 6; **3,** 11; **1,** **12.** 1, 2, 5; **13.** 4; **14,** 1, 5; **15.** 1.

Nutrition

OBJECTIVES

- Explain the importance of a balance between energy intake and energy requirements.
- List the end products of carbohydrate, protein, and fat metabolism.
- Explain the significance of saturated, unsaturated, and polyunsaturated fats.
- Describe the ChooseMyPlate and discuss its value in planning meals for good nutrition.
- List the current dietary guidelines for the general population.
- Explain the variance in nutritional requirements throughout growth and development.
- Discuss the major methods of nutritional assessment.
- Identify three major nutritional problems and describe patients at risk.

- Establish a plan of care to meet the nutritional needs of a patient.
- Describe the procedure for initiating and maintaining enteral feedings.
- Describe the methods for avoiding complications of enteral feedings.
- Describe the methods for avoiding complications of parenteral nutrition.
- Discuss medical nutrition therapy in relation to three medical conditions.
- Discuss how to implement diet counseling and patient teaching in relation to patient expectations.

Nutrition is a basic component of health and is essential for normal growth and development, tissue maintenance and repair, cellular metabolism, and organ function. The human body needs an adequate supply of nutrients for essential functions of cells. **Food security** is critical for all members of a household. This means that all household members have access to sufficient, safe, and nutritious food to maintain a healthy lifestyle. Household members have sufficient food available on a consistent basis and the resources to obtain appropriate food for a nutritious diet. Food also holds symbolic meaning. Giving or taking food is part of ceremonies, social gatherings, holiday traditions, religious events, the celebration of birth, and the mourning of death. The difficulty of the decision to withdraw food in a terminal illness, even in the form of intravenous (IV) nutrients, is a testament to the symbolic power of food and feeding.

Florence Nightingale understood the importance of nutrition, stressing a nurse's role in the science and art of feeding during the mid-1800s. Since then the nurse's role in nutrition and diet therapy has changed. Medical nutrition therapy (MNT) uses nutrition therapy and counseling to manage diseases (American Dietetic Association, 2010b). In some illnesses such as type 1 diabetes mellitus (DM) or mild hypertension, diet therapy is often the major treatment for disease control (ADA, 2012; AHA, 2010). Other conditions such as severe inflammatory bowel disease require specialized nutrition support such as enteral nutrition (EN) or parenteral nutrition (PN). Current standards of care promote optimal nutrition in all patients, including a low-fat diet and limiting red meat specifically (ACS, 2015; AHA, 2010).

The U.S. Department of Health and Human Services (USDHHS) and the Public Health Service established nutritional goals and objectives for *Healthy People 2020* (USDHHS, 2015). *Healthy People 2020* is the United States' contribution to the "Health for All" strategy of the World Health Organization (WHO, 2015). *Healthy People 2020* (Box 45-1) continues the objectives initiated in *Healthy People 2000* and *Healthy People 2010,* with overall goals of promoting health and reducing chronic disease. All nutrition-related objectives include baseline data from which progress is measured. The challenge remains to motivate consumers to put these dietary recommendations into practice.

SCIENTIFIC KNOWLEDGE BASE

Nutrients: The Biochemical Units of Nutrition

The body requires fuel to provide energy for cellular metabolism and repair, organ function, growth, and body movement. The **basal metabolic rate (BMR)** is the energy needed at rest to maintain life-sustaining activities (breathing, circulation, heart rate, and temperature) for a specific amount of time. Factors such as age, body mass, gender, fever, starvation, menstruation, illness, injury, infection, activity level, and thyroid function affect energy requirements. The **resting energy expenditure (REE),** or resting metabolic rate, is the amount of energy you need to consume over a 24-hour period for your body to maintain all of its internal working activities while at rest. Factors that affect metabolism include illness, pregnancy, lactation, and activity level.

When the **kilocalories (kcal)** of the food we eat meets our energy requirements, our weight does not change (Nix, 2012). When the kilocalories ingested exceed our energy demands, we gain weight. Likewise, if the kilocalories ingested fail to meet our energy requirements, we lose weight.

Nutrients are the elements necessary for the normal function of numerous body processes. We meet energy needs through the intake of a variety of nutrients: carbohydrates, proteins, fats, water, vitamins, and minerals. The **nutrient density** of food refers to the proportion of essential nutrients to the number of kilocalories. High–nutrient dense

---

> **BOX 45-1   Examples of Nutrition Objectives for *Healthy People 2020***
>
> **Weight and Growth**
> - Increase proportion of adults who are at a healthy weight (body mass index [BMI] 18.5 to 24.9).
> - Reduce the proportion of adults who are obese.
> - Reduce the proportion of children (2 to 11 years) who are overweight or obese.
>
> **Food and Nutrient Consumption**
> - Decrease saturated fat intake in population 2 years and older.
> - Increase the variety of vegetables and fruit intake in the population 2 years and older.
> - Increase grain product intake and consumption of calcium in the population 2 years and older.
> - Reduce sodium daily intake in the population 2 years and older.
>
> **Iron Deficiency and Anemia**
> - Reduce prevalence of iron deficiency in children and childbearing women.
> - Reduce prevalence of anemia in pregnant women in third trimester to 20%.
>
> **Schools, Work Sites, and Nutrition Counseling**
> - Increase work-site nutrition-education and weight-management program offerings.
> - Offer nutrition assessment and individualized planning at primary care sites.
> - Increase the percentage of schools that offer nutritious foods and beverages outside of school meals.
> - Increase the number of states with nutrition standards for food and beverages provided to preschool-age children in child care.
>
> **Food Security**
> - Increase food security to 94% of households.

Data from U.S. Department of Health and Human Services: *Healthy people 2020,* 2010, http://www.healthypeople.gov/hp2020/objectives.

---

foods such as fruits and vegetables provide a large number of nutrients in relationship to kilocalories. Low–nutrient dense foods such as alcohol or sugar are high in kilocalories but nutrient poor.

Carbohydrates. **Carbohydrates,** composed of carbon, hydrogen, and oxygen, are the main source of energy in the diet. Each gram of carbohydrate produces 4 kcal/g and serves as the main source of fuel (glucose) for the brain, skeletal muscles during exercise, erythrocyte and leukocyte production, and cell function of the renal medulla. We obtain carbohydrates primarily from plant foods, except for lactose (milk sugar). Carbohydrate classification occurs according to their carbohydrate units, or **saccharides**.

Monosaccharides such as glucose (dextrose) or fructose do not break down into a more basic carbohydrate unit. Disaccharides such as sucrose, lactose, and maltose are composed of two monosaccharides and water. **Simple carbohydrates** is the classification for both monosaccharides and disaccharides; they are found primarily in sugars. Polysaccharides such as glycogen make up carbohydrate units too (i.e., complex carbohydrates). They are insoluble in water and digested to varying degrees. Starches are polysaccharides.

The body is unable to digest some polysaccharides because we do not have enzymes capable of breaking them down. **Fiber,** a polysaccharide, is the structural part of plants that is not broken down by our digestive enzymes. The inability to break down fiber means that it does not contribute calories to the diet. Therefore insoluble fibers, including

cellulose, hemicellulose, and lignin, are not digestible. Soluble fibers dissolve in water and include barley, cereal grains, cornmeal, and oats.

Proteins. Proteins provide a source of energy (4 kcal/g); they are essential for the growth, maintenance, and repair of body tissue. Collagen, hormones, enzymes, immune cells, deoxyribonucleic acid (DNA), and ribonucleic acid (RNA) are all made of protein. In addition, blood clotting, fluid regulation, and acid-base balance require proteins. Proteins transport nutrients and many drugs in the blood. Ingestion of proteins maintains nitrogen balance.

The simplest form of protein is the **amino acid**, consisting of hydrogen, oxygen, carbon, and nitrogen. Because the body does not synthesize **indispensable amino acids,** we need these to be provided in our diet. Examples of indispensable amino acids are histidine, lysine, and phenylalanine. The body synthesizes **dispensable amino acids**. Examples of amino acids synthesized in the body are alanine, asparagine, and glutamic acid. Amino acids can link together. Albumin and insulin are simple proteins because they contain only amino acids or their derivatives. The combination of a simple protein with a nonprotein substance produces a complex protein such as lipoprotein, formed by a combination of a lipid and a simple protein.

A complete protein, also called a *high-quality protein,* contains all essential amino acids in sufficient quantity to support growth and maintain nitrogen balance. Examples of foods that contain complete proteins are fish, chicken, soybeans, turkey, and cheese. Incomplete proteins are missing one or more of the nine indispensable amino acids and include cereals, legumes (beans, peas), and vegetables. Complementary proteins are pairs of incomplete proteins that, when combined, supply the total amount of protein provided by complete protein sources.

Achieving **nitrogen balance** means that the intake and output of nitrogen are equal. When the intake of nitrogen is greater than the output, the body is in positive nitrogen balance. Positive nitrogen balance is required for growth, normal pregnancy, maintenance of lean muscle mass and vital organs, and wound healing. The body uses nitrogen to build, repair, and replace body tissues. Negative nitrogen balance occurs when the body loses more nitrogen than it gains (e.g., with infection, burns, fever, starvation, head injury, and trauma). The increased nitrogen loss is the result of body tissue destruction or loss of nitrogen-containing body fluids. Nutrition during this period needs to provide nutrients to put patients into positive balance for healing.

Protein provides energy but, because its essential role is to promote growth, maintenance, and repair, a diet needs to provide adequate kilocalories from nonprotein sources. When there is sufficient carbohydrate in the diet to meet the energy needs of the body, protein is spared as an energy source.

Fats. Fats (**lipids**) are the most calorie-dense nutrient, providing 9 kcal/g. Fats are composed of triglycerides and fatty acids. **Triglycerides** circulate in the blood and are composed of three fatty acids attached to a glycerol. **Fatty acids** are composed of chains of carbon and hydrogen atoms with an acid group on one end of the chain and a methyl group at the other. Fatty acids can be *saturated,* in which each carbon in the chain has two attached hydrogen atoms; or *unsaturated,* in which an unequal number of hydrogen atoms are attached and the carbon atoms attach to one another with a double bond. **Monounsaturated fatty acids** have one double bond, whereas **polyunsaturated fatty acids** have two or more double carbon bonds. The various types of fatty acids referred to in the dietary guidelines have significance for health and the incidence of disease.

We also classify fatty acids as essential or nonessential. Linoleic acid, an unsaturated fatty acid, is the only essential fatty acid in humans.

Linolenic acid and arachidonic acid, another type of **unsaturated fatty acids,** are important for metabolic processes. The body manufactures them when linoleic acid is available. Deficiency occurs when fat intake falls below 10% of daily nutrition. Most animal fats have high proportions of **saturated fatty acids**, whereas vegetable fats have higher amounts of unsaturated and polyunsaturated fatty acids.

Water. Water is critical because cell function depends on a fluid environment. Water makes up 60% to 70% of total body weight. Lean people have a greater percent of total body water than obese people do because muscle contains more water than any other tissue except blood. Infants have the greatest percentage of total body water because of greater surface area, and older people have the least. When deprived of water, a person usually cannot survive for more than a few days.

We meet our fluid needs by drinking liquids and eating solid foods high in water content such as fresh fruits and vegetables. Digestion produces fluid during food oxidation. In a healthy individual fluid intake from all sources equals fluid output through elimination, respiration, and sweating (see Chapters 41 and 45). An ill person has an increased need for fluid (e.g., with fever or gastrointestinal [GI] losses). By contrast, he or she also has a decreased ability to excrete fluid (e.g., with cardiopulmonary or renal disease), which often leads to the need for fluid restriction.

Vitamins. **Vitamins** are organic substances present in small amounts in foods that are essential to normal metabolism. They are chemicals that act as catalysts in biochemical reactions. When there is enough of any specific vitamin to meet the catalytic demands of the body, the rest of the vitamin supply acts as a free chemical and is often toxic to the body. Certain vitamins are currently of interest in their role as antioxidants. These vitamins neutralize substances called *free radicals,* which produce oxidative damage to body cells and tissues. Researchers think that oxidative damage increases a person's risk for various cancers. Antioxidant vitamins include beta-carotene and vitamins A, C, and E (Nix, 2012).

The body is unable to synthesize vitamins in the required amounts. Vitamin synthesis depends on dietary intake. Vitamin content is usually highest in fresh foods that have minimal exposure to heat, air, or water before their use. Vitamin classifications include fat soluble or water soluble.

Fat-Soluble Vitamins. The **fat-soluble vitamins** (A, D, E, and K) are stored in the fatty compartments of the body. With the exception of vitamin D, people acquire vitamins through dietary intake. Because the body has a high storage capacity for these vitamins, toxicity is possible when a person takes large doses of them. **Hypervitaminosis** of fat-soluble vitamins results from megadoses (intentional or unintentional) of supplemental vitamins, excessive amounts in fortified food, and large intake of fish oils.

Water-Soluble Vitamins. The **water-soluble vitamins** are vitamin C and the B complex (which is eight vitamins). The body does not store water-soluble vitamins; thus we need them provided in our daily food intake. Water-soluble vitamins absorb easily from the GI tract. Although they are not stored, toxicity can still occur.

Minerals. **Minerals** are inorganic elements essential to the body as catalysts in biochemical reactions. They are classified as **macrominerals** when the daily requirement is 100 mg or more and microminerals or **trace elements** when less than 100 mg is needed daily. Macrominerals help to balance the pH of the body, and specific amounts are necessary in the blood and cells to promote acid-base balance. Interactions occur among trace minerals. For example, excess of one trace mineral sometimes causes deficiency of another. Selenium

Salivary glands
Saliva moistens and lubricates food
Amylase digests carbohydrates

Mouth
Breaks up food particles
Assists in producing
  spoken language

Esophagus
Transports food

Pharynx
Swallows

Gallbladder
Stores and
concentrates bile

Stomach
Stores and churns food
HCl activates enzymes,
  breaks up food, kills germs
Mucus protects stomach wall
Limited absorption

Liver
Breaks down and builds up
  many biological molecules
Stores vitamins and iron
Destroys old blood cells
Destroys poisons
Produces bile to aid digestion

Pancreas
Hormones regulate blood
  glucose levels
Bicarbonates neutralize
  stomach acid

Small intestine
Completes digestion
Mucus protects gut wall
Absorbs nutrients, most water

Large intestine
Reabsorbs some water, ions,
  and vitamins
Forms and stores feces

Anus
Opening for elimination of feces

Rectum
Stores and expels feces

FIGURE 45-1 Summary of digestive system anatomy/organ function. *HCl,* Hydrochloric acid.

is a trace element that also has antioxidant properties. Silicon, vanadium, nickel, tin, cadmium, arsenic, aluminum, and boron play an unidentified role in nutrition. Arsenic, aluminum, and cadmium have toxic effects.

Anatomy and Physiology of the Digestive System

Digestion. Digestion of food is the mechanical breakdown that results from chewing, churning, and mixing with fluid and chemical reactions in which food reduces to its simplest form. Each part of the GI system has an important digestive or absorptive function (Figure 45-1). **Enzymes** are the protein-like substances that act as catalysts to speed up chemical reactions. They are an essential part of the chemistry of digestion.

Most enzymes have one specific function. Each enzyme works best at a specific pH. For example, the enzyme amylase in the saliva breaks down starches into sugars. The secretions of the GI tract have very different pH levels. Saliva is relatively neutral, gastric juice is highly acidic, and the secretions of the small intestine are alkaline.

The mechanical, chemical, and hormonal activities of digestion are interdependent. Enzyme activity depends on the mechanical breakdown of food to increase its surface area for chemical action. Hormones regulate the flow of digestive secretions needed for enzyme supply. Physical, chemical, and hormonal factors regulate the secretion of digestive juices and the motility of the GI tract. Nerve stimulation from the parasympathetic nervous system (e.g., the vagus nerve) increases GI tract action.

Digestion begins in the mouth, where chewing mechanically breaks down food. The food mixes with saliva, which contains ptyalin (salivary amylase), an enzyme that acts on cooked starch to begin its conversion to maltose. The longer an individual chews food, the more starch digestion occurs in the mouth. Proteins and fats are broken down physically but remain unchanged chemically because enzymes in the mouth do not react with these nutrients. Chewing reduces food particles to a size suitable for swallowing, and saliva provides lubrication to ease swallowing of the food. The epiglottis is a flap of skin that closes over the trachea as a person swallows to prevent aspiration. Swallowed food enters the esophagus, and wavelike muscular contractions (**peristalsis**) move the food to the base of the esophagus, above the cardiac sphincter. Pressure from a bolus of food at the cardiac sphincter causes it to relax, allowing the food to enter the fundus, or uppermost part, of the stomach.

The chief cells in the stomach secrete pepsinogen; and the pyloric glands secrete gastrin, a hormone that triggers parietal cells to secrete hydrochloric acid (HCl). The parietal cells also secrete HCl and intrinsic factor (IF), which is necessary for absorption of vitamin B_{12} in the ileum. HCl turns pepsinogen into pepsin, a protein-splitting enzyme. The body produces gastric lipase and amylase to begin fat and starch digestion, respectively. A thick layer of mucus protects the lining of the stomach from autodigestion. Alcohol and aspirin are two substances directly absorbed through the lining of the stomach. The stomach acts as a reservoir where food remains for approximately 3 hours, with a range of 1 to 7 hours.

Food leaves the antrum, or distal stomach, through the pyloric sphincter and enters the duodenum. Food is now an acidic, liquefied mass called **chyme**. Chyme flows into the duodenum and quickly mixes with bile, intestinal juices, and pancreatic secretions. The small intestine secretes the hormones secretin and cholecystokinin (CCK). Secretin activates release of bicarbonate from the pancreas, raising the pH of chyme. CCK inhibits further gastrin secretion and initiates release of additional digestive enzymes from the pancreas and gallbladder.

Manufactured in the liver, bile is then concentrated and stored in the gallbladder. It acts as a detergent because it emulsifies fat to permit enzyme action while suspending fatty acids in solution. Pancreatic secretions contain six enzymes: amylase to digest starch; lipase to break down emulsified fats; and trypsin, elastase, chymotrypsin, and carboxypeptidase to break down proteins.

Peristalsis continues in the small intestine, mixing the secretions with chyme. The mixture becomes increasingly alkaline, inhibiting the action of the gastric enzymes and promoting the action of the duodenal secretions. Epithelial cells in the small intestinal villi secrete enzymes (e.g., sucrase, lactase, maltase, lipase, and peptidase) to facilitate digestion. The major part of digestion occurs in the small intestine, producing glucose, fructose, and galactose from carbohydrates; amino acids and dipeptides from proteins; and fatty acids, glycerides, and glycerol from lipids. Peristalsis usually takes approximately 5 hours to pass food through the small intestine.

Absorption. The small intestine, lined with fingerlike projections called *villi*, is the primary absorption site for nutrients. Villi increase the surface area available for absorption. The body absorbs nutrients by means of passive diffusion, osmosis, active transport, and pinocytosis (Table 45-1).

Absorption of carbohydrates, protein, minerals, and water-soluble vitamins occurs in the small intestine and are then processed in the liver and released into the portal vein circulation. Fatty acids are absorbed in the lymphatic circulatory systems through lacteal ducts at the center of each microvilli in the small intestine.

TABLE 45-1 Mechanisms for Intestinal Absorption of Nutrients

Mechanism	Definition
Active transport	An energy-dependent process whereby particles move from an area of greater concentration to an area of lesser concentration. A special "carrier" moves the particle across the cell membrane.
Passive diffusion	The force by which particles move outward from an area of greater concentration to one of lesser concentration. The particles do not need a special "carrier" to move outward in all directions.
Osmosis	Movement of water through a semipermeable membrane that separates solutions of different concentrations. Water moves to equalize the concentration pressures on both sides of the membrane.
Pinocytosis	Engulfing of large molecules of nutrients by the absorbing cell when the molecule attaches to the absorbing cell membrane.

Data from Nix S: *Williams' basic nutrition and diet therapy,* ed 14, St Louis, 2012, Mosby.

Approximately 85% to 90% of water is absorbed in the small intestine (McCance et al., 2013). The GI tract manages approximately 8.5 L of GI secretions and 1.5 L of oral intake daily. The small intestine resorbs 9.5 L, and the colon absorbs approximately 0.4 L. Elimination of the remaining 0.1 L occurs via feces. In addition, electrolytes and minerals are absorbed in the colon, and bacteria synthesize vitamin K and some B-complex vitamins. Finally, feces form for elimination.

Metabolism and Storage of Nutrients. **Metabolism** refers to all of the biochemical reactions within the cells of the body. Metabolic processes are anabolic (building) or catabolic (breaking down). **Anabolism** is the building of more complex biochemical substances by synthesis of nutrients. It occurs when an individual adds lean muscle through diet and exercise. Amino acids are anabolized into tissues, hormones, and enzymes. Normal metabolism and anabolism are physiologically possible when the body is in positive nitrogen balance. **Catabolism** is the breakdown of biochemical substances into simpler substances and occurs during physiological states of negative nitrogen balance. Starvation is an example of catabolism when wasting of body tissues occurs.

Nutrients absorbed in the intestines, including water, transport through the circulatory system to the body tissues. Through the chemical changes of metabolism, the body converts nutrients into a number of required substances. Carbohydrates, protein, and fat metabolism produce chemical energy and maintain a balance between anabolism and catabolism. To carry out the work of the body, the chemical energy produced by metabolism converts to other types of energy by different tissues. Muscle contraction involves mechanical energy, nervous system function involves electrical energy, and the mechanisms of heat production involve thermal energy.

Some of the nutrients required by the body are stored in tissues. The major form of body reserve energy is fat, stored as adipose tissue. Protein is stored in muscle mass. When the energy requirements of the body exceed the energy supplied by ingested nutrients, stored energy is used. Monoglycerides from the digested part of fats convert to glucose by gluconeogenesis. Amino acids are also converted to fat and stored or catabolized into energy through gluconeogenesis. All body

cells except red blood cells and neurons oxidize fatty acids into **ketones** for energy when dietary carbohydrates (glucose) are not adequate. Glycogen, synthesized from glucose, provides energy during brief periods of fasting (e.g., during sleep). It is stored in small reserves in liver and muscle tissue. Nutrient metabolism consists of three main processes:

1. Catabolism of glycogen into glucose, carbon dioxide, and water (**glycogenolysis**)
2. Anabolism of glucose into glycogen for storage (**glycogenesis**)
3. Catabolism of amino acids and glycerol into glucose for energy (**gluconeogenesis**)

Elimination. Chyme moves by peristaltic action through the ileocecal valve into the large intestine, where it becomes feces (see Chapter 47). Water absorbs in the mucosa as feces move toward the rectum. The longer the material stays in the large intestine, the more water is absorbed, causing the feces to become firmer. Exercise and fiber stimulate peristalsis, and water maintains consistency. Feces contain cellulose and similar indigestible substances, sloughed epithelial cells from the GI tract, digestive secretions, water, and microbes.

Dietary Guidelines

Dietary Reference Intakes. **Dietary reference intakes (DRIs)** present evidence-based criteria for an acceptable range of amounts of vitamins and nutrients for each gender and age-group (IOM, 2015). There are four components to the DRIs. The estimated average requirement (EAR) is the recommended amount of a nutrient that appears sufficient to maintain a specific body function for 50% of the population on the basis of age and gender. The recommended dietary allowance (RDA) is the average needs of 98% of the population, not the exact needs of the individual. The adequate intake (AI) is the suggested intake for individuals based on observed or experimentally determined estimates of nutrient intakes and used when there is not enough evidence to set the RDA. The tolerable upper intake level (UL) is the highest level that likely poses no risk of adverse health events. It is not a recommended level of intake (Tolerable upper-level intake, 2010).

Food Guidelines. The U.S. Department of Health and Human Services (USDHHS) and the U.S. Department of Agriculture (USDA) published the *Dietary Guidelines for Americans 2015-2020* and provide average daily consumption guidelines for the five food groups: grains, vegetables, fruits, dairy products, and meats (Box 45-2). These guidelines are for Americans over the age of 2 years. As a nurse, consider the food preferences of patients from different cultural groups, vegetarians, and others when planning diets. The U.S. Department of Agriculture developed the *ChooseMyPlate* program to replace the *My Food Pyramid* program. *ChooseMyPlate* provides a basic guide for making food choices for a healthy lifestyle (Figure 45-2). It includes guidelines for balancing calories; decreasing portion size; increasing healthy foods; increasing water consumption; and decreasing fats, sodium, and sugars (USDA, 2011).

Daily Values. The U.S. Food and Drug Administration (FDA) created **daily values** for food labels in response to the 1990 Nutrition Labeling and Education Act (NLEA). The FDA first established two sets of reference values. The referenced daily intakes (RDIs) are the first set, comprising protein, vitamins, and minerals based on the RDA. The daily reference values (DRVs) make up the second set and consist of nutrients such as total fat, saturated fat, cholesterol, carbohydrates, fiber, sodium, and potassium. Combined, both sets make up the daily values used on food labels. Daily values did not replace RDAs but provided a separate, more understandable format for the public. Daily

---

BOX 45-2 2015-2020 Dietary Guidelines for Americans: Key Recommendations for the General Population

- Adopt a healthy eating pattern at an appropriate calorie level with a variety of nutrient-dense food and beverages among all the food groups.
- Maintain body weight in a healthy range.
- Encourage physical activity and decrease sedentary activities.
- Encourage fruits, vegetables, whole-grain products, seafood, and fat-free or low-fat milk.
- Eat a variety of proteins, including lean meats, seafood, poultry, eggs, legumes, nuts, seeds, and soy products.
- Limit saturated fats and trans fats, consuming less than 10% of calories per day from saturated fats.
- Limit added sugar or sweeteners so that less than 10% of calories are from added sugars.
- Consume less than 2300 milligrams (mg) of sodium per day.
- Choose and prepare foods with little salt and eat potassium-rich foods.
- Limit intake of alcohol to moderate use (i.e., one drink daily for women and two drinks daily for men).
- Practice food safety to prevent bacterial foodborne illness. Use food-safety principles of *C*lean, *S*eparate, *C*ook, and *C*hill.

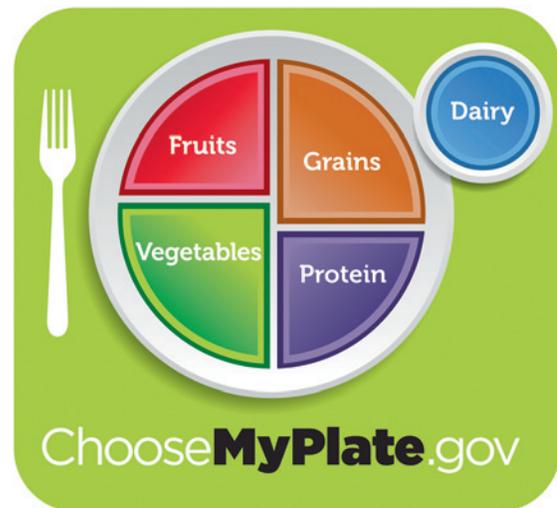
Data from US Department of Health and Human Services and US Department of Agriculture: *Dietary guidelines for Americans 2015-2020,* 8e, http://health.gov/dietaryguidelines/2015/guidelines. Accessed January 11, 2016.


FIGURE 45-2 ChooseMyPlate. (From US Department of Agriculture: ChooseMyPlate, 2011, http://www.choosemyplate.gov).

values are based on percentages of a diet consisting of 2000 kcal/day for adults and children 4 years or older.

NURSING KNOWLEDGE BASE

Sociological, cultural, psychological, and emotional factors are associated with eating and drinking in all societies. We celebrate holidays and events with food, bring it to those who are grieving, and use it for medicinal purposes. We incorporate it into family traditions and rituals and often associate food with eating behaviors. You need to understand patients' values, beliefs, and attitudes about food and how these values affect food purchase, preparation, and intake to affect eating patterns.

Nutritional requirements depend on many factors. Individual caloric and nutrient requirements vary by stage of development, body composition, activity levels, pregnancy and lactation, and the presence of disease. Registered dietitians (RDs) use predictive equations that take into account some of these factors to estimate patients' nutritional requirements.

Factors Influencing Nutrition

Environmental Factors. Environmental factors beyond the control of individuals contribute to the development of obesity. Obesity is an epidemic in the United States. Presently 68.7% of Americans are overweight or obese (CDC, 2015). In the annual "F is for Fat" report, authored by the Robert Woods Johnson Foundation and the Trust for America's Health (2013), the adult obesity rate, which consistently increased for three decades, now has leveled off. Proposed contributing factors for obesity are sedentary lifestyle, work schedules, and poor meal choices often related to the increasing frequency of eating away from home and eating fast food (Wang et al., 2013). Environmental factors can limit a person's likelihood of healthy eating and participation in exercise or other activities of healthy living. Lack of access to full-service grocery stores, high cost of healthy food, widespread availability of less healthy foods in fast-food restaurants, widespread advertising of less healthy food, and lack of access to safe places to play and exercise are environmental factors that contribute to obesity (Hedwig et al., 2013).

Developmental Needs

Infants Through School-Age. Rapid growth and high protein, vitamin, mineral, and energy requirements mark the developmental stage of infancy. The average birth weight of an American baby is 7 to 7½ lbs. (3.2 to 3.4 kg). An infant usually doubles birth weight at 4 to 5 months and triples it at 1 year. Infants need an energy intake of approximately 90 to 110 kcal/kg of body weight per day, with premature infants needing 105 to 130 kcal/kg per day (Nix, 2012). Commercial formulas and human breast milk both provide approximately 20 kcal/oz. A full-term newborn is able to digest and absorb simple carbohydrates, proteins, and a moderate amount of emulsified fat. Infants need about 100 to 120 mL/kg/day of fluid because a large part of total body weight is water.

Breastfeeding. The American Academy of Pediatrics strongly supports breastfeeding for the first 6 months of life and breastfeeding with complementary foods from 6 to 12 months (AAP, 2012). Breastfeeding has multiple benefits for both infant and mother, including fewer food allergies and intolerances; fewer infant infections; easier digestion; convenience, availability, and freshness; temperature always correct; economical because it is less expensive than formula; and increased time for mother and infant interaction.

Formula. Infant formulas contain the approximate nutrient composition of human milk. Protein in the formula is typically whey, soy, cow's milk base, casein hydrolysate, or elemental amino acids. Infants with allergies or intolerant to cow's milk should consume soy protein–based formulas instead (Nix, 2012).

Infants should not have regular cow's milk during the first year of life. It is too concentrated for an infant's kidneys to manage, increases the risk of milk-product allergies, and is a poor source of iron and vitamins C and E (Nix, 2012). Furthermore, children under 1 year of age should never ingest honey and corn syrup products because they are potential sources of the botulism toxin, which increases the risk of infant death.

Introduction to Solid Food. Breast milk or formula provides sufficient nutrition for the first 4 to 6 months of life. The development of fine-motor skills of the hand and fingers parallels an infant's interest in food and self-feeding. Iron-fortified cereals are typically the first semisolid food to be introduced. For infants 4 to 11 months, cereals are the most important nonmilk source of protein (Dunne, 2012).

Adding foods to an infant's diet depends on the infant's nutrient needs, physical readiness to handle different forms of foods, and the need to detect and control allergic reactions. Introducing foods that have a high incidence of causing allergic reaction such as wheat, egg white, nuts, citrus juice, and chocolate should happen later in the infant's life (Nix, 2012). In addition, caregivers should introduce new foods one at a time, approximately 4 to 7 days apart to identify allergies. It is best to introduce new foods before milk or other foods to avoid satiety (Hockenberry and Wilson, 2015).

The growth rate slows during toddler years (1 to 3 years). A toddler needs fewer kilocalories but an increased amount of protein in relation to body weight; consequently, appetite often decreases at 18 months of age. Toddlers exhibit strong food preferences and become picky eaters. Small, frequent meals consisting of breakfast, lunch, and dinner with three interspersed high nutrient–dense snacks help improve nutritional intake (Hockenberry and Wilson, 2015). Calcium and phosphorus are important for healthy bone growth.

Toddlers who consume more than 24 ounces of milk daily in place of other foods sometimes develop milk anemia because milk is a poor source of iron. Toddlers need to drink whole milk until the age of 2 years to make sure that there is adequate intake of fatty acids necessary for brain and neurological development. Avoid certain foods such as hot dogs, candy, nuts, grapes, raw vegetables, and popcorn because they present a choking hazard. Dietary requirements for preschoolers (3 to 5 years) are similar to those for toddlers. They consume slightly more than toddlers, and nutrient density is more important than quantity.

School-age children, 6 to 12 years old, grow at a slower and steadier rate, with a gradual decline in energy requirements per unit of body weight. Despite better appetites and more varied food intake, you need to assess school-age children's diets carefully for adequate protein and vitamins A and C. They often fail to eat a proper breakfast and have unsupervised intake at school. High fat, sugar, and salt result from too-liberal intake of snack foods. Physical activity level decreases consistently; and high-calorie, readily available food increases in consumption, leading to an increase in childhood obesity (Hedwig et al., 2013).

In the last 20 years the prevalence of overweight children has risen. The percent of obesity in children ages 6 to 11 years has doubled to 17%, and the percent of overweight adolescents has more than tripled to 17.6% (Li and Hooker, 2010). A combination of factors contributes to the problem, including a diet rich in high-calorie foods, food advertising targeting children, inactivity, genetic predisposition, use of food as a coping mechanism for stress or boredom or as a reward or celebration, and family and socioeconomic factors (Tuan et al., 2012). Childhood obesity contributes to medical problems related to the cardiovascular system, endocrine system, and mental health. With the increase in obesity, the incidence of type 2 diabetes in children is also increasing. Prevention of childhood obesity is critical because of its long-term effects. Family education is an important component in decreasing the prevalence of this problem. Promote healthy food choices and eating in moderation along with increased physical activity.

Adolescents. During adolescence physiological age is a better guide to nutritional needs than chronological age. Energy needs increase to meet greater metabolic demands of growth. Daily requirement of protein also increases. Calcium is essential for the rapid bone growth of adolescence, and girls need a continuous source of iron to replace menstrual losses. Boys also need adequate iron for muscle development. Iodine supports increased thyroid activity, and use of

iodized table salt ensures availability. B-complex vitamins are necessary to support heightened metabolic activity.

Many factors other than nutritional needs influence the adolescent's diet, including concern about body image and appearance, desire for independence, eating at fast-food restaurants, peer pressure, and fad diets. Nutritional deficiencies often occur in adolescent girls because of dieting and use of oral contraceptives. An adolescent boy's diet is often inadequate in total kilocalories, protein, iron, folic acid, B vitamins, and iodine. Snacks provide approximately 25% of a teenager's total dietary intake. Fast food, particularly value-size or super-size meals, is common and adds extra salt, fat, and kilocalories. Skipping meals or eating meals with unhealthy choices of snacks contributes to nutrient deficiency and obesity (Hockenberry and Wilson, 2015). Furthermore, research on public school lunch programs demonstrates that adolescents have higher body mass indexes (BMIs) than students enrolled in private school lunch programs (Li and Hooker, 2010).

Fortified foods (nutrients added) are important sources of vitamins and minerals. Snack food from the dairy, fruit, and vegetable groups are good choices. To counter obesity, increasing physical activity is often more important than curbing intake. The onset of eating disorders such as **anorexia nervosa** or **bulimia nervosa** often occurs during adolescence. Recognition of eating disorders is essential for early intervention (Box 45-3).

Sports and regular moderate-to-intense exercise necessitate dietary modification to meet increased energy needs for adolescents. Carbohydrates, both simple and complex, are the main source of energy, providing 55% to 60% of total daily kilocalories. Protein needs increase to 1 to 1.5 g/kg/day. Fat needs do not increase. Adequate hydration is very important. Adolescents need to ingest water before and after exercise to prevent dehydration, especially in hot, humid environments.

BOX 45-3 Diagnostic Criteria for Eating Disorders

Anorexia Nervosa
- Restriction of energy intake relative to requirements, leading to a significantly low body weight in relation to age, sex, developmental trajectory, and physical health
- Intense fear of gaining weight or of becoming fat, or persistent behavior that interferes with weight gain, even though at a significantly low weight
- Disturbance in the way in which one's body weight, size, or shape is experienced; undue influence of body weight or shape on self-evaluation; or persistent lack of recognition of the seriousness of the current low body weight (e.g., the person claims to "feel fat" even when emaciated, believes that one area of the body is "too fat" even when obviously underweight)

Bulimia Nervosa
- Recurrent episodes of binge eating (rapid consumption of a large amount of food in a discrete period of time)
- A feeling of lack of control over eating behavior during eating binges
- Recurrent inappropriate compensatory behaviors to prevent weight gain, such as self-induced vomiting, use of laxatives or diuretics, strict dieting or fasting, or vigorous exercise
- Binge eating and inappropriate compensatory behaviors that both occur, on average, at least once a week for 3 months
- Self-evaluation unduly influenced by body shape and weight

Vitamin and mineral supplements are not required, but intake of iron-rich foods is required to prevent anemia.

Parents have more influence on adolescents' diets than they believe. Effective strategies include limiting the amount of unhealthy food choices kept at home; encouraging smart snacks such as fruits, vegetables, or string cheese; and enhancing the appearance and taste of healthy foods (Mayo Clinic Staff, 2015). Some ways to promote healthy eating include making healthy food choices more convenient at home and at fast-food restaurants and discouraging adolescents from eating while watching television or using the computer.

Pregnancy occurring within 4 years of menarche places a mother and fetus at risk because of anatomical and physiological immaturity. Malnutrition at the time of conception increases risk to the adolescent and her fetus. Most teenage girls do not want to gain weight. Counseling related to nutritional needs of pregnancy is often difficult, and teens tolerate suggestions better than rigid directions. The diet of pregnant adolescents is often deficient in calcium, iron, and vitamins A and C. The American College of Obstetricians and Gynecologists recommends prenatal vitamin and mineral supplements.

Young and Middle Adults. There is a reduction in nutrient demands as the growth period ends. Mature adults need nutrients for energy, maintenance, and repair. Energy needs usually decline over the years. Obesity becomes a problem because of decreased physical exercise, dining out more often, and increased ability to afford more luxury foods. Adult women who use oral contraceptives often need extra vitamins. Iron and calcium intake continues to be important.

Pregnancy. Poor nutrition during pregnancy causes low birth weight in infants and decreases chances of survival. Generally meeting the needs of a fetus is at the expense of the mother. However, if nutrient sources are not available, both suffer. The nutritional status of the mother at the time of conception is important. Significant aspects of fetal growth and development often occur before the mother suspects the pregnancy. The energy requirements of pregnancy relate to the mother's body weight and activity. The quality of nutrition during pregnancy is important, and food intake in the first trimester includes balanced parts of essential nutrients with emphasis on quality. Protein intake throughout pregnancy needs to increase to 60 g daily. Calcium intake is especially critical in the third trimester, when fetal bones mineralize. Providing iron supplements to meet the mother's increased blood volume, fetal blood storage, and blood loss during delivery is important.

Folic acid intake is particularly important for DNA synthesis and the growth of red blood cells. Inadequate intake can lead to fetal neural tube defects, anencephaly, or maternal megaloblastic anemia (Nix, 2012). Women of childbearing age need to consume 400 mcg of folic acid daily, increasing to 600 mcg daily during pregnancy. Prenatal care usually includes vitamin and mineral supplementation to ensure daily intakes; however, pregnant women should not take additional supplements beyond prescribed amounts.

Lactation. The lactating woman needs 500 kcal/day above the usual allowance because the production of milk increases energy requirements. Protein requirements during lactation are greater than those required during pregnancy. The need for calcium remains the same as during pregnancy. There is an increased need for vitamins A and C. Daily intake of water-soluble vitamins (B and C) is necessary to ensure adequate levels in breast milk. Fluid intake needs to be adequate but not excessive. Excretion of caffeine, alcohol, and drugs occurs through breast milk. Therefore lactating mothers need to avoid their ingestion.

Older Adults. Adults 65 years and older have a decreased need for energy because their metabolic rate slows with age. However, vitamin and mineral requirements remain unchanged from middle adulthood.

BOX 45-4 FOCUS ON OLDER ADULTS

Factors Affecting Nutritional Status

- Age-related gastrointestinal changes that affect digestion of food and maintenance of nutrition include changes in the teeth and gums, reduced saliva production, atrophy of oral mucosal epithelial cells, increased taste threshold, decreased thirst sensation, reduced gag reflex, and decreased esophageal and colonic peristalsis (Touhy and Jett, 2010).
- The presence of chronic illnesses (e.g., diabetes mellitus, end-stage renal disease, cancer) often affects nutrition intake (CDC, 2015).
- Adequate nutrition in older adults is affected by multiple causes such as lifelong eating habits, culture, socialization, income, educational level, physical functional level to meet activities of daily living (ADLs), loss, dentition, and transportation (Touhy and Jett, 2010).
- Adverse effects of medications cause problems such as anorexia, gastrointestinal bleeding, xerostomia, early satiety, and impaired smell and taste perception (Burcham and Rosenthal, 2016).
- Cognitive impairments such as delirium, dementia, and depression affect ability to obtain, prepare, and eat healthy foods.

Numerous factors influence the nutritional status of the older adult (Box 45-4). Age-related changes in appetite, taste, smell, and the digestive system affect nutrition (Touhy and Jett, 2010). For example, older adults often experience a decrease in taste cells that alters food flavor and may decrease intake. Multiple factors contribute to the risk of food insecurity in the older adult. Income is significant because living on a fixed income often reduces the amount of money available to buy food. Health is another important influence that affects a person's desire and ability to eat. Lack of transportation or ability to get to the grocery store because of mobility problems contributes to inability to purchase adequate and nutritious food. Often availability of nutritionally adequate and safe foods is limited or uncertain.

Maintaining good oral health is significant throughout adulthood, particularly as an individual ages. Difficulty chewing, missing teeth, having teeth in poor condition, and oral pain result from poor oral health. These often contribute to malnutrition and dehydration in older adults (Touhy and Jett, 2010). Poor oral hygiene and periodontal disease are potential risk factors for systemic diseases such as joint infections, ischemic stroke, cardiovascular disease, DM, and aspiration pneumonia (Borrelli and Talih, 2012).

The older adult is often on a therapeutic diet; has difficulty eating because of physical symptoms, lack of teeth, or dentures; or is at risk for drug-nutrient interactions (Table 45-2). Caution older adults to avoid grapefruit and grapefruit juice because they alter absorption of many drugs. Thirst sensation diminishes, leading to inadequate fluid intake or dehydration (see Chapter 42). Symptoms of dehydration in older adults include confusion; weakness; hot, dry skin; furrowed tongue; rapid pulse; and high urinary sodium. Some older adults avoid meats because of cost or because they are difficult to chew. Cream soups and meat-based vegetable soups are nutrient-dense sources of protein. Cheese, eggs, and peanut butter are also useful high-protein alternatives. Milk continues to be an important food for older women and men who need adequate calcium to protect against osteoporosis (a decrease of bone mass density). Screening and treatment are necessary for both older men and women. Vitamin D supplements are important for improving strength and balance, strengthening bone health, and preventing bone fractures and falls. The diet of older adults needs to contain choices from all food groups and often requires a vitamin and mineral supplement. MyPlate for Older Adults addresses the specific nutritional needs for older adults and encourages physical activity (Tufts University, 2011).

The USDHHS Administration on Aging (AOA) requires states to provide nutritional screening services to older adults who benefit from home-delivered or congregate meal services. This program requires meals to provide at least one third of the DRI for an older adult and meet the Dietary Guidelines for Americans (American Dietetic Association, 2010a). Homebound older adults with chronic illnesses have additional nutritional risks. They frequently live alone with little or no social or financial resources to help obtain or prepare nutritionally sound meals, contributing to the risk for food insecurity. Approximately 19% of older adults experience some degree of food insecurity resulting from low income or poverty (American Dietetic Association, 2010a). Increased nutrition screening by the nurse results in early recognition and treatment of nutritional deficiencies. Undernourishment of older adults often results in health problems that lead to admission to acute care hospitals or long-term care facilities.

Alternative Food Patterns

Long before the FDA issued recommended allowances and guidelines, many people followed special patterns of food intake on the basis of religion (Table 45-3), cultural background (Box 45-5), health beliefs, personal preference, or concern for the efficient use of land to produce food. Such special diets are not necessarily more or less nutritious than diets based on the MyPlate or other nutritional guidelines because good nutrition depends on a balanced intake of all required nutrients.

Vegetarian Diet. A common alternative dietary pattern is the vegetarian diet. **Vegetarianism** is the consumption of a diet consisting predominantly of plant foods. Some vegetarians are ovolactovegetarian (avoid meat, fish, and poultry but eat eggs and milk), lactovegetarians (drink milk but avoid eggs), or vegans (consume only plant foods). Through careful selection of foods, individuals following a vegetarian diet can meet recommendations for proteins and essential nutrients (Nix, 2012). Zen macrobiotic (primarily brown rice, other grains, and herb teas) and fruitarian (only fruit, nuts, honey, and olive oil) diets are nutrient poor and frequently result in malnutrition. Knowledge related to complementary use of high and low biological value proteins is necessary. Children who follow a vegetarian diet are especially at risk for protein and vitamin deficiencies such as vitamin B_{12}. Careful planning helps to ensure a balanced, healthy diet.

CRITICAL THINKING

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require you to anticipate information, analyze the data, and make decisions regarding your patient's care. During assessment consider all elements that build toward making an appropriate nursing diagnosis (Figure 45-3).

Integrate knowledge from nursing and other disciplines, previous experiences, and information gathered from patients and families regarding customary food preferences and recent diet history. Use of professional standards such as the DRIs, the USDA MyPlate dietary guidelines, and *Healthy People 2020* objectives provide guidelines to assess and maintain patients' nutritional status. Other professional standards by the AHA (2010), the American Diabetes Association (ADA, 2012), The ACS (2015), and the American Society for Parenteral and Enteral Nutrition (National Guideline Clearinghouse, 2013) are

TABLE 45-2 Sample of Drug-Nutrient Interactions*

Drug	Effect	Drug	Effect
Analgesic		**Antihypertensive**	
Acetaminophen	Decreased drug absorption with food; overdose associated with liver failure	Captopril (Capoten)	Taste alteration, anorexia
Aspirin	Absorbed directly through stomach; decreased drug absorption with food; decreased folic acid, vitamins C and K, and iron absorption	Hydralazine	Enhanced drug absorption with food, decreased vitamin B_6
		Labetalol (Normodyne)	Taste alteration (weight gain for all beta-blockers)
Antacid		Methyldopa	Decreased vitamin B_{12}, folic acid, iron
Aluminum hydroxide	Decreased phosphate absorption		
Sodium bicarbonate	Decreased folic acid absorption	**Antiinflammatory**	
		All steroids	Increased appetite and weight, increased folic acid, decreased calcium (osteoporosis with long-term use); promotes gluconeogenesis of protein
Antiarrhythmic			
Amiodarone (Cordarone)	Taste alteration		
Digitalis	Anorexia, decreased renal clearance in older people	**Antiparkinson**	
		Levodopa (Dopar)	Taste alteration, decreased vitamin B_6 and drug absorption with food
Antibiotic			
Penicillin	Decreased drug absorption with food, taste alteration	**Antipsychotic**	
		Chlorpromazine	Increased appetite
Cephalosporin	Decreased vitamin K	Thiothixene	Decreased riboflavin, increased need
Rifampin (Rifadin)	Decreased vitamin B_6, niacin, vitamin D		
Tetracycline	Decreased drug absorption with milk and antacids; decreased nutrient absorption of calcium, riboflavin, vitamin C caused by binding	**Bronchodilator**	
		Albuterol sulfate	Appetite stimulant
		Theophylline	Anorexia
Trimethoprim/ sulfamethoxazole	Decreased folic acid	**Cholesterol Lowering**	
		Cholestyramine (Prevalite)	Decreased fat-soluble vitamins (A, D, E, K); vitamin B_{12}; iron
Anticoagulant			
Warfarin (Coumadin)	Acts as antagonist to vitamin K	**Diuretic**	
		Furosemide (Lasix)	Decreased drug absorption with food
Anticonvulsant		Spironolactone (Aldactone)	Increased drug absorption with food
Carbamazepine (Tegretol)	Increased drug absorption with food		
Phenytoin (Dilantin)	Decreased calcium absorption; decreased vitamins D and K and folic acid; taste alteration; decreased drug absorption with food	Thiazides	Decreased magnesium, zinc, and potassium
		Laxative	
		Mineral oil	Decreased absorption of fat-soluble vitamins (A, D, E, K), carotene
Antidepressant			
Amitriptyline	Appetite stimulant	**Platelet Aggregate Inhibitor**	
Clomipramine (Anafranil)	Taste alteration, appetite stimulant	Dipyridamole (Persantine)	Decreased drug absorption with food
Fluoxetine (Prozac) (selective serotonin reuptake inhibitors [SSRIs])	Taste alteration, anorexia	**Potassium Replacement**	
		Potassium chloride	Decreased vitamin B_{12}
		Tranquilizer	
		Benzodiazepines	Increased appetite

TABLE 45-3 Religious Dietary Restrictions

Muslim	Christianity	Hinduism	Judaism	Church of Jesus Christ of Latter-Day Saints (Mormons)	Seventh-Day Adventists Church
Pork Alcohol Caffeine Ramadan fasting sunrise to sunset for a month Ritualized methods of animal slaughter required for meat ingestion	Some faiths such as Baptists have minimal or no alcohol Some meatless days may be observed during the calendar year, commonly during Lent	All meats Fish, shellfish with some restrictions Alcohol	Pork Predatory fowl Shellfish (eat only fish with scales) Rare meats Blood (e.g., blood sausage) Mixing of milk or dairy products with meat dishes Must adhere to kosher food preparation methods 24 hr of fasting on Yom Kippur, a day of atonement No leavened bread eaten during Passover (8 days) No cooking on the Sabbath from sundown Friday to sundown Saturday	Alcohol Tobacco Caffeine such as teas, coffees, and sodas	Pork Shellfish Fish Alcohol Caffeine Vegetarian or ovolactovegetarian diets encouraged

BOX 45-5 CULTURAL ASPECTS OF CARE

Nutrition

Food patterns developed as a child, habits, and culture interact to influence food intake. Culture also influences the meaning of food not related to nutrition. Eating is associated with sentiments and feelings such as "good" and "bad." For example, children are often rewarded for "being good" with a treat such as candy. They then associate candy with "being good." Food frequently enhances interpersonal relationships and demonstrates love and caring.

The incidence of lactose intolerance around the world occurs in the following ethnic or racial groups: Asian-Pacific, African and African-American, Native American, Mexican American, Middle Eastern, and Caucasians. The incidence is highest in Asian-Pacific populations and lowest in Caucasians. It affects nutrient absorption. Calcium deficiency often results, causing decreased bone mass density.

The theory of hot and cold foods predominates in many cultures. The origin appears to be from Hippocratic beliefs concerning health and the four humors. Arabs were keepers of this knowledge during the Dark Ages and later influenced the Spanish to adopt this belief system in the later Middle Ages. The foundation of the theory is keeping harmony with nature by balancing "cold," "hot," "wet," and "dry." Some cultures believe that hot is warmth, strength, and reassurance; whereas cold is menacing and weak. Classification has nothing to do with spiciness but is a symbolic representation of temperature (Giger and Davidhizar, 2012). Different cultures also have beliefs about food and special dishes that should be eaten when sick (e.g., chicken soup during illness).

Implications for Patient-Centered Care
- Ask patient or family caregiver to identify the meaning that types of food have for each patient.
- Lactose and other food intolerances unique to specific cultures require diet adaptation to meet nutrient, mineral, and vitamin daily intake requirements.
- When patients use hot and cold foods as part of their cultural health practices, dietary modifications are necessary. Hot foods include rice, grain cereals, alcohol, beef, lamb, chili peppers, chocolate, cheese, temperate zone fruits, eggs, peas, goat's milk, cornhusks, oils, onions, pork, radishes, and tamales. By contrast, cold foods are beans, citrus fruits, tropical fruits, dairy products, most vegetables, honey, raisins, chicken, fish, and goat.
- Ask patient or family caregiver if there are:
  - Specific conditions such as menstruation, cancer, pneumonia, earache, colds, paralysis, headache, and rheumatism, which are cold illnesses and require hot foods.
  - Other conditions such as pregnancy, fever, infections, diarrhea, rashes, ulcers, liver problems, constipation, kidney problems, and sore throats, which are hot conditions and require cold foods.

available. These standards are evidence based and regularly updated for optimal patient care.

NURSING PROCESS

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care.

Assessment

During the assessment process thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care. Early recognition of malnourished or at-risk patients has a strong positive influence on both short- and long-term health outcomes. Studies demonstrate a link between malnutrition in adult hospitalized patients and readmission rates, higher mortality rates, and increased cost (Tappenden et al., 2013). Patients who are malnourished on admission are at greater risk of life-threatening complications such as arrhythmia, sepsis, or hemorrhage during hospitalization.

Through the Patient's Eyes. Assess patients' nutritional status by using the nursing history to gather information about factors that usually influence nutrition. You are in an excellent position to recognize signs of poor nutrition and take steps to initiate change. Close contact with patients and their families enables you to observe physical status, food intake, food preferences, weight changes, and response to therapy. Always ask patients about their food preferences, values regarding nutrition, and expectations from nutritional therapy. In attempting to affect eating patterns, you need to understand patients' values, beliefs, and attitudes about food. Also assess family traditions

Knowledge
- Normal nutrition parameters
- Anatomy and physiology of gastrointestinal system
- Cultural influences on nutrition
- Developmental factors affecting nutrition
- Effects of medications on nutrition
- Patient-centered care principles for assessing patient's values and preferences

Experience
- Caring for patients with altered nutrition
- Observation of nutritional practices of friends and family
- Personal assessment of nutritional practices

ASSESSMENT
- Identify the signs and symptoms associated with altered nutrition
- Gather data from patients regarding nutritional practices
- Determine patient's nutritional energy needs
- Obtain patient's dietary history
- Assess effects illness is having on ability to prepare meals at home

Standards
- Apply intellectual standards of accuracy, completeness, and significance when obtaining a health history for patients with altered nutrition
- Compare gathered data with established nutritional standards (e.g., dietary reference intake, MyPlate, *Healthy People 2020,* and healthy eating index)

Attitudes
- Be open minded about the patient's nutritional practices when obtaining nutritional assessment
- Display confidence when collecting data related to culture, socioeconomic status, physical functioning, dietary restrictions, and personal preferences as necessary to complete a nutritional assessment

and rituals related to food, cultural values and beliefs, and nutritional needs. Determine how these factors affect food purchase, preparation, and intake.

Screening. Nutrition screening is an essential part of an initial assessment. Screening a patient is a quick method of identifying **malnutrition** or risk of malnutrition using simple tools (Holst et al., 2013). Nutrition screening tools gather data on the current condition, stability of the condition, assessment of whether it will worsen, and if the disease process accelerates. These tools typically include objective measures such as height, weight, weight change, primary diagnosis, and the presence of other co-morbidities (Holst et al., 2013). Combine multiple objective measures with subjective measures related to nutrition to adequately screen for nutritional problems. Identification of risk factors such as unintentional weight loss, presence of a modified diet, or the presence of altered nutritional symptoms (i.e., nausea, vomiting, diarrhea, and constipation) requires nutritional consultation.

Several standardized nutritional screening tools are available for use in outpatient and inpatient settings. The Subjective Global Assessment (SGA) uses the patient history, weight, and physical assessment data to assess nutritional status (Tsai et al., 2013). The SGA is a simple, inexpensive technique that is able to predict nutrition-related complications. The Mini Nutritional Assessment (MNA) (Figure 45-4) screens older adults in home care programs, nursing homes, and hospitals. The tool has 18 items divided into screening and assessment. If a patient scores 11 or less on the screening part, the health care provider completes the assessment part. A total score of less than 17 indicates protein-energy malnutrition (Guigoz and Vellas, 1999; Guigoz et al., 1996). In conclusion, malnutrition screening tools (MSTs) are an effective way to measure nutritional problems for patients in a variety of health care settings.

Assess patients for malnutrition when they have conditions that interfere with their ability to ingest, digest, or absorb adequate nutrients. Use standardized tools to assess nutrition risks when possible. Congenital anomalies and surgical revisions of the GI tract interfere with normal function. Patients receiving only an IV infusion of 5% or 10% dextrose are at risk for nutritional deficiencies. Chronic diseases or increased metabolic requirements are risk factors for development of nutritional problems. Infants and older adults are at greatest risk.
